FROM THE DEPARTMENTS OF CLINICAL PHYSIOLOGY I AND II, UNIVERSITY OF GÖTEBORG, SWEDEN

On the relation between blood pressure and blood flow in the canine brain with particular regard to the mechanism responsible for cerebral blood flow autoregulation

BY

BARBRO EKSTRÖM-JODAL

GÖTEBORG 1970

This thesis is based on the following papers, which are published in this supplement

I. On the relation between blood pressure and blood flow in the cerebral cortex of dogs. By Barbro Ekström-Jodal Egil Häggendal and Nils Johan Nilsson 29–42.

II. The cerebral venous oxygen saturation during rapid changes in the arterial blood pressure An oximetric study in dogs. By Barbro Ekström-Jodal Egil Häggendal and Nils Johan Nilsson 43–50

III. Effect of increased venous pressure on cerebral blood flow in dogs. By Barbro Ekström-Jodal 51–61

These papers will be referred to in the text by the given Roman numerals.

INTRODUCTION

Autoregulation of blood flow in the restricted sense that there is a tendency to keep the flow constant in spite of variations in perfusion pressure is a characteristic feature of the pressure flow relation in the brain, as well as in skeletal muscle, kidney intestine, liver and myocardium, as discussed at the symposium on autoregulation of blood flow in 1963 (Johnson 1964 a) The first evidence of such a regulation was presented in 1902 by Baylis, who studied the effects of changes in the arterial blood pressure on the volume of the hind limbs of dogs cats and rabbits. He found signs of an active regulation of blood flow in response to changes of the arterial blood pressure, acting in the direction to keep the flow constant This regulation also observed in the kidney and intestine, was independent of nervous influence

The mechanism by which the response is effectuated is, however still a matter of debate. Several different theories have been discussed, as reviewed by Johnson (1964 b) but the following three have been most emphasized.

In view of the contraction observed in other muscles in response to stretch Baylis postulated that the muscular coat of arterios reacts in a similar way to rises in the intravascular pressure He also suggested that there would exist a certain tone already in response to the normal blood pressure a lowering of the pressure implying a diminished stimulus, thus leading to dilatation. This hypothesis forms the basis for the *myogen c theory* which has been extensively described by Folkow (1964) It implies the existence of a basal tone, resulting from vasomotion An increased transmural pressure potentiating vasomotion would lead to a rise in vascular resistance and vice versa Th precapillary resistance vessels are considered to be the site of the changes in resistance and the important consequ nce would be the prevention of oedema formation when the arterial blood pressure is raised

The *metabolic theory* for flow autoregulation (Berne 1964) implies in principle that primarily the flow passively follows changes in the perfusion pressure leading to an altered chemical situation in the tissue Secondarily this hange in concentra tion of the metabolites induces changes of the calibre of the resistance vessels, which act to keep the flow constant Much interest has been focused on oxygen and on different products of metabolism uch as carbon di xide and lactic acid as being the possible trigger of the reaction, but so far no single substance has been hown to be responsible. Autoregulation according to this theory is thus a flow-dependent

phenomenon and the teleological view that it is designed to guarantee the chemical homeostasis of the tissue seems natural.

The *tissue pressure theory* does not include any active smooth muscle response in the vessel walls but ascribes autoregulation to purely mechanical events. Thus, when the arterial blood pressure is raised there is an increase in the outward filtration of fluid owing to the changed pre- to postcapillary pressure ratio Provided the organ is enclosed in a capsule that is stiff enough an increase in the tissue pressure will be produced The low pressure vessels with little rigidity in the wall, *i.e.* the veins should be the section of the vasculature most sensitive to such a pressure increase tending to collapse and thereby raise the postcapillary resistance The reverse course of events would take place, when the arterial blood pressure is lowered, resulting in a pressure-flow relation characteristic for flow autoregulation

Concerning the regulation of the cerebral blood flow there have been wide differences in opinions from time to time Already in 1783 Alexander Monro the younger as quoted by Bayliss and Hill (1895) presented the view that the quantity of blood within the skull must be almost invariable considering the brain substance enclosed in the rigid skull as practically incompressible This view did not seem to allow for the *dilatation of the pial vessels later observed by Donders (1851) in combination with* asphyxia, but it was vividly supported by Bayliss and Hill (1895) who especially criticized the report by Roy and Sherrington (1890) The latter authors recognized two factors of importance in the regulation of the cerebral blood flow Firstly changes in the arterial blood pressure were found to effect an alteration of the blood flow in the same direction, and secondly some intrinsic control probably independent of nervous influence was suggested This suggestion was partly based on observations made during asphyxia, of an expansion of the brain, which could not be ascribed to blood pressure changes Bayliss and Hill repeating these experiments, could not find evidence for any active regulation of cerebral blood flow and concluded that under physiological conditions the blood flow passively follows the arterial and venous blood pressures. This view further extended by Hill (1896) became dominant during the following decades and was upheld despite the later discovery by Bayliss (1902) of an active vascular response to blood pressure changes in other vascular areas

The first systematic study of the effect on the cerebral vessels of blood pressure changes *per se* in which clear signs of an autoregulatory response were found was presented by Fog (1934) using the pial window technique of Forbes (1928) Irrespective of how the arterial blood pressure changes were achieved (arterial bleeding or stimulation of the vagus or depressor nerves aortic compression or stimulation of the sympathetic nerves) the response to a pressure increase was vasoconstriction and to a pressure decrease vasodilatation In this work and later (1937 and 1938) Fog suggested that variations in the endovascular pressure induce the changes observed in the diameter of the pial vessels

The existence of flow autoregulation in response to changes of the arterial blood

pressure in the cerebral circulation has later been confirmed in a number of studies using different techniques (Forbes, Nason and Wortman 1937 Carlyle and Grayson 1955 Rapela and Green 1964 Hirsch and Körner 1964 Harper 1965 Häggendal and Johansson 1965 Bozzao *et al* 1968 for reviews see also Lassen 1959 and 1964) Moreover autoregulation has been shown to occur in response to increased intracranial pressure (Noell and Schneider 1948, Rapela and Green 1964 Shulman and Verdier 1967 Häggendal *et al.* 1970 a) Other investigators have reported a passive pressure-flow relation in isolated brains (Geiger and Magnes 1947 Sagava and Guyton 1961) The discrepancy of results may be attributable to the method used as cerebral autoregulation appears to be a vulnerable phenomenon, easily damaged by for instance traumatic preparation procedures (Fog 1934, Rapela and Green 1964)

The tissue pressure hypothesis at first seems to be a quite possible explanation for blood flow autoregulation in the brain with its very rigid enclosure. It is, however probably excluded by the fact, that autoregulation takes place to the same extent, where the perfusion pressure is reduced by intracranial pressure increases, as when the arterial blood pressure is lowered

In discussing the other two mechanisms mentioned above a commonly held opinion has been that both are actually engaged (*e.g* Lassen 1959 and 1964 see also Harper and Häggendal 1968) but some facts concerning the general regulation of cerebral blood flow seem to have favoured the concept of a mechanism governed by metabolic factors. Thus, it is well known from numerous reports, that the cerebral blood vessels react readily to changes in the arterial blood-gas tensions, so that hypoxia and hypercapnia induce vasodilatation, and hypocapnia vasoconstriction, for a review see Lassen (1959) Changes in the tensions of oxygen or carbon dioxide in the tissue have been considered likely to provide the sensitive mechanism required for the flow autoregulation to the extent observed in the brain (Rapela and Green 1964, see also Lassen 1964 and Harper 1965)

The myogenic theory discussed by Forbes, Nason and Wortman (1937) and Fog (1938) as a quite possible explanation of the reactions found, has received some support in more recent years. Häggendal and Johansson (1965) reported findings that appeared inconsistent with the metabolic theory but explainable in terms of the myogenic theory A preliminary study of the influence of changes in the transmural pressure, *as opposed to changes in the perfusion pressure*, on the cerebrovascular resistance was presented at the International CBF Symposium 1969 by Ekström-Jodal *et al* suggestive of a non-metabolic, probably myogenic mechanism. At the same symposium there was also presented a study by Held Gottstein and Niedermayer (1969) showing an autoregulatory response on a lower flow level when there was a pulsatile as compared to a non-pulsatile flow with the same mean pressure. This was interpreted as indicating a myogenic mechanism.

For a recent review of autoregulation of cerebral blood flow the reader is referred to Häggendal Nilsson and Norbäck (1970)

phenomenon and the teleological view that it is designed to guarantee the chemical homeostasis of the tissue seems natural.

The *tissue pressure theory* does not include any active smooth muscle response in the vessel walls but ascribes autoregulation to purely mechanical events. Thus, when the arterial blood pressure is raised there is an increase in the outward filtration of fluid owing to the changed pre- to postcapillary pressure ratio Provided the organ is enclosed in a capsule that is stiff enough an increase in the tissue pressure will be produced. The low pressure vessels with little rigidity in the wall i.e. the veins, should be the section of the vasculature most sensitive to such a pressure increase tending to collapse and thereby raise the postcapillary resistance The reverse course of events would take place when the arterial blood pressure is lowered resulting in a pressure-flow relation characteristic for flow autoregulation.

Concerning the regulation of the cerebral blood flow there have been wide differences in opinions from time to time. Already in 1783 Alexander Monro the younger as quoted by Bayliss and Hill (1895) presented the view that the quantity of blood within the skull must be almost invariable considering the brain substance, enclosed in the rigid skull as practically incompressible. This view did not seem to allow for the dilatation of the pial vessels later observed by Donders (1851) in combination with asphyxia but it was vividly supported by Bayliss and Hill (1895) who especially criticized the report by Roy and Sherrington (1890) The latter authors recognized two factors of importance in the regulation of the cerebral blood flow Firstly changes in the arterial blood pressure were found to effect an alteration of the blood flow in the same direction and, secondly some intrinsic control, probably independent of nervous influence was suggested This suggestion was partly based on observations, made during asphyxia, of an expansion of the brain, which could not be ascribed to blood pressure changes. Bayliss and Hill, repeating these experiments could not find evidence for any active regulation of cerebral blood flow and concluded that under physiological conditions the blood flow passively follows the arterial and venous blood pressures. This view further extended by Hill (1896) became dominant during the following decades and was upheld despite the later discovery by Bayliss (1902) of an active vascular response to blood pressure changes in other vascular areas

The first systematic study of the effect on the cerebral vessels of blood pressure changes *per se* in which clear signs of an autoregulatory response were found, was presented by Fog (1934) using the pial window technique of Forbes (1928) Irrespective of how the arterial blood pressure changes were achieved (arterial bleeding or stimulation of the vagus or depressor nerves; aortic compression or stimulation of the sympathetic nerves) the response to a pressure increase was vasoconstriction and to a pressure decrease vasodilatation. In this work and later (1937 and 1938) Fog suggested that variations in the endovascular pressure induce the changes observed in the diameter of the pial vessels

The existence of flow autoregulation in response to changes of the arterial blood

METHODOLOGICAL CONSIDERATIONS

General procedure

Unselected mongrel dogs, anaesthetized with pentobarbital were used The animals were artificially ventilated, and changes in the blood gas situation were achieved by administration of different gas mixtures. The arterial blood pressure was changed by bleeding or reinfusion of blood. Measurements of cerebral blood flow were not performed until 15 minutes after changes of ventilation and until 5 minutes after changes of blood pressure in order to assure a steady state

Measurement of cerebral blood flow

For the study of such a vulnerable process as the autoregulation of blood flow in the brain a leading principle in the choice of methods must be that as little trauma as possible is inflicted. In this respect the radioactive gas elimination technique of Lassen *et al* (1963) has definite advantages. No direct interference with the brain tissue is involved, because the elimination of intraarterially injected radioactive krypton (Kr^{85}) is recorded through the intact skull with a scintillation detector Another advantage with this method, in experiments where numerous flow measurements are desired, is that it includes no blood loss. In this study the injections were made via a catheter into the intact left vertebral artery close to the base of the skull, leading to a high concentration of the indicator in the brain with little extracerebral contamination The catheter left in an unwedged position hardly interferes with the blood supply of the brain Norbäck (1966) using the same technique reported that the difference between the blood pressure measured in the aorta and at the tip of the catheter in the vertebral artery was only 10 mm Hg

The elimination curve obtained was resolved into two main components, considered representative of the two major types of tissue in the brain, *i.e* grey and white matter (Lassen *et al* 1963) Experimental evidence for the correctness of this assumption was presented by Häggendal Nilsson and Norbäck (1965) and the reader is referred to this study for details of the curve analysis. A third slow component was often recognized probably due to such factors as administration of small amounts of indicator to extracerebral tissue and to recirculation. By the use of a careful collimation the background activity registered in the curves could be kept low and did not significantly affect the solution of the curves. Flow correspond

ing to the different components can be calculated with the equation for an exponential clearance function if the elimination rate of the indicator from the tissue and the partition coefficient of the indicator between tissue and blood are known. The value of the partition coefficient for Krypton is influenced by changes in the hematocrit of the blood (Lassen *et al* 1963 Glass and Harper 1962 Ingvar and Lassen 1962) but as only minor differences between the measurements were encountered no corrections were considered necessary and the value of 0 95 for cerebral grey matter was used throughout the study The flow in the grey matter *i e* the flow calculated from the fast component of the clearance curve is given in the results. One reason for this is that cerebral venous blood required for the calculation of the cerebral metabolic rate of oxygen can most conveniently be sampled in dogs from the superior sagittal sinus which has been found to drain predominantly cerebral grey matter (see below) Furthermore the component representative of grey matter is less influenced by possible errors in drawing the third slow component in the γ curve (Häggendal Nilsson and Norbäck 1965) Using the same method of flow determination and curve analysis as was used in this study Häggendal (1965) studied the error of the method in subsequent measurements, which was found to be around 10 % of the mean value.

Analysis of blood from the superior sagittal sinus

Cerebral venous blood was withdrawn via a needle bored through the skull bone down into the sinus. In combination with practically every measurement of cerebral blood flow simultaneous samples were taken from the sinus and a femoral artery for the determination of oxygen saturation and capacity pH and carbon dioxide tension the metabolic rate of oxygen in the grey matter could then be calculated. In the oximetric studies (II) the oxygen saturation of blood from the superior sagittal sinus was continuously followed during rapid changes in the arterial blood pressure changes in the oxygen saturation being taken as a relative measure of changes in the blood flow In these procedures, of course it is of critical importance that the sagittal sinus blood is representative of venous blood from the grey matter A substantial contribution of extracerebral blood could be expected to change the results, and in studies of cortical metabolism Gleichmann *et al.* (1962) used the blood from the superior sagittal sinus as representative of cortical venous blood only after elimination of the diploic veins. However earlier results from this laboratory by Häggendal Nilsson and Norbäck (1965) with registration of the β curve from sagittal sinus blood did not indicate any important extracerebral contribution and Häggendal and Norbäck (1966) did not find any changes in the venous oxygen saturation when blood was withdrawn with varying rates, which is in accordance with the findings in the present study (II) However care was taken to draw the samples relatively slowly (about 5 ml/min) in order to avoid a possible error from this source

The contribution of blood from white matter to the superior sagittal sinus is small enough to be almost negligible (Häggendal, Nilsson and Norbäck 1965) Moreover a contribution of a certain amount of blood from white matter should probably not invalidate the results as the relation between both flow and oxygen consumption in grey and white matter is about 5 to 1 (Homburger *et al* 1946 Häggendal Nilsson and Norbäck 1965 Gleichmann *et al.* 196–) giving the same arterio-venous oxygen difference for the two tissues. This relation between cerebral blood flow and oxygen consumption in grey and white matter seems to remain constant during the different conditions studied. Thus flow in white matter is autoregulated in the same pressure range as flow in grey matter (Bonnal *et al* 1968 James, Millar and Purves 1969) The latter authors found a similar percentual increase of flow in white as in grey matter when the arterial oxygen tension was lowered from normal to around 40 mm Hg and also when the arterial carbon dioxide tension was changed within the range from around 25 to 65 mm Hg

For the oxymetric studies it is of major interest that the cerebral oxygen consumption is constant during each registration. Available information indicates that this is the case Thus no changes in oxygen uptake were found by Hirsch *et al.* (1955) in combination with blood flow reductions down to around 50 % of the normal value. Häggendal and Norbäck (1966) demonstrated a maintained oxygen uptake in hypotension, even when this was so pronounced that the cerebral blood flow was reduced Moreover the cerebral metabolic rat of oxygen is unaffected by wide variations in the arterial carbon dioxide tension, as indicated by the studies of Kety and Schmidt (1948) and of James, Millar and Purves (1969)

be an all-or none phenomenon but rather a more less pronounced attenuation of the mechanism, as indicated by studies on the effect of artificial perfusion on the response (Rapela and Green 1964) Furthermore in the present study the perfect readjustment to the original venous oxygen saturation found in the oximetric study (II) when the arterial blood pressure was changed within the autoregulatory range supports the view that the autoregulatory mechanism in the brain is capable of maintaining constancy of flow

The pressure-flow relation in hypotension has not been extensively studied so far However Harper (1965) demonstrated a linear relationship in hypotension. Also in hypercapnia (Harper 1965) and hypoxia (Häggendal and Johansson 1965) linear relationships have been presented On the other hand Fog (1934) and Forbes Nason and Wortman (1937) reported contractions of the directly observed pial arteries in response to marked blood pressure reductions Furthermore, Rapela and Green (1964) found a pressure-flow relation in hypercapnia indicating a passive vascular bed *i e* curvilinear with the convexity towards the pressure axis The above-mentioned linearity implicates an ability of the vessel wall to react to some extent to pressure changes and/or metabolic factors.

In the present work the study of the pressure-flow relation in hypotension below the autoregulatory range (I) was facilitated by induction of a primary flow increase by hypercapnia or papaverine infusion before reducing the arterial blood pressure in small steps. A curvilinear relation was found with the convexity towards the pressure axis. No difference in the relation was observed whether hypercapnia or papaverine was used This appearance of the relation does not, however exclude an ability of an active response of some kind being retained in hypotension although not strong enough completely to counteract the effect of the pressure changes on the elastic vessel walls. In hypoxia profound enough to impair autoregulation metabolic factors, resulting from the hypoxia, might give rise to a vasodilatation when the pressure is reduced (see below) On the other hand the normal autoregulation in this case might be only impaired not abolished which would also modify the response (*cf p* 19)

Time relations in the autoregulatory response (II)

When the arterial blood pressure was changed within the autoregulatory pressure range by rapid withdrawal or infusion of blood, the cerebral venous oxygen saturation, continuously analysed oximetrically was found first to change in the same direction as the pressure, but then to return gradually towards the basal level (Fig 1 II) The time for this response to be complete *i e* from the pressure increase or decrease to the point where the control level of oxygen saturation was reestablished was about 45 and 10 seconds respectively These figures are in accordance with or somewhat shorter than those reported in other studies (for references see paper II)

Reactive hyperemia (I)

This term denotes an increased cerebral blood flow in normotension, combined with a passive pressure-flow relation, elicited by a period of reduced perfusion pressure. The phenomenon has been observed both when the reduction of the perfusion pressure has been accomplished by a rise in the intracranial pressure (Noell and Schneider 1948, Häggendal *et al.* 1969 and 1970 b) and after periods of pronounced arterial hypotension (Freeman and Ingvar 1968). Usually the period of hypotension preceding the reactive hyperemia has been combined with a substantial flow reduction. In some of the reported cases, however, no flow reduction had been observed (Häggendal *et al.* 1970 b), which is interesting with regard to the mechanism behind the phenomenon. In an attempt to a further evaluation of the role of hypoxia for the appearance of reactive hyperemia, the flow reaction to arterial blood pressure increases after a period of hypotension with reduction of flow was studied in animals, where a primary vasodilatation had been induced by hypercapnia or papaverine infusion. In spite of the fact that the blood flow had not been reduced to values below normal and that the venous oxygen tension had not been lower than about 40 mm Hg a marked flow increase was encountered (Fig. 7 I), which gradually subsided. These results confirm those obtained by Häggendal *et al.* (1970 b) and indicate that tissue hypoxia is not a prerequisite for reactive hyperemia. Nor does carbon dioxide accumulated in the tissue during the hypotension seem likely to uphold such a long lasting vasodilatation. It might be of interest to compare this derangement of the normal pressure-flow relation to the luxury perfusion syndrome. This term was recently introduced by Lassen (1966) and denotes a state characterized by "an over-abundant cerebral blood flow relative to the metabolic needs of th brain tissue". With normal arterial oxygen saturation "bright red venous blood" would be the cardinal feature of the syndrome. In cases where the high oxygen saturation in the venous blood is the result of the flow increase ordinarily seen when the normal autoregulation is impaired, the two terms, reactive hyperemia and luxury perfusion, are synonymous as far as the blood pressure and the arterial oxygen content are high enough. However it is clear that the combination of high flow values and "red veins" is compatible with a normal pressure-flow relation *e.g.* in hypercapnia. On the other hand a deranged pressure-flow relation may be associated with dark venous blood in hypotension and/or pronounced hypoxia.

The pressure-flow relation in arterial hypoxia (I)

In combination with an extreme arterial hypoxia Häggendal and Johansson (1963) found signs of an abolished autoregulation. In the present study however it was possible to demonstrate a well functioning regulation in some cases even when the arterial oxygen saturation was reduced down to 40 per cent and a certain degree of flow increase had occurred. From a consideration of the general relation between

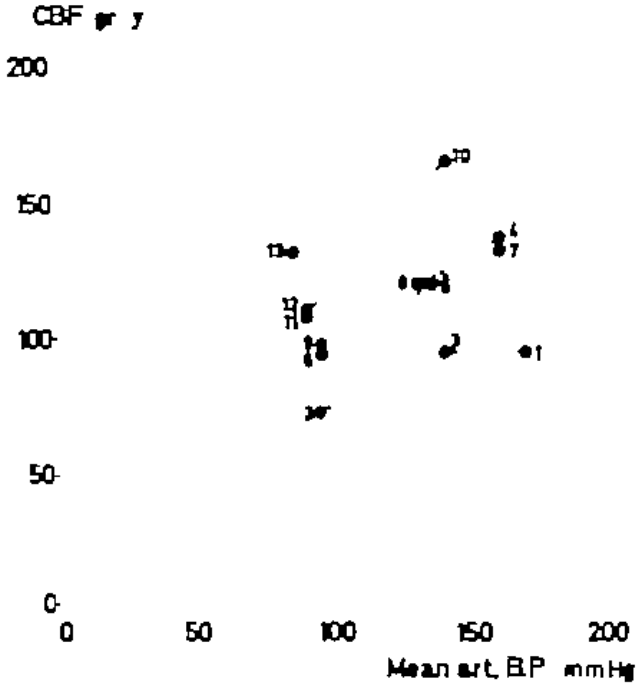

Fig 2. Relation between mean rterial blood pressure and cerebral blood flow in grey matt (CBF_{grey} ml/100 gmin) in one animal at different values of arterial oxygen saturation. Tho numbers mark the hronological order of the measurements and refer to the numbers in Table II Measurements performed at about the same arterial xygen saturation are connected by broken lines. An imperfect autoregulation is illustrated in hypoxia. In hypotension below the autoregulatory range there is a vascular dilatation in response to decreasing arterial oxygen saturation down to a certain limit (no 11) With maintained low arterial oxygen saturation and blood pressure a further vasodilatation beyond this limit is induced by intra venous administration of glucose (no. 13).

arterial oxygen saturation and cerebral blood flow (see Fig 2, I) it seems improbable that a complete abolishment of autoregulation could take place at a higher oxygen saturation than where the steep increase in blood flow begins, because such an abolishment would be expected to cause a comparatively large flow increase The vasodilatation encountered in pronounced hypoxia is probably related to tissue hypoxia (Noell and Schneider 1944 Häggendal Nilsson and Norbäck 1966) and in this range of arterial oxygen saturation optimal conditions for metabolic blood flow autoregulation should be provided. In Fig 2 and Table II the results are presented from an experiment where some points may be of interest in this connection Autoregulation in this animal was impaired but not completely abolished at an arterial oxygen saturation of about 55 per cent (nos 4 5 6) At an arterial pressure, where the blood flow in the normoxic situation was reduced due to low blood pressure the flow was higher in hypoxia. When the measurements were reposted after about 43 minutes (nos 7 8) no signs of reactive hyperemia were found With increasing arterial hypoxia a further vasodilatation was encountered in normotension (no 10) In hypotension there was a flow increase when the arterial oxygen saturation was lowered from 57 t 46 per cent (nos 6 11) and there seemed to be a tendency to

Table II. Data obtained from the experiment presented in Fig. —. The numbers refer to those in the figure.

Abbreviations

P_{aO_2} = Arterial oxygen tension.
P_{vO} = Venous oxygen tension in blood from the superior sagittal sinus.
CVR = Cerebrovascular resistance calculated from mean arterial blood pressure and CBF_{N2O}.
For the remaining abbreviations see legend to Table I.

keep the venous oxygen tension constant (22–24 mm Hg nos. 6, 8–11) over a wide blood pressure range when the arterial oxygen saturation was varied between 57 and 36 per cent. Decreasing the arterial oxygen saturation in hypotension from 46 to 38 per cent did not induce any further vasodilatation and the venous oxygen tension and the oxygen uptake decreased, indicating an inability to respond to arterial hypoxia while the cerebrovascular resistance was still fairly high. This finding would be in line with earlier observations that maximal vasodilatation does not seem to take place even at very pronounced arterial hypoxia if the arterial carbon dioxide tension is not simultaneously increased (Häggendal and Johansson 1965). Against the background of a theory of hydrogen ions as the factor by which hypoxia acts on the vessels (Skinhoj 1966, Betz and Kozak 1967, Lassen 1968) a hypothetical explanation for the limited vasodilatatory response could be an insufficient supply of substrate required for the increasing anaerobic metabolism. Evidence of an interference with glycolysis in the brain due to substrate depletion in hypoxia was discussed by Cohen (1960). An indication that this might be a limiting factor for hypoxic vasodilatation is the flow increase encountered in hypotension after administration of glucose (no. 13), when no further dilatation had occurred with decreasing arterial oxygen saturation (nos. 11–12). In this animal 40 ml of a 10 per cent solution of glucose were given, which did not appreciably alter the oxygen capacity of the blood.

Reaction of the cerebral vessels to changes in the arterial carbon dioxide tension in hypotension (I)

Different results have been reported in the comparatively few studies published concerning the ability of the cerebral blood vessels to dilate in response to an increase of the arterial carbon dioxide tension, when autoregulation is exhausted. Thus Harper (1965) reported lack of response in hypotension. On the other hand Häggendal and Johansson (1965) studying the situation when autoregulation was impaired by extreme hypoxia found a scattering of the pressure-flow relation that could be attributed to differences in the arterial carbon dioxide tension and Häggendal *et al* (1969 and 1970a) also demonstrated a reactivity to carbon dioxide when the perfusion pressure was lowered beyond the autoregulatory range by induced increase in the intracranial pressure. The investigation of this reaction in hypotension meets with some difficulties in that the ensuing flow changes can be expected to be relatively small and the passive-elastic properties of the vessel wall imply changes in the vascular dimensions as a result of even small pressure changes.

In Fig. 6 I, a reaction to carbon dioxide in hypotension below the autoregulatory range is illustrated in terms of cerebral vascular resistance. There is a tendency to vasodilatation with increasing arterial carbon dioxide tension. With the oximetric technique a similar reaction was noticed during severe hypotension i.e. higher cerebral venous oxygen saturation with higher concentration of carbon dioxide in the inspired air.

Discussion

The compatibility of these results with the metabolic theory for the autoregulation of blood flow will be discussed. It is obvious that a metabolic mechanism being basically flow-dependent cannot keep the flow absolutely constant, some change is necessary to evoke a stimulus. Since the regulation, as discussed above is practically perfect it follows that an extremely sensitive mechanism would be required. The metabolic factors most discussed as eliciting the reaction have been oxygen, acting directly or via some metabolite resulting from tissue hypoxia, carbon dioxide and the hydrogen ion concentration in the tissue (Rapela and Green 1964, Lassen 1964). The latter factor has attracted further attention recently in view of the theory stating that changes in the hydrogen ion concentration may be the common link for the influence on the vessels by both oxygen and carbon dioxide (Skinhøj 1966, Betz and Kozak 1967, Zwetnow, Kjällquist and Siesjo 1968, Severinghaus 1968, Lassen 1968). In fact none of these factors seems likely to be able to establish a very sensitive regulation.

Thus the reaction of the vessels in response to changes in the arterial oxygen saturation is quite small around the physiological values and there is no marked vasodilatation until the arterial hypoxia has become pronounced (Fig. 2 I) (Häggendal and Johansson 1965). The constrictive effect of an elevation of the arterial oxygen tension is practically negligible (Lambertsen 1961, Reivich 1964). Further

more the presence of autoregulation at supernormal flow levels seems almost conclusively to rule out hypoxia as the regulatory factor

Concerning carbon dioxide the effect on vascular resistance by changes in its arterial tension is pronounced also around the normal value There is however evidence against carbon dioxide being a primarily important factor As discussed by Harper (Harper and Häggendal 1968) an increase in the hydrogen ion concentration in the extracellular fluid corresponding to a change in the arterial carbon dioxide tension from 40 to about 70 mm Hg would be required to reduce the vascular resistance to the extent observed, when the arterial blood pressure is lowered within the autoregulatory range

In addition when the lower limit for autoregulation is reached in hypotension the metabolic theory implies that the vessels are maximally dilated due to the regulatory factors. The fact that the response to both carbon dioxide and oxygen is retained below the autoregulatory pressure range adds to the improbability of *either being the main autoregulatory agent.*

A vasodilatatory influence of hypoxia in combination with a flow reduction secondary to a fall in blood pressure could be expected to be especially pronounced in severe hypoxia since here vasodilatation in response to a small decrease in oxygen availability is known to be very marked in normotension It might even be so large as to create a fairly effective autoregulatory response Such a regulation might be discussed in the case illustrated in Fig 2 where there are signs of an imperfect autoregulation Whether the autoregulatory tendency noted in the hypoxic state is a result of a hypoxic influence modifying a passive pressure-flow relation or is an expression of an impairment of the ordinary mechanism in the higher pressure range is not possible to judge In the hypotensive state however a metabolic influence would seem to be responsible for the cerebrovascular dilatation.

The relatively long time period required for flow adjustment has been assumed to favour a metabolic theory since a myogenic mechanism might be expected to induce a faster response (Harper 1960) In vitro studies on the reaction of vascular smooth muscle to quick stretch have shown, however that the response may require about 60 seconds to become fully developed (Sparks 1964), thereby differing from other smooth muscle *e.g* in the urinary bladder which exhibits a much faster response.

In regard to the mechanism responsible for the reactive hyperemia it should be pointed out that in paper I *the main problem studied was whether it was possible* to induce the phenomenon under conditions where metabolic factors could reasonably be excluded. No more detailed analysis of the duration and degree of hypotension was performed It seems likely that metabolic factors might contribute to the induction and maintenance of reactive hyperemia in some circumstances but they are not a prerequisite *for the appearance* of the phenomenon It may be discussed whether the reactive hyperemia demonstrated in paper I is of the same origin as the transitory passive flow response occurring in combination with pressure rises in the autoregulatory range as demonstrated in paper II using the oximetric technique.

PART II

EFFECT OF INCREASED VENOUS PRESSURE ON THE CEREBRAL BLOOD FLOW

An autoregulatory mechanism depending on vascular smooth muscle response secondary to changes in the chemical environment, should be effective when the perfusion pressure, and thus flow is altered irrespective of how this change is achieved A myogenic mechanism on the other hand, would in principle be independent of the perfusion pressure and respond to changes in the transmural pressure. Such considerations have been the background for an experimental approach previously used in different vascular beds employing increases in the venous pressure while the level of the arterial blood pressure is controlled preferably so that the venous and arterial blood pressures are raised to the same extent (see Folkow 1962) In this situation the perfusion pressure is maintained constant, while the transmural pressure is raised. In a passive vascular bed this would lead to an increased flow due to distension of the elastic vessel wall while in an actively responding vascular bed, governed by metabolic factors there would be a tendency to keep flow constant If the response were due to stretch of the smooth muscles, a contraction would ensue which if powerful enough would cause a flow reduction This latter kind of response has been found in skeletal muscle and intestine (Folkow 1949 Folkow and Öberg 1961 Johnson 1959 and 1964 c)

The brain cannot be directly subjected to this otherwise convenient procedure of differentiating, the effects of the two mechanisms as it is enclosed in the rigid skull and any change in the venous pressure consequently will lead to a change in the tissue pressure altering the transmural pressure in proportion In the present study this difficulty was overcome by the removal of large parts of the skull and dura over both hemispheres thereby providing conditions for expansion of the tissue The venous pressure was raised by inflation of a balloon attached to a catheter and placed in the right atrium of the heart No special measures were taken to maintain the arterial blood pressure during the increase in venous pressure since any additional surgical trauma was considered undesirable The inflation of the balloon tended to cause a moderate decrease of the arterial blood pressure presumably due to a reduction of the cardiac output. Such a decrease of the arterial pressure would curtail the possibility of revealing differences in the cerebrovascular response as the

accompanying decrease in transmural pressure would counteract the increase induced by the venous pressure rise. This difficulty was avoided by using a reference value for each animal (see paper *III*)

In Fig 2, III, was demonstrated a difference in the percentual changes of the cerebrovascular resistance if the perfusion pressure was reduced by venous pressure increase or by arterial pressure decrease. A reduced perfusion pressure induced by elevation of the venous pressure was accompanied by either unaltered or increased cerebrovascular resistance, while arterial pressure reductions were accompanied by proportionate lowering of the resistance When the arterial blood pressure was reduced by bleeding with the venous pressure maintained high and constant there was autoregulation on a lower flow level than with normal venous pressure (Fig 1 III)

Discussion

These results indicate a mechanism triggered by changes in the transmural pressure to be responsible for the cerebral blood flow autoregulation. No attempts to block possible nervous influence were made but available information from other vascular beds, where the response was shown to be independent of nervous factors make it unlikely that such an influence would be important in the case of the brain Furthermore the adrenergic innervation of the intracerebral vessels is sparse (Carlsson Falck and Hillarp 1962) On the basis of earlier studies it has been concluded that the nervous supply to the brain vessels is hardly of any functional significance (Sokoloff 1959) Although interest in this problem is now growing (Rapela, Green and Denison 1967 Langfitt and Kassell 1968 Mchedlishvili 1969 James, Millar and Purves 1969) there is no evidence to suggest that nervous vasomotor control should be of decisive importance for autoregulation in the brain

The myogenic hypothesis then remains to be considered This theory described in detail by Folkow in 1964, has recently been reviewed by Mellander and Johansson (1968) In short, parallels have been drawn to the function of the smooth muscles of the ureter and intestine which show spontaneous rhythmic contractions the frequency of which increases in response to stretch (Boxler 1948, Bülbring [illegible]) Evidence of vascular smooth muscle automaticity has been revealed by electrophysiological studies, beginning with the report of Funaki (1958) who recorded action potentials with microelectrodes in the muscle cells of the small vessels in the frog tongue. Furthermore rhythmic activity has been demonstrated in small pre- and postcapillary vessels studied microscopically *in situ* in the [illegible] (Nicoll and Webb 1955 Wiederman 1957 and 1968). This vasomotion, has been suggested to create the "basal tone" remaining in most vascular areas after elimination of all known extrinsic regulatory influence.

The observation that the basal tone is least pronounced in those vascular areas which show inefficient or no autoregulation (Folkow 1964) might suggest the regulation in response to changes in the transmural pressure is effective

same mechanism direct studies on small precapillary vessels have shown that vasomotion does become potentiated in response to an increase in the transmural pressure (Nicoll and Webb 1955 Wiedeman 1960) although the extent to which this increase in vasomotion can account for flow constancy has not been exactly established. Such a mechanism would, however explain one contradiction in the original theory namely that if the stimulus were distension it would seem to be abolished if the resistance to flow were upheld by a continuous contraction of the smooth muscle cells. With the concept of a changed frequency of contractions when the pressure is altered, a perfect constancy of flow although still remarkable implies no real contradiction Observations like those reported in paper I of well functioning autoregulation at high flow levels and of reactivity to oxygen and carbon dioxide in hypotension might possibly be explained in terms of a differentiated response to different stimuli in separate parts of the precapillary resistance section Some experimental evidence of such a response exists Thus studies in skeletal muscle during exercise have indicated that metabolic factors are comparatively more important than the transmural pressure as determiners of the tone of the resistance vessels and vice versa concerning the precapillary sphincter region (Lundvall Mellander and Sparks 1967)

GENERAL SUMMARY AND CONCLUSIONS

Different aspects on the pressure-flow relation in the brain have been studied and discussed with regard to the mechanism responsible for cerebral blood flow autoregulation.

Evidence of an ability of the autoregulatory mechanism to establish a perfect flow constancy in response to arterial blood pressure changes at normal and high flow levels was presented

The pressure-flow relation in hypotension below the autoregulatory pressure range in conditions with a primarily induced vasodilatation was found to be curvilinear with the convexity towards the pressure axis.

A cerebrovascular reaction to changes in the arterial tensions of both carbon dioxide and oxygen was demonstrated in hypotension, which indicates a possibility of this apparently passive pressure-flow relation being modified by metabolic factors.

With rapid changes of the arterial blood pressure there was initially a change of flow in terms of a change in the cerebral venous oxygen saturation in the same direction After that, within the autoregulatory pressure range, the flow gradually returned to th control level, this response being completed in about 40 seconds from the beginning of the alteration of the pressure

Reactive hyperemia could be elicited after a period of hypotension without signs of tissue hypoxia and it was suggested that this might be a prolongation of the normal transitory flow increase following pressure rises within the normotensive pressure range

During arterial hypoxia autoregulation was effective even when a hypoxic vasodilatation had occurred. In extreme arterial hypoxia an impairment of the autoregulatory function was noted, the pressure-flow relation however was not "purely passive In hypotension below th autoregulatory pressure range a vasodilatation was encountered with decreasing arterial oxygen saturation which might establish an important regulation when the normal autoregulation is impaired.

On account of the results obtained metabolic f ctors were considered unlikely to be responsible for the normal autoregulation of cerebral blood flow This was further stressed by the results from the following group of experiments. Here studies on the vascular response to increase of the venous pressure compared to the response to arterial blood pressure reductions were performed after removal of the skull coverings n an attempt to separate the effect on flow by changes in the perfusion pressure from

those by changes in the transmural pressure. A mechanism most likely of myogenic nature stimulated by changes in the transmural pressure was demonstrated to be responsible for the normal cerebral blood flow autoregulation.

In view of the increasing availability of methods to study regional cerebral blood flow and metabolism applicable to diseased states a detailed knowledge of the normal pressure-flow relation and the reaction of the blood vessels to different influences in different pressure ranges is important The present work might increase the possibilities for a sound clinical approach to the study of problems concerning cerebral blood flow

ON THE RELATION BETWEEN BLOOD PRESSURE AND BLOOD FLOW IN THE CEREBRAL CORTEX OF DOGS

by

BARBRO EKSTRÖM-JODAL, EGIL HÄGGENDAL AND
NILS JOHAN NILSSON

ABSTRACT

Barbro Ekström-Jodal, Egil Häggendal and Nils Johan Nilsson. *On the relation between blood pressure and blood flow in the cerebral cortex of dogs* Acta physiol scand. 1970 Suppl 350 29–42 Some different aspect on the pressure-flow relation in the brain were studied in anaesthetized dogs with the radioactive gas elimination technique including external γ registration At high flow levels, primary vasodilatation being induced by hyperoxpnia or intravenous papaverine infusion, there was an effective autoregulation of flow in response to arterial blood pressure changes. In pronounced hypotension the pressure-flow relat on was found to be curvilinear with the convexity towards the pressure axis; an ability to react to changes in the arterial carbon dioxide tension was, however demonstrated At arterial hypoxia autoregulation functioned well, ven at very low values of oxygen saturation Reactive hyperemia could be elicited after a period of hypotension without preceding subnormal flow values. These results are discussed with respect to the metabolic theory for the mechanism responsible for cerebral blood flow autoregulation

INTRODUCTION

Mainly two theories for the mechanism behind the autoregulation of the cerebral blood flow in the sense that the flow is kept constant in spite of variations in the blood pressure are discussed at present The *metabolic theory* (e.g. Harper 1966) implies that the flow is autoregulated by the changes in chemical conditions in the

tissue, which arise when the blood flow passively follows increases or decreases in the perfusion pressure. The other theory the *myogenic* ascribes autoregulation to a myogenic response in the vascular wall induced by changes in the transmural pressure (see Folkow 1962 and 1964) So far neither of these theories has been definitively proved. In the nineteen sixties interest has been much concentrated on the role of metabolic factors in effecting cerebral blood flow autoregulation (Lassen 1964 Rapela and Green 1964 see also Harper and Häggendal 1968)

The present work is a study on the influence of some metabolic factors on the cerebral blood vessels during different blood gas and blood pressure conditions and deals with

Pressure-flow relations especially the problem of flow autoregulation when the blood vessels are dilated by different agents (carbon dioxide or papaverine)

Pressure-flow relations during graded arterial hypoxia.

Pressure flow relations during pronounced hypotension i e arterial pressure below the autoregulatory pressure range

The reactivity of the cerebral blood vessels to carbon dioxide during pronounced hypotension.

Reactive hyperemia elicited without preceding subnormal blood flow

METHODS

Thirty mongrel dogs with body weights of 12 to 20 kg were used The animals were anaesthetized with pentobarbital intravenously in a dose of 25–30 mg per kg body weight The operative procedure was completed within one to two hours with the animals breathing spontaneously After this the experiments were performed in muscle relaxation by suxamethonium chloride and the animals were ventilated with an adjustable pump through an endotracheal tube The body temperature controlled in the oesophagus was maintained at 37–38 C with the aid of an electrical heating pad Clotting was prevented by intravenous administration of heparin

The arterial tensions of carbon dioxide and oxygen were changed by ventilation with different gas mixtures No blood flow measurements were performed until 15 min after a change The arterial carbon dioxide tension was considered constant if there were no greater differences between measurements than ± 2 mm Hg at unchanged ventilation Results from measurements where the difference exceeded these limits were discarded Blood samples for analysis of oxygen saturation hemoglobin concentration, pH and carbon dioxide tension were drawn simultaneously from a femoral artery through a polyethylene catheter and from the superior sagittal sinus via a needle bored through the skull about three cm rostral to the occipital

protuberance. Oxygen saturation (Holmgren and Pernow 1950 Bjurs and Nilsson 1965) and hemoglobin concentration (Drabkin and Austin 1935) were determined spectrophotometrically concerning the latter with modifications according to the Decision of the Standardizing Committee of the European Society of Haematology concerning Haemoglobinometry 1963 and the oxygen capacity was calculated on the basis of the hemoglobin concentration. Determinations of pH and carbon dioxide tension were made according to the micro method of Siggaard Andersen *et al.* (1960) with corrections for low oxygen saturation. The arterial and venous oxygen tensions were calculated with the Blood Gas Calculator of Severinghaus (Radiometer Copenhagen) from the hemoglobin dissociation curve for dogs.

The arterial blood pressure was electromanometrically recorded from the catheter in the femoral artery Mean pressures were obtained by electrical integration, and the heart level was chosen as the reference point. The arterial blood pressure thus recorded, which was regarded as a measure of the cerebral perfusion pressure was changed by bleeding or retransfusion through a polyethylene catheter in the other femoral artery The blood was kept at 37–38 C in a reservoir before retransfusion Measurements of cerebral blood flow were not performed until 5 min after any change in blood pressure except in the studies on reactive hyperemia, where ~ min were allowed to pass.

The cerebral blood flow measurements were made with the radioactive gas elimination method of Lassen *et al* (1963) as described by Haggendal, Nilsson and Norbäck (1965) For intraarterial injections of the indicator the left vertebral artery was catheterized with a thin polyethylene catheter (PE 100) inserted through the external thoracic and subclavian arteries about 5–8 cm up into the intact vertebral artery Rapid injections (~ 3 sec) of radioactive krypton (Kr^{85}) dissolved in saline (1–2 ml) were given. The elimination was registered externally with a scintillation detector coupled to a ratemeter (Tracerlab Nuclear Instrumentation) with a time constant of 1.5 sec and recorded linearly on a potentiometer writer (Beckman Laboratory Potentiometric Recorder) The clearance curves were followed for 10–15 min Influence on the curves from extracerebral tissue was reduced by lead collimation of the detector After semilogarithmic plotting the curves were resolved according to the compartment analysis method as described by Häggendal Nilsson and Norbäck (1965) The values for the fast component considered representative of flow in the cerebral grey matter are given in the results

The studies of the passive pressure flow relation in pronounced hypotension and of the reactive hyperemia were facilitated by an initially high blood flow level, induced by hypercapnia or papaverine infusion The mean arterial blood pressure was lowered in steps of about 10 mm Hg Papaverine was infused intravenously at a rate of 0.4–0.5 mg per kg body weight and minute. Several measurements of cerebral blood flow were made before the first bleeding to control that the influence of papaverine on the cerebral blood vessels was constant

RESULTS

Pressure-flow relations at high levels of cerebral blood flow

Fig 1 demonstrates pressure-flow relations in four hypercapnic animals and in four animals where cerebral vasodilatation was induced by papaverine infusion. The actual flow values were very different in different animals. In spite of this there was in all cases perfect or almost perfect flow constancy with arterial blood pressure reductions over a wide range. It can be noted that even at the highest blood flow levels the ability to autoregulate was preserved down to a quite low arterial blood pressure In all of these animals the arterial oxygen saturation was normal and the venous oxygen saturation thus high on account of the increased cerebral blood flow

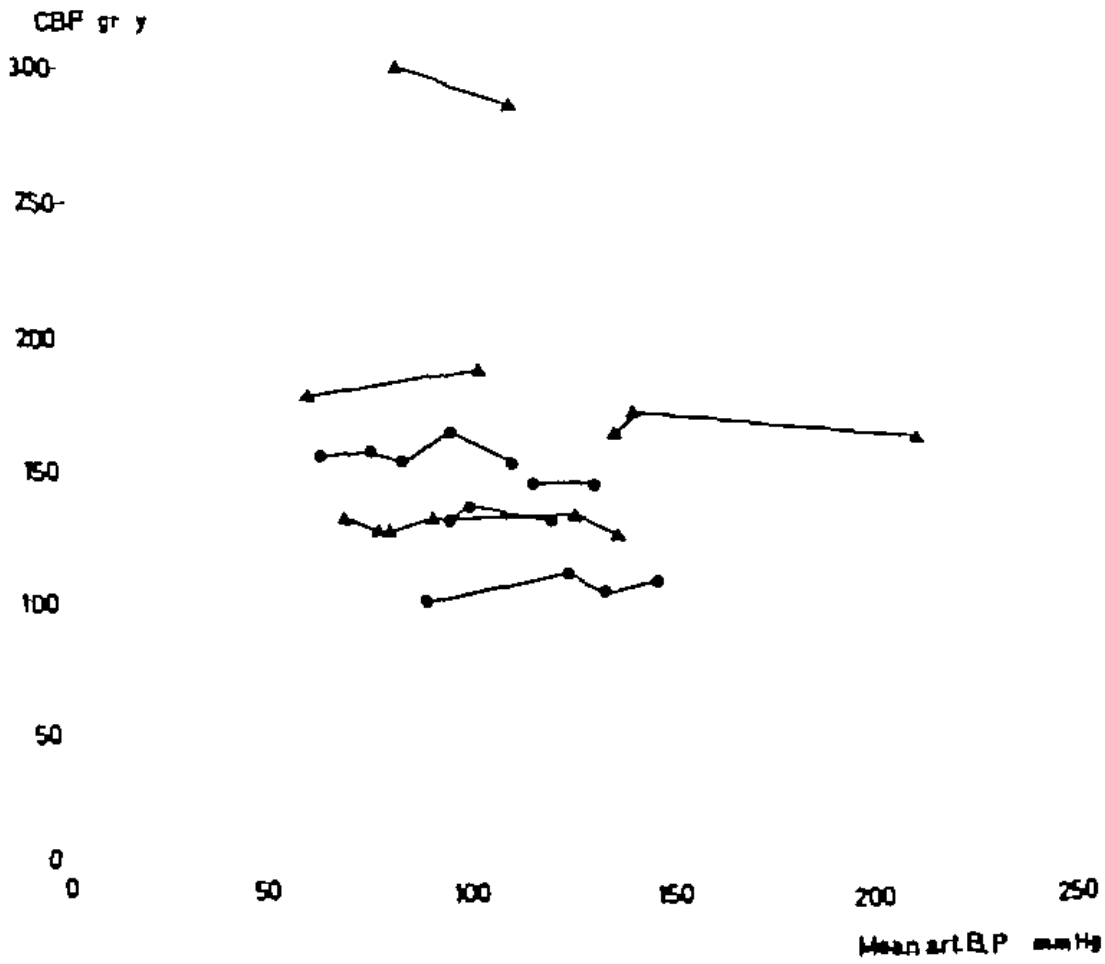

Fig. 1 The relation between mean arterial blood pressure and cerebral blood flow in grey matter (CBF_{grey} ml/l) gmin) in animals with a primary vasodilatation, induced by hypercapnia (filled circles) or papaverine infusion (filled triangles) Effective autoregulation is demonstrated within a wide arterial blood pressure range on different flow levels.

Pressure-flow relations during graded hypoxia

Fig. 2 shows the correlation between cerebral blood flow and arterial oxygen saturation (nine animals) with emphasis on preserved ability to autoregulate. Filled circles mean that with unaltered blood gas tensions the blood flow remained nearly constant in spite of blood pressure reductions of at least 45 mm Hg. Open circles imply that autoregulation was not tested. A typical experiment illustrating the ability of autoregulation even at pronounced arterial hypoxia is presented in Fig. 3. In this experiment the flow increased from about 50 to 85 ml/100 gmin when the arterial oxygen saturation was lowered from 95 to 40 per cent and the autoregulation was still functioning.

Pressure-flow relations during pronounced hypotension

The pressure-flow relation at blood pressures below the autoregulatory range was studied in one group of animals. These experiments were performed during cerebrovascular dilatation induced either by papaverine infusion (Fig. 4 and 5 a) in four animals or by carbon dioxide inhalation (Fig. 5 b) in another four animals. Auto-

Fig. 2. Correlation between arterial oxygen saturation ($S_{a_{O_2}}$) and blood flow in cerebral grey matter (CBF_{grey} ml/100 gmin). Filled circles indicate that autoregulation was tested to be well functioning when the arterial blood pressure was changed with the blood gases maintained constant. Open circles mean that autoregulation was not tested at that level of arterial oxygen saturation. Mean arterial blood pressure within the range of 128–140 mm Hg and arterial carbon dioxide tension 40–44 mm Hg.

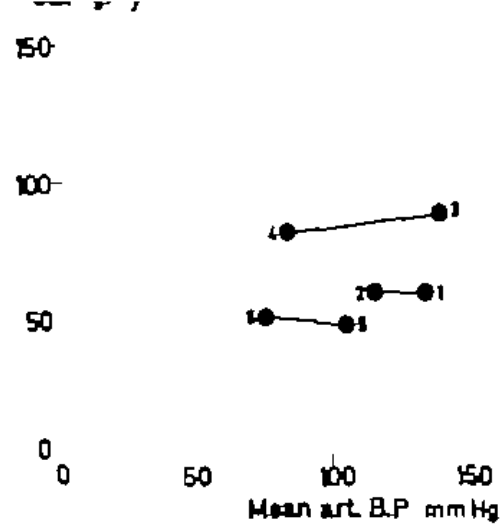

Fig 3. The relation between mean arterial blood pressure and blood flow in cerebral grey matter (CBF_{grey}, ml/100 gmin) in one animal studied at different levels of arterial oxygen saturation (S_{aO_2}) with a fairly constant arterial carbon dioxide tension (P_{aCO_2})
The numbers indicate the chronological order of measurements. CMR_O stands for cerebral metabolic rate of oxygen.

Measurement Number	P_{aCO_2} mm Hg	S_{aO_2} %	CMR_{O_2} ml/100 gmin
1	29	64	4.9
	29	61	4.7

Efficient autoregulation is illustrated at different levels of arterial oxygen saturation.

Fig 4 Relation between mean arterial blood pressure and flow in cerebral grey matter (CBF_{grey} ml/100 gmin) in an animal with intact autoregulation during intravenous infusion of papaverine. The relation is curvilinear with the inflection point at the pressure axis in hypotension

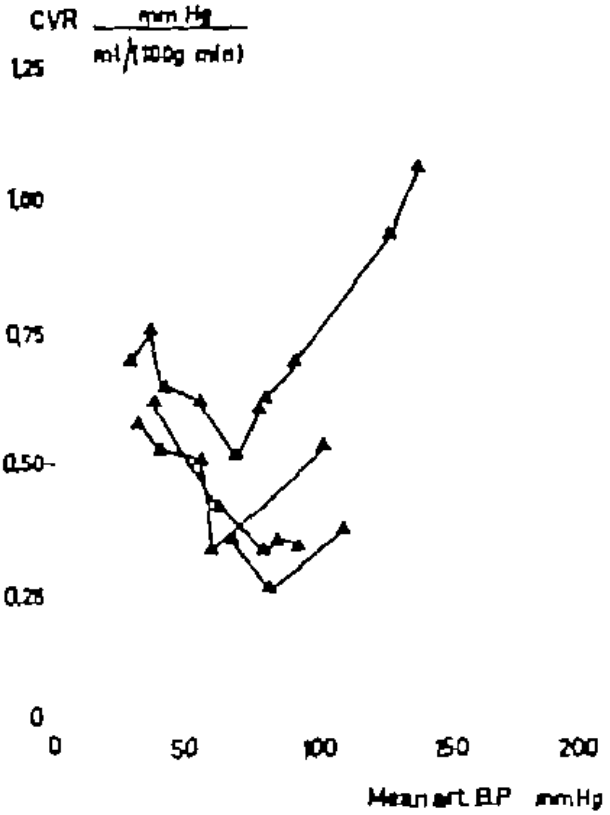

Fig. 5 a. Correlation between mean arterial blood pressure and cerebro vascular resistance (CVR) in dogs, where a primary vasodilatation was induced by intravenous papaverine infusion. From the lowest value obtained during autoregulation the CVR increased in hypotension. In two animals the increase was most pronounced initially and in one animal there was a practically constant increase in CVR thereby indicating a curvilinear pressure-flow relation as shown in Fig. 4. In another animal only one hypotensive flow measurement was obtained resulting in an increased CVR, which is indicative of either a curvilinear pressure-flow relation or a linear relation intersecting on the pressure axis.

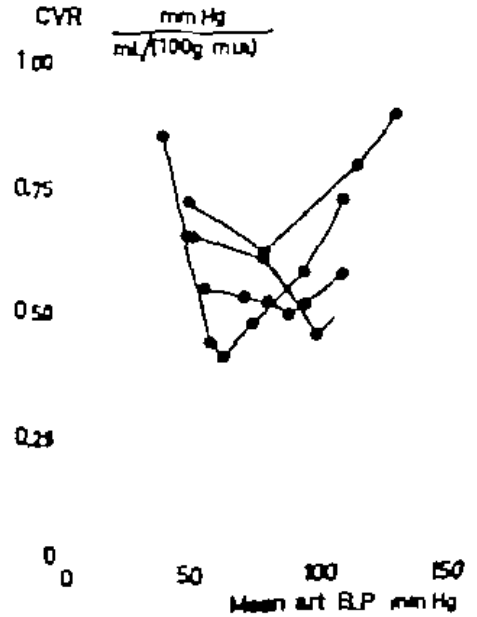

Fig. 5 b. The same correlation as in Fig. 3 a for hypercapnic animals.

regulation was first demonstrated at the supernormal flow level and when the flow had just begun to decrease at a certain blood pressure value the following pressure-flow relation was studied by further reducing the blood pressure in small steps. This part of the pressure-flow relation was curvilinear with the convexity towards the pressure axis as illustrated in Fig 4 In Fig 5 a and b the same phenomenon is expressed as the relation between the arterial blood pressure and the cerebrovascular resistance. Initially a successive decrease in the cerebrovascular resistance is observed when the arterial blood pressure was lowered, indicating normal autoregulation Then, in response to blood pressure reductions below the autoregulatory range there was a marked increase in the resistance.

Reactivity of the cerebral blood vessels to carbon dioxide in pronounced hypotension

Fig 6 shows the relation between the arterial carbon dioxide tension and the cerebrovascular resistance at an arterial blood pressure of 120 mm Hg which was demonstrated to be within the autoregulatory range for all the nine animals included (filled circles) The figure also illustrates the same relation for seven dogs in hypo-

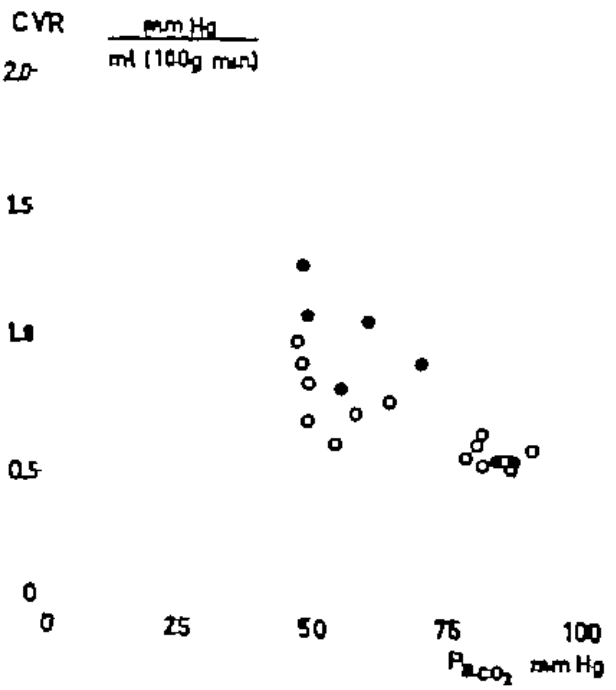

Fig 6. Correlation between arterial carbon dioxide tension (P_{aCO_2}) and cerebrovascular resistance (CVR) in two groups of dogs: one with mean arterial blood pressure 120 mm Hg (filled circles), which was within the autoregulatory range; the other at mean arterial blood pressure below the autoregulatory range (open circles) In both groups there was a decreasing CVR, when $P_{a.CO_2}$ was raised.

Table I. Values from one animal where the mean arterial blood pressure was kept 50 mm Hg, which was tested to be below the autoregulatory range when the carbon dioxide tension (P_{aCO_2}) was 49 and 78 mm Hg. A response to changes in P_{aCO_2} is seen at a fairly constant arterial oxygen saturation (S_{aO_2}). The cerebral metabolic rate for oxygen is practically unchanged between measurements.

CBF_{grey} ml/100 gmin	CMR_O ml/100 gmin	S_{aO} %	P_{aC} mm Hg

94	3.6	83	78

tension, tested to be below the autoregulatory range (open circles) although in this case the representation is not restricted to one single blood pressure value but different blood pressures are represented at most of the different values of arterial carbon dioxide tensions. The influence on these results of different hypotensive blood pressures will be discussed. There was a decrease in cerebrovascular resistance with increasing arterial carbon dioxide tension both in the hypotensive and the normotensive animals. The resistance however tended to be lower during hypotension especially when the hypercapnia was only moderate.

Table I is an example of the cerebrovascular reactivity to carbon dioxide in one animal, where the autoregulation was exhausted due to induced severe hypotension. The arterial blood pressure was kept constant (50 mm Hg) while the arterial carbon dioxide tension was changed in steps. It can be seen how the flow increased in response to the raised carbon dioxide tension. In this experiment loss of autoregulation was tested at the arterial carbon dioxide tension of 49 and 78 mm Hg. It cannot be excluded that in the hypocapnic state an ability of autoregulation was preserved.

Experiments on reactive hyperemia

Fig. 7 illustrates the pressure-flow relation, when the arterial blood pressure was reinstituted after a period of pronounced hypotension with failing autoregulation. Throughout these experiments the cerebral blood vessels were dilated by hypercapnia (4 dogs) or papaverine (3 dogs) as described earlier. The blood pressure was then lowered stepwise. The autoregulatory flow levels for the different animals are indicated in the figure. Reactive hyperemia ensued even in those experiments, where the blood flow during the hypotension had never decreased below normal values. The oxygen tension in the cerebral venous blood was never below 40 mm Hg.

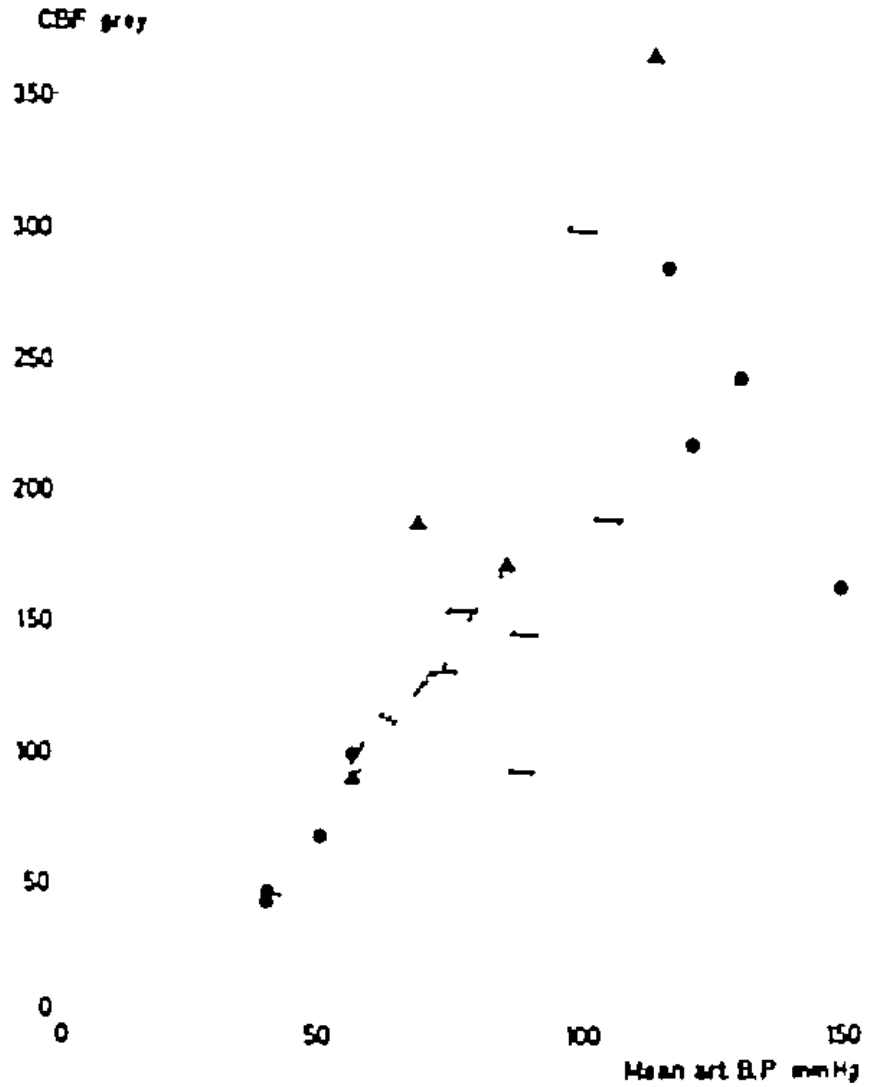

Fig. Illustration of reactivity to hypercapnia in two groups of dogs, one hypertensive group (filled circles) and one group during intravenous dopamine infusion (filled triangles). The lowest values of cortical blood flow in grey matter (CBF_{grey} ml/100 gram) obtained in hypotension and the highest values obtained in the post hypercapnic period are connected by broken lines. Solid lines indicate the autoregulatory flow levels.

DISCUSSION

Methodological considerations

The purpose of this investigation was to study some different aspects of the pressure-flow relationship in the cerebral circulation in an attempt to evaluate the role of mechanical factors in autoregulation. Such a study requires methods implying as little trauma as possible since the normal autoregulation seems to be a vulnerable process easily interfered with by surgical preparative procedures (Rapela and Green 1964). The method of investigation in the present study of Lassen *et al.* (1963) meets this

demand in that it includes γ registration through the intact skull. There is good experimental evidence that the fast component in the compartive γ curve is an expression of blood flow through the cerebral grey matter (Häggendal Nilsson and Norbäck 1965) The correct estimation of this component according to the compartment analysis method requires steady state conditions during a comparatively long period of time, depending on the blood flow With normal values for blood gases and blood pressure the time needed for a measurement is 10–15 min. This condition may not always be fulfilled in the studies of reactive hyperemia, this fact, however cannot alter the qualitative results even if the actual values are probably subject to a larger degree of uncertainty than is ordinarily inherent in the method. In some cases this uncertainty is indicated in the values for the cerebral metabolic rate of oxygen calculated from these values of blood flow and the arterio-venous oxygen difference obtained during the flow registrations 5–6 min after the pressure increase. These values being often somewhat higher than otherwise in the same animal.

The partition coefficient 0.95 for Kr^{85} between cortex and blood was used for the calculation of cerebral blood flow from the clearance curves throughout the experiments. The value of the partition coefficient is dependent upon the hematocrit value of the blood (Lassen *et al* 1963 Ingvar and Lassen 1962 Glass and Harper 1962) Since, however there were only moderate variations in this factor between measurements in the run of each experiment as well as between different animals, corrections were not considered necessary

Sagittal sinus blood was used as representative of venous blood from the cerebral grey matter Häggendal, Nilsson and Norbäck (1965) and Häggendal and Norbäck (1966) have demonstrated that the sagittal sinus blood emanates predominantly from the cerebral grey matter and contains no extracerebral contributions of importance.

In the experiments where papaverine was infused at a constant rate the cerebral blood flow was measured several times at the same blood pressure to check that an equilibrium was reached with respect to the papaverine effect. It was also tested that the flow gradually returned to the previous autoregulatory level after reactive hyperemia with constant papaverine infusion.

General discussion

The present results concerning autoregulation on high cerebral blood flow levels seem to exclude tissue hypoxia as the main stimulus to cerebral autoregulation, because the induced high flow with normal arterial oxygen content implies a rise in tissue and venous oxygen tension.

It should be stressed that the ability to autoregulate is really retained at decreased cerebrovascular resistance due to *e.g.* high carbon dioxide tension, since the opinion is often encountered that the autoregulation is lost at moderate to severe hyper

capnia (Harper 1965). The present results demonstrate a well functioning autoregulation in these circumstances even at pronounced blood pressure reductions.

The experiments on pressure flow relations during graded arterial hypoxia demonstrate that the hypoxic vasodilatation occurs at a higher arterial oxygen saturation than the inhibition of cerebral autoregulation (Figs 1 and 2). It was mentioned already by Ekelund in 1931 that such an inhibition may be elicited by hypoxia. As it has been shown that hypoxic cerebral vasodilatation is induced from the tissue (Newell and Schneider 1941, Häggendal, Nilsson and Norlbäck 1966), the present results of maintained autoregulation even at pronounced arterial hypoxia can at least theoretically be due to metabolic factors i.e. tissue hypoxia.

It can be noticed that not even during the most pronounced hypoxia were maximal flow values obtained (*Fig. 2*). This is in accordance with earlier suggestions that maximal vasodilatation does not occur due to arterial hypoxia (Häggendal and Johansson 1965). It might even be possible that a sudden abolishment of the normal autoregulation, elicited by the hypoxia, adds to the steep flow increase at low values of arterial oxygen saturation.

The pressure flow relation in hypotension below the autoregulatory range would be expected to be curvilinear with the convexity towards the pressure axis provided the vascular bed (Folkow and Lofving 1950). Green, Rapela and Conrad (1963) have described a transient curvilinear pressure-flow relation in the brain in combination with pressure changes within the autoregulatory range, but did not discuss the pressure flow relation in hypotension. When studying the pressure flow relation in pronounced hypercapnia, though curves characteristic of a passive pressure flow relation were found (Rapela and Green 1964), Harper (1965) in summing up results from different animals found a linear relation at high arterial carbon dioxide tensions. In hypoxic animals studied by Häggendal and Johansson (1965) the pressure flow relation was also practically linear. This might indicate some degree of active smooth muscle response under these circumstances. The finding of such linear pressure flow relations are interesting with regard to the mechanism of autoregulation as the *metabolic theory implies that the reactivity of the vessels* to chemical stimuli should be exhausted when the constancy of flow is no longer upheld in hypotension (Harper 1965). In the present study we invariably found a curvilinear relation as would be expected in a truly passive vascular bed. The *findings* however *must rule out the possibility that some active vascular* reaction still exists though not strong enough to counteract completely the effect of the lowered intravascular pressure.

Variability of the cerebral vessels to react to chemical stimuli is demonstrated in hypercapnia and hypoxia (Figs. 1 and 2, Table I). The figures obtained for cerebral vascular resistance obtained at different arterial blood pressure levels within the autoregulatory range. There was however no tendency for a higher blood pressure in the higher range of arterial oxygen saturations which would indicate any activity

owing to the curvilinear relation between pressure and flow demonstrated in Figs. 4 and 5 a and b. A quantitative analysis of the difference in reactivity to carbon dioxide in normotension and hypotension has not been made due to this curvilinear pressure-flow relation in hypotension.

The reactivity of the cerebral vessels to arterial hypoxia in hypotension has not been studied in detail, but in one experiment, where the arterial carbon dioxide tension was 47 mm Hg and the arterial oxygen saturation was decreased from 95 to 47 per cent with the blood pressure kept at 70 mm Hg, there was an increase in cerebral blood flow from 60 to 82 ml/100 g/min. The cerebral metabolic rate of oxygen was 4.8 and 5.2 ml/100 g/min respectively and the blood pressure 70 mm Hg, was tested to be below the autoregulatory range. An effect of hypoxic stimuli is indicated by this experiment.

Tissue hypoxia during the period of reduced perfusion pressure has been considered important for the occurrence of reactive hyperaemia (Zweifach, Kjällquist and Siesjö 1968). Our data indicate that reactive hyperaemia can be observed after blood pressure decreases with flow still above normal and with high venous oxygen tension. Thus tissue hypoxia does not seem to be necessary for eliciting this vascular response.

This investigation was supported by grants from the Medical Faculty of the University of Göteborg and the Swedish Medical Research Council (Projects B69-14X 2683-G01, K69-14X 2720-01A).

CEREBRAL VENOUS OXYGEN SATURATION DURING RAPID CHANGES IN THE ARTERIAL BLOOD PRESSURE AN OXIMETRIC STUDY IN DOGS

by

BARBRO EKSTRÖM-JODAL, EGIL HÄGGENDAL AND
NILS JOHAN NILSSON

ABSTRACT

Barbro Ekström-Jodal, Egil Häggendal and Nils Johan Nilsson. *Cerebral venous oxygen saturation during rapid changes in the arterial blood pressure. An oximetric study in dogs.* Acta physiol. scand. 1970 Suppl. 350 43–50 Time relations and efficiency of the autoregulatory response to arterial blood pressure changes were studied in anaesthetized dogs, alterations in the cerebral venous oxygen saturation being taken as a relative measure of changes in blood flow Blood withdrawn from the superior sagittal sinus was continuously analysed in a cuvette oximeter during rapid changes of the arterial blood pressure, brought about by withdrawal or infusion of blood The time period from a change of blood pressure to a fully developed response was around 40–45 sec Within the autoregulatory pressure range a complete flow adjustment took place sometimes with a transitory overcompensation. Below this pressure range no compensation appeared

INTRODUCTION

Previous works from this laboratory on the autoregulation of cerebral blood flow have concentrated on the investigation of the efficiency of autoregulation as well as on its limitations and the nature of the mechanism behind it (Häggendal and Johansson 1965, Ekström-Jodal *et al* 1969 Ekström-Jodal, Häggendal and Nilsson 1970 Ekstrom-Jodal 1970) In these studies a steady state has been desired during the actual flow measurements, and therefore a certain time has always been allowed to elapse after each change in the flow situation before a new determination was made.

The problem of the time required for the establishment of the autoregulatory flow adjustment has not been extensively investigated. Fog in his classical paper from 1934 reported reactive changes in the diameter of the pial arteries to appear within 1.5–2.0 min after a change of arterial blood pressure. In 1964 Rapela and Green diverting the outflow from the venous sinuses through an electromagnetic flowmeter probe could observe the time course of the autoregulation and found it to become effective within 0.5–1.0 min. Hirsch and Körner (1964) on the other hand measuring discontinuously the outflow from the superior sagittal sinus give values of several minutes. Betz (1968) noted a delay of 0.5–2.0 minutes for the blood flow to return to the orginal value. Kanzow (1969) reported a time of 30–60 sec. Thus there is still some uncertainty about the time value. The problem is difficult to study especially considering the delicacy of the autoregulatory mechanism, which can easily be damaged by traumatic surgical procedures.

In this work a cuvette oximeter has been used for continuous recording of the oxygen saturation of blood withdrawn from the superior sagittal sinus during rapid changes of the arterial blood pressure by bleeding or reinfusion of blood. The changes in oxygen saturation have been taken as an expression of changes in the cerebral blood flow. Apart from illustrating the time course of the transient events during pressure changes the method also provides an opportunity to evaluate the extent of the flow alterations.

METHODS

Experiments were performed on dogs weighing 12–30 kg. The animals were anaesthetized with pentobarbital in a dose of 25–30 mg per kg body weight. The experiments were performed during muscle relaxation with succamethonium chloride and ventilation with an adjustable pump through an endotracheal tube. The body temperature controlled in the oesophagus was maintained at 37–38° C by intermittent heating.

The arterial blood pressure was recorded from a polyethylene catheter inserted into the femoral artery with a transducer of the inductance type and recorded on one channel of a two-channel pen-recorder (Servogor II, Texas Instruments). The arterial mean pressure was obtained by electrical integration. The arterial blood pressure was changed rapidly as far as possible by withdrawal or reinfusion of blood through a wide bore (I.D. 2.50) polyethylene catheter inserted into the opposite femoral artery.

The oximetric analyses were performed on blood withdrawn from the superior sagittal sinus via a needle inserted through the intact skull of the heparinized animal about 3 cm rostral to the occipital protuberance. The photometric linearly responding cuvette instrument described by Nilsson (1963) was used equipped with interference filters having the wavelengths 525 and 805 mμ. The deflections were registered on a tangential Atlas mean value amplifier (Atlas-Werke, Bremen) the output

of which was recorded on the other channel of the potentiometer writer The arrangement of the oximeter was in principle the same as that earlier used by Nilsson (1956 1957). The cuvette was attached to the needle in the superior sagittal sinus by a thin polyethylene catheter (PE 160) kept as short as possible (about 3 cm) to minimize time lag in the recording system. The volume of the measuring system (puncture needle polyethylene tube and oximeter cuvette) amounted to about 0 3 ml. Blood was continuously drawn through the oximeter cuvette with a motor driven syringe at a constant rate of 5 ml/min. In some cases also the rates of 3.5 or 7.5 ml/min were used for comparison.

For calibration, samples of sagittal sinus blood drawn through the oximeter were analysed spectrophotometrically (Holmgren and Persow 1950 Bjure and Nilsson 1955) at several different levels of oxygen saturation.

RESULTS

Fig. 1 represents an original recording of mean arterial blood pressure and cerebral venous oxygen saturation, made during a period of about 20 min, when the animal exhibited irregular variations in mean arterial blood pressure. The exact nature of these variations was not analysed, they are probably at least partly due to a cardiac arrhythmia. It can be seen that the irregularities in the blood pressure, if they are rapid enough, are reflected in the oximeter tracing as corresponding variations with a time lag of about 5 seconds. The autoregulation is not effective against these sudden pressure changes so that a certain degree of pressure-passive flow variation appears.

At a the arterial pressure is reduced from about 125 to a little over 100 mm Hg, and the oxygen saturation displays a concomitant fall. After about 13 seconds the fall changes into a rise although the pressure remains low and even shows a slightly falling tendency Thus rise in venous oxygen saturation we interpret as the effect of an increase in cerebral blood flow the reduction in vascular resistance being brought about by the autoregulatory mechanism. The saturation reaches its original level about 40 seconds after the beginning of the fall in arterial blood pressure· then a transitory overshoot ensues. At "b the arterial blood pressure is raised by reinfusion of the withdrawn blood After th ordinary delay of about 5 seconds the saturation begins to rise only to fall again after another 10 seconds in spite of a continued rise of the blood pressure. This fall, again a result of autoregulation which now increases the vascular resistance to keep the flow at its previous value restores the saturation to the original level within about 35 seconds from the beginning of restitution of the pressure A certain tendency to over regulation is seen in this situation also.

Fig 2 illustrates a different type of reaction. In this animal arterial pressure was reduced from 80–90 to about 50 mm Hg the latter value can be presumed to be about the lower limit of autoregulation Initially th change in venous oxygen

EFFECT OF INCREASED VENOUS PRESSURE ON CEREBRAL BLOOD FLOW IN DOGS

by

BARBRO EKSTRÖM-JODAL

ABSTRACT

Barbro Ekström-Jodal. *Effect of increased venous pressure on cerebral blood flow in dogs* Acta physiol. scand. 1970 Suppl. 350 51–61 The study performed on anaesthetized dogs, concerns the mechanism behind the cerebral blood flow autoregulation. The cerebral perfusion pressure was reduced by increasing the venous or decreasing the arterial blood pressure in order to separate the cerebrovascular response to changes in the transmural pressure from the response to changes in the perfusion pressure. The brain was provided with conditions for tissue expansion by removal of a large part of the skull and dura over both hemispheres The venous pressure was increased by obstructing the venous return to the heart. Cerebral blood flow was measured with the radioactive gas elimination technique using external γ registration. With proportionate reductions of the perfusion pressure the cerebrovascular resistance was consistently higher when the reduction was caused by a venous pressure increase as when it was caused by an arterial pressure decrease. When the venous pressure was maintained high while the arterial blood pressure was reduced, there was autoregulation on a lower flow level as when the venous pressure was normal. The results indicate that a change of transmural pressure is the adequate stimulus to cerebral blood flow autoregulation, probably acting via a basically myogenic response in the vessel wall

INTRODUCTION

In a previous paper (Ekström-Jodal, Häggendal and Nilsson 1970) evidence was presented against the theory which regards metabolic factors as the main cause of the autoregulation of cerebral blood flow in response to changes in blood pressure.

such evidence against the *metabolic* theory has focused interest on myogenic factors which are supposed to establish autoregulation in other vascular beds e.g. in skeletal muscle and intestine (for references see Mellander and Johansson 1968). The myogenic theory, based on Bayliss' hypothesis from 1902, has been comprehensively described by Folkow in 1964. It implies vascular smooth muscle automaticity, the adequate stimulus of which is the distension offered by the transmural pressure. The experimental approach in demonstrating the myogenic mechanism has often been based on primary increases of the venous blood pressure. Thus, in skeletal muscle of reserpine treated cats Folkow and Öberg (1961) found higher vascular resistance when a reduction of the perfusion pressure to the same value was achieved by increasing the venous pressure as when it was achieved by decreasing the arterial pressure. The difference in vascular resistance was explained by the higher transmural pressure in the former case potentiating vasomotion in precapillary resistance vessels.

Enclosed in the rigid skull however the brain offers special difficulties in this kind of experiment because any change in the venous pressure is followed by an equally large change in the tissue pressure. In the present study an attempt has been made to overcome this difficulty by removing most of the fronto-parieto-temporal part of the skull and opening the dura to give the tissue an opportunity to expand thus minimizing the increase in tissue pressure. A differentiation of the effects on vascular resistance by changes in the perfusion pressure and in the transmural pressure should then be possible yielding further information on the mechanism behind the autoregulation of cerebral blood flow. Preliminary results on this subject have been given at the International CBF Symposium in Mainz 1960 (Ekstrom Jodal Haggendal Nilsson and Norback 1960).

METHODS

The experiments were performed on ten mongrel dogs with body weights of 15–18 kg. The animals were anaesthetized with pentobarbital intravenously in a dose of about 30 mg per kg body weight. The operative procedure was completed with the animal breathing spontaneously. After that the animals were kept curarized with tubocurarine chloride and ventilated with an adjustable pump through an endotracheal tube. The body temperature measured in the oesophagus was maintained at 37–38°C by an electric heating.

The skull was removed over a large part of the hemispheres. A thin plastic catheter (PE 10) was inserted into the exposed superior sagittal sinus and left in an anterograde position. Clotting was prevented by flushing of the catheter with a heparin saline solution. The dura was carefully opened over both hemispheres leaving the middle part of each with the sagittal sinus intact. Desiccation of the brain surface was prevented by covering it with a skull preparation with a thin (15 μm) Mylar film

Arterial and cerebral venous blood pressures were electromanometrically recorded using a polyethylene catheter inserted into one femoral artery and the catheter in the superior sagittal sinus, respectively. Mean pressures were obtained by electrical integration, and the heart level was taken as the reference point. The perfusion pressure was calculated as the difference between the mean arterial and venous blood pressures. The arterial blood pressure was changed by withdrawal or reinfusion of blood through a polyethylene catheter in the other femoral artery. When stored outside the body the blood was kept in a reservoir at a temperature of 37–38 C.

The venous blood pressure was increased by means of a balloon catheter inserted through the right external jugular vein to a position with the balloon in the right atrium. The balloon was filled with maximally 30 ml of isotonic saline solution at 37–38°C, the exact volume being adjusted with respect to the effects observed on the venous pressure measured in the superior sagittal sinus and on the mean arterial pressure. With this technique the venous pressure in the superior sagittal sinus could be raised to maximally 96 mm Hg.

In combination with each measurement of blood flow the arterio-venous oxygen difference was calculated from oxygen determinations in blood samples drawn simultaneously from a femoral artery and the superior sagittal sinus. The oxygen saturation (Holmgren and Pernow 1969, Bjurø and Nilsson 1965) and the hemoglobin concentration (Drabkin and Austin 1935) were measured spectrophotometrically, the latter with modifications according to the Decision of the Standardizing Committee of the European Society of Haematology concerning Haemoglobinometry 1963. From these determinations oxygen capacity and content were calculated. Carbon dioxide tension and pH in the same blood samples were measured with the micro method of Siggaard Andersen *et al.* (1960).

The measurements of cerebral blood flow (CBF) were performed with the radioactive gas elimination method of Lassen *et al.* (1963), using intraarterial injections of radioactive krypton (Kr^{85}) and external registration. For methodological details see Ekström-Jodal, Haggendal and Nilsson (1970). The values given in the results are those calculated for cerebral grey matter (CBF_{grey}, ml/100 g·min).

PROCEDURE

The experiments included the following maneuvers:

Measurement of cerebral blood flow, blood pressure and blood gases with normal arterial and venous blood pressures;

Elevation of the venous pressure by inflation of the balloon in the right atrium followed by the same measurements;

Deflation of the balloon and control of autoregulation by arterial bleeding at normal venous pressure.

In three cases the cerebrovascular response to arterial blood pressure variations was studied at elevated venous pressure.

In some of the experiments the level of cerebral blood flow was elevated initially by adding five per cent carbon dioxide to the inspired air

A condition for accepting an experiment was that autoregulation could be demonstrated by arterial bleeding when the venous pressure was restored to normal after the measurements with an elevated venous pressure In six animals this condition was fulfilled and another animal (no VI in Table 1) was included in the table for reasons given below Thus three animals were discarded

RESULTS

The successful experiments are summarized in Table I. The lower case letters indicate the chronological order of the measurements. In experiment no I the blood gas situation changed spontaneously when autoregulation in response to arterial bleeding was tested in spite of constant artificial ventilation, probably due to pulmonary atelectasis Therefore the measurements at c and d were only used to prove autoregulation there was very little difference in arterial oxygen saturation and carbon dioxide tension between them. The comparison between cerebral blood flow at normal and increased venous pressures for this animal in Fig 2 refers to a and b

In experiment no. VI autoregulation was not tested by arterial bleeding because the arterial blood pressure decreased spontaneously This animal is nevertheless included in the table as it shows a considerably higher flow value at lower perfusion pressure when the venous pressure has its lowest value.

Fig 1 illustrates two examples (no. V and VII, open and filled symbols, respectively) where the cerebral blood flow was kept high by the administration of carbon dioxide to the inspired air There is a clear reduction of cerebral blood flow with elevation of the venous pressure (squares) that cannot be explained by the small fluctuations in the arterial carbon dioxide tension. Autoregulation in response to arterial bleeding is demonstrated with both normal (circles) and raised (squares) venous pressure on different levels of cerebral blood flow In Fig 2 all experiments in the table except no VI are illustrated. Percentual changes in the perfusion pressure from a reference value are given along the abscissa and the corresponding percentual changes in the cerebrovascular resistance (CVR) along the ordinate. The reference value (zero point) for perfusion pressure is the arterial pressure during the period of increased venous pressure (concerning experiment no. IV 140 V 110 and VII 133 mm Hg) minus the normal venous pressure. For cerebral vascular resistance the reference value is calculated from the measured cerebral blood flow at these pressures if such a measurement could be made However there was usually a moderate decrease in the arterial blood pressure when the balloon was filled, presumably due to the cardiac output being reduced by the obstruction of venous return to the heart. Thus in many cases no measurement of cerebral blood flow was performed at exactly the same arterial blood pressure, when the venous pressure was normal as when it was elevated. The blood flow used for the calculation of the

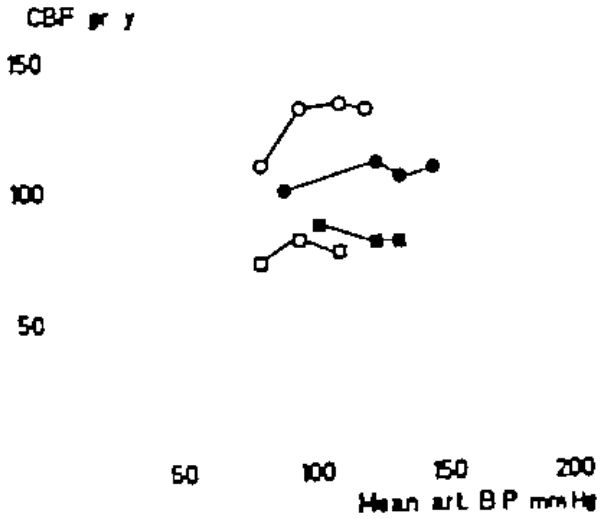

Fig. 1 Relation between mean arterial blood pressure and cerebral blood flow in grey matter (CBF_{grey} ml/100 gmin) i tx dogs (no. V open symbols; no. VII, filled symbols) at normal enous pressure (circles) and t increased enous pressure (squares) Aut regulation on d fferent flow levels is illustrated.

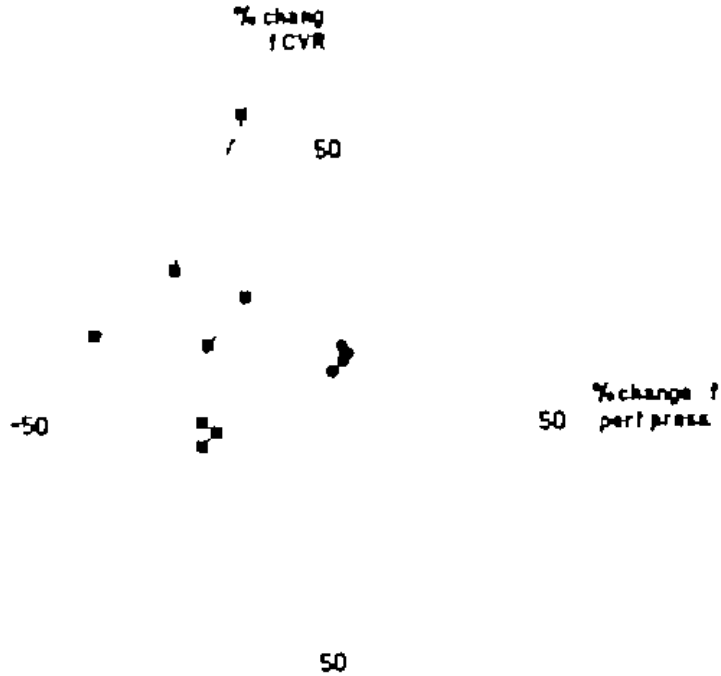

Fig. 2. Correlation between percentual hanges i the perfusion pressure and percentual changes in the cerebrovascular resistance (CVR) when the perfusion pressure was hanged by arterial bleeding (filled ircles) or by venous pressure increase (filled squares). With changes in the arterial blood pressure there are proportional changes in CVR, proving the existance of autoregulation. Lowering of the perfusion pressure by elevation of the enous pressure on the contrary leads to an unchanged or increased CVR. The autoregulatory response when the arterial blood pressure was lowered with the enous pressure maintained high, parallels the decline bserved with arterial bleeding at normal venous pressure. The values of CVR representing this response are connected by bi ken lines.

zero point for vascular resistance was then deduced from the connecting line between the blood flow measured during the autoregulation control measurements at arterial pressures higher and lower than the pressure in question. In animal no II autoregulation was only tested at lower arterial blood pressures and in no III only at higher but in both cases the arterial blood pressure during the venous pressure increase, 115 and 95 mm Hg respectively can be regarded as being within the so-called autoregulatory range With changes in the perfusion pressure brought about by changes in the arterial blood pressure a continuous, corresponding increase or decrease in the cerebrovascular resistance from the reference value can be observed as an expression of autoregulation. In one case (V) the decrease in the vascular resistance was broken, and even a slight increase was encountered, a finding probably explained by this value being obtained just below the pressure range of autoregulation

With elevation of the venous pressure there was a practically unchanged vascular resistance in some animals and an increase in others. Pronounced increases in the cerebral vascular resistance were found in two experiments where the cerebral blood flow was raised by hypercapnia In the cases where autoregulation was tested by bleeding with maintained high venous pressure the cerebral vascular resistance was observed to decline along a line practically parallel to the relation obtained when bleeding was performed with normal venous pressure

DISCUSSION

The present study was aimed at differentiating changes in the perfusion pressure from changes in the transmural pressure as possible stimuli to autoregulation of th cerebral blood flow With the skull and dura widely opened it was considered likely that the brain was provided with good possibilities for expansion so that the tissue pressure, i.e. the external pressure on the vessels, should not rise in proportion to the venous pressure increase. Therefore the rise in venous pressure can be expected to increase the transmural pressure. Relatively extensive surgery was required to achieve this, and since the autoregulation of the cerebral blood flow is known to be a vulnerable process which can be interfered with by for instance surgical trauma (Fog 1934 Rapela and Green 1964) a certain risk of failure had to be accepted In fact, three animals out of ten had to be excluded because they did not show a normal vascular response to arterial bleeding probably because of traumatic preparation. The method of increasing the venous pressure by obstructing the venous return to the heart was chosen, since it was considered the least traumatic way Also the flow method used the radioactive gas elimination method of Lassen *et al.* (1963) fulfills the requirement of being gentle to the tissue The value of 0.95 for the partition coefficient of Kr^{85} between cortex and blood was used throughout the experiments, although the value is known to be affected by the hematocrit (Lassen *et al.* 1963 Ingvar and Lassen 1961, Glass and Harper 1962), but a

Prejunctional Supersensitivity in the Rat Portal Vein as Related to its Pattern of Innervation

By

Börje Johansson, Bengt Ljung, Torbjörn Malmfors and Lars Olson

Abstract

Johansson B, B. Ljung, T. Malmfors and L. Olson. *Prejunctional supersensitivity in the rat portal vein as related to its pattern of innervation.* Acta physiol. scand. 1970. Suppl. 349. 5–16.

The smooth muscle of the portal-mesenteric vein of the rat is arranged in an inner circular layer (10 to 20μ thick) and an outer longitudinal layer (50 to 70μ thick). The latter is mainly found in the portal vein proper beginning a few mm caudal to the entrance of the gastro-splenic vein and extending to the liver hilus. Studies with the histochemical fluorescence technique of Falck and Hillarp showed a two-dimensional adrenergic network located between the two layers of muscle and some scattered adrenergic fibres at the mid entero-medial border. In view of this pattern of innervation it was of interest to investigate the degree of "supersensitivity" after denervation. Mechanical responses of isolated portal veins from control and ganglionectomized (coeliac and mesenteric) rats were recorded. Chronic denervation caused a parallel displacement of the noradrenaline (NA) dose-response curve to the left, corresponding to a change of ED_{50} from 1.2×10^{-6} M to 0.9×10^{-7} M. The ED_{50} values for innervated and denervated preparations treated with cocaine were 0.4×10^{-7} and 0.3×10^{-7} M respectively. The degree of the prejunctional supersensitivity to NA shows that the neuronal uptake effectively removes exogenous NA from the vicinity of the activated receptors, which therefore must be near the nerve endings. Consequently the smooth muscle cells which are lost to the nerves play a major role not only in the neural responses but also in the response to exogenous NA. Excitation then spreads by myogenic mechanisms through the muscle layers of the media.

Studies concerning the mechanisms behind the supersensitivity to sympathomimetic amines, which develops in smooth muscle after elimination of its adrenergic nerve supply, have contributed to the understanding of these neuroeffector systems. Many adrenergic agents, particularly the physiological transmitter noradrenaline

(NA) are taken up into the nerve terminals by an active membrane mechanism (see Iversen 1967). The concentration of NA at the effector cells is thereby reduced. After nerve degeneration or pharmacological blockade of the uptake an apparent increase in sensitivity to exogenous NA results, the prejunctional supersensitivity (*cf.* Trendelenburg 1966). This phenomenon has been studied most extensively in tissues like the nictitating membrane where the adrenergic innervation is dense and appears to reach most of the individual muscle cells (*cf.* Malmfors 1965). Chronic denervation of sufficient duration can also lead to non-specific postjunctional supersensitivity (Trendelenburg 1966).

The adrenergic nerve supply in vascular smooth muscle is in most cases arranged in a two-dimensional way so that only a limited number of the muscle cells is close to the nerve terminals and hence directly innervated (Norberg and Hamberger 1964, Ehinger, Falck and Sporrong 1967, Norberg 1967). Studies on supersensitivity after denervation in blood vessels have for the main part been performed on isolated strips of large elastic arteries and on perfused vessels of different types. The results have been quite variable, which may reflect differences in the functional organization of the neuroeffector systems of different sections of the vascular bed which are as yet not satisfactorily understood.

The isolated rat portal vein has been used in a series of recent studies aimed at an integrated understanding of the nervous control of propagating vascular smooth muscle (see Ljung 1970). In the present study morphological aspects on the adrenergic innervation, as revealed by the histochemical fluorescence method of Falck and Hillarp, have been correlated to the development of supersensitivity after denervation in the portal vein. The results obtained seem to elucidate certain principles in the neuroeffector organization of vascular smooth muscle.

A preliminary report of the present results was presented at the XIII Scandinavian Congress of Physiology (Johansson *et al.* 1969).

Methods

I. Operative procedures

Rats of the Sprague-Dawley strain of about 250 g body weight and of either sex were used. The animals were given atropine sulphate (1 mg/kg, s.c.) preoperatively and were anesthetized with ether. The abdomen was opened in the midline and under a dissection microscope the coeliac and mesenteric ganglia on both sides were removed together with the bundles of postganglionic fibres running towards the portal vein. The abdominal wall was sutured in layers. Sham operations were performed at the same time, involving only laparotomy and suture. All animals recovered satisfactorily.

II. Organ bath experiments

On the day of the experiment one sham operated and one ganglionectomized rat were killed by a blow on the neck. The portal veins were dissected out, cut open longitudinally and mounted for isometric recording in a 20 ml organ bath as described previously (e.g. Arnason *et al.* 1967).

The composition of the Krebs solution was in mM: NaCl 12.; KCl 4.73; $NaHCO_3$ 18.5; KH_2PO 1 19; $MgCl_2$ 1.19; $CaCl_2$ 2.49; glucose 11.5 and $CaNa_2$ ersenate 0 026. It was continuously bubbled with 4% CO in O_2. Temperature was kept at 38°C.

A pair of platinum electrodes, 5 mm apart, were placed in the bath on either side of each preparation. These were connected to a Grass stimulator for field stimulation with square wave impulses of 15 V amplitude between the electrodes and 0.8 msec duration. Control experiments showed that responses of isolated portal veins to such stimulation at 4 to 16 imp/sec were completely abolished by adrenergic blocking drugs (guanethidine, phenoxybenzamine). This indicates that the sympathetic nerves in the vascular wall but not the smooth muscle cells themselves, were stimulated (*cf* Paton 1955, Paterson 1965). Field stimulation was used in the present experiments as one indicator of the completeness of denervation.

The preparations were allowed to accomodate in the bath for 1 hr before the actual experiment started. Following the test with electrical field stimulation a dose-response curve to NA was determined by sequential administration of increasing concentrations of the amine in the range of 10 to 10^{-4} M. The exposure periods were of 3 min duration and the intervals between them 15 min or more, allowing complet recovery of the normal spontaneous activity In order to void β-adrenergic influence on the dose-response relationship β-receptor blockade was maintained throughout the experiments by giving propranolol, 10 M, for 5 min every 60 min. In one group of experiments the preparations were continuously exposed to cocaine, 10 M, during the determination of the NA dose-response curve.

The excitatory effects of graded concentrations of acetylcholine on denervated and innervated preparations were studied in experiments of similar design as with NA.

Contractile activity was recorded on a Grass polygraph and continuously quantified by means f an electronic integrating device. Excitatory drug responses were calculated as the difference between the mean tension development (dyn/min) during the 3 min exposure period and the preceding 3 min of spontaneous activity The data from each preparation were expressed as a per cent of its maximal response to the agent. Mean dose-response curves and mean ED_{50} values (concentration required for 50 per cent of maximal response) were calculated for the different sets of experiments. These calculations were performed by means of computer program which determined the least squares fit of all data points from each group for a hyperbolic dose-response function.

After each experiment the portal veins were mounted as stretch preparations on glass slides and allowed to dry for histochemical studies.

III Fluorescence Histochemistry

The histochemical fluorescence method of Falck and Hillarp (Falck, Hillarp, Thieme and Torp 1962, see also Corrodi and Jonsson 1967 Norberg 1967) was used for studies of the adrenergic innervation of the portal-mesenteric vein. In addition to the examination of the portal veins used in the organ bath studies, more detailed analysis was performed on preparations of the portal vein and the adjacent 10 mm of the anterior mesenteric vein, especially dissected for this purpose. Some vessels were opened longitudinally stretched and dried as whole mounts on glass slides (Malmfors 1965). These as well as those used for the functional studies were dried for more than 1 hr in desiccator containing P_2O_5. They were then treated with paraformal lehyde gas for 1 hr at 80 C. In some cases the portal-mesenteric vein was quenched at different degrees of stretch in propane cooled by liquid nitrogen, freeze-dried (Olson and Ungerstedt 1970), treated with formaldehyde gas, embedded and sectioned. The stretch preparations and the sections were examined in fluorescence microscope with a 400 mμ activation filter and 500 mμ secondary filter

We want xpress our sincere gratitude to professor Arne Brändström and mr Lars Palmer Alf Hassle, Goteborg, for applying their computer program to our data.

11 Drugs

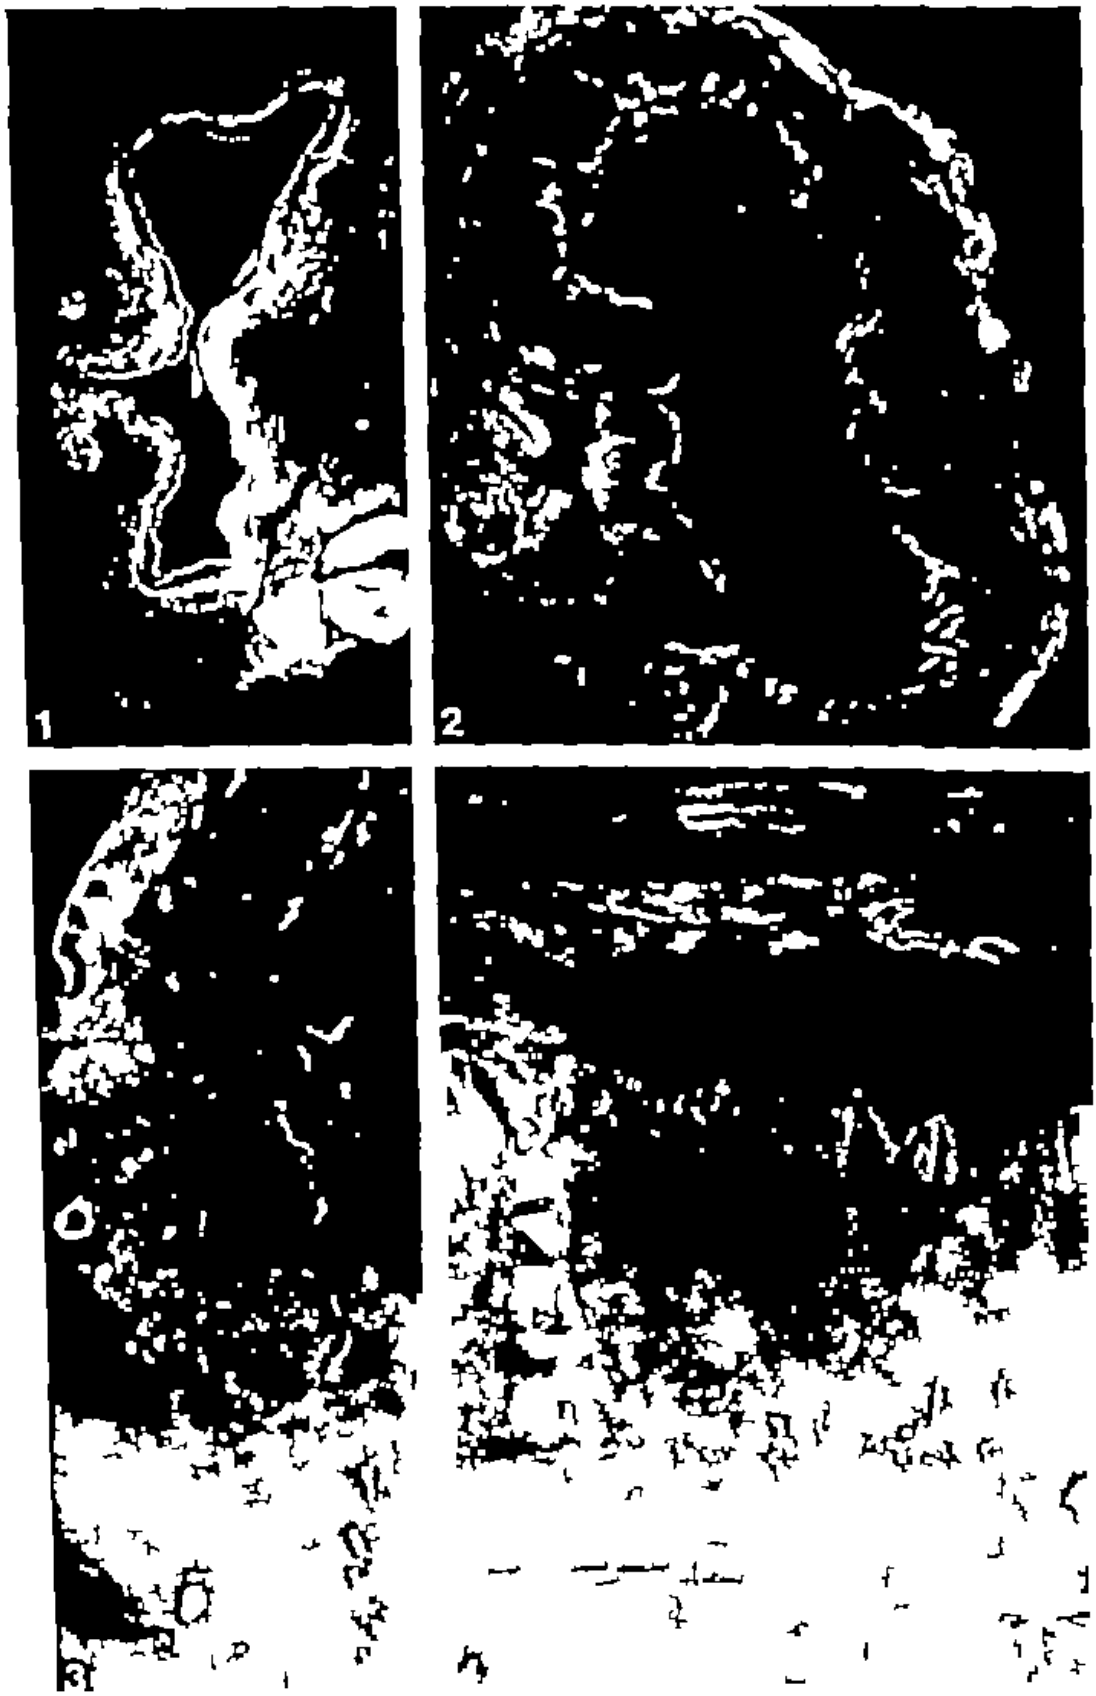
The following drugs were used: l-noradrenaline bitartrate (Noradrenaline conc. Astra), Cocaine hydrochloride, acetylcholine bromide and propranolol hydrochloride. Fresh stock solutions, 10 M, were prepared on the day of the experiment. These were diluted with saline immediately prior to injection to the bath.

Results

I Fluorescence histochemistry

The media of the portal mesenteric vein is composed of an inner muscle layer in which the cells show predominantly circular orientation and an outer longitudinal layer. The circular muscle is 10–20μ thick and about equally well developed along the entire length of the vessel. The outher longitudinal muscle coat 50–70μ thick, is found mainly within a part of the vein extending from about 5 mm caudal to the entrance of the gastro-splenic vein to the liver hilus. The longitudinal muscle thus forms a relatively thick and well defined "cuff" surrounding the circular layer.

Transverse sections of the caudal part of the portal mesenteric preparation showed the fluorescent nerve fibres to be located at the outer border of the thin circular muscle (Fig. 1). In sections of the portal vein proper which included the longitudinal muscle fluorescent fibres were found between, but not within, the two muscle layers and further on the outside of the longitudinal layer (Fig. 2 and 3). The former system of fibres was a rarefied continuation of the terminal plexus surrounding the circular muscle in those parts of the vein where the longitudinal sheath was lacking and seemed in some tangential sections to be close to the circular muscle layer (Fig. 4). The nerve fibres on the outside of the longitudinal muscle were few and irregularly arranged; only a small fraction of them were of the varicose terminal type.



Stretch preparations of the portal mesenteric vein showed a system of adrenergic nerve fibres consisting of smooth non terminal axons with weak fluorescence and more intensely fluorescent varicose terminals. The adrenergic ground plexus was quite dense within the caudal part of the mesenteric vein and the nerve fibres had

Fig. 1. Transverse section (10μ) of the mesenteric vein. The thin media consisting of a circular muscle layer is limited towards the lumen by the supravitally fluorescent internal elastic membrane and towards the adventitia by the specifically fluorescent adrenergic nerves. Three bundles of non terminal adrenergic axons can be seen in the connective tissue surrounding the vessel. 80×

Fig. 2. Transverse section (10μ) of the portal vein. A thin inner circular muscle layer and thick outer longitudinal muscle layer can be seen. The fluorescent adrenergic nerves are located between these two muscle layers. On the surface of the longitudinal layer few fluorescent nerve fibres are detected. Nerve fibres penetrate into the muscle layer. 80×.

Fig. 3. Same as Fig. 2. The adrenergic nerve plexus is clearly seen between the two muscle layers. A few fluorescent mast cells can be seen in the adventitia (left). 120×.

Fig. 4. Tangential longitudinal section (10μ) of the portal vein. The longitudinal muscle layers can be seen on both sides of the tangentially sectioned circular layer. The nerves located between the muscle layers (see Fig. 3) have a tendency to accompany the circular layer. A few nerve fibres can be seen on the outside of the longitudinal layer. 120×.

I Fluorescence histochemistry

The media of the portal mesenteric vein is composed of an inner muscle layer in which the cells show predominantly circular orientation and an outer longitudinal layer The circular muscle is 10–20μ thick and about equally well developed along the entire length of the vessel The outher longitudinal muscle coat 50–70μ thick is found mainly within a part of the vein extending from about 5 mm caudal to the entrance of the gastro-splenic vein to the liver hilus. The longitudinal muscle thus forms a relatively thick and well defined "cuff" surrounding the circular layer

Transverse sections of the caudal part of the portal mesenteric preparation showed the fluorescent nerve fibres to be located at the outer border of the thin circular muscle (Fig 1) In sections of the portal vein proper which included the longitudinal muscle fluorescent fibres were found between but not within the two muscle layers and further on the outside of the longitudinal layer (Fig 2 and 3) The former system of fibres was a rarefied continuation of the terminal plexus surrounding the circular muscle in those parts of the vein where the longitudinal sheath was lacking and seemed in some tangential sections to be close to the circular muscle layer (Fig 4) The nerve fibres on the outside of the longitudinal muscle were few and irregularly arranged only a small fraction of them were of the varicose terminal type

Stretch preparations of the portal mesenteric vein showed a system of adrenergic nerve fibres consisting of smooth non terminal axons with weak fluorescence and more intensely fluorescent varicose terminals. The adrenergic ground plexus was quite dense within the caudal part of the mesenteric vein and the nerve fibres had

Fig. 1 Transverse section (10μ) of the mesenteric vein. The thin media consisting of a circular muscle layer is limited towards the lumen by the unspecifically fluorescent internal elastic membrane and towards the adventitia by the specifically fluorescent adrenergic nerves. Three bundles of non terminal adrenergic axons can be seen in the connective tissue surrounding the vessel. 80 ×

Fig. 2 Transverse section (10μ) of the portal vein. A thin inner circular muscle layer and thick outer longitudinal muscle layer can be seen. The fluorescent adrenergic nerves are located between these two muscle layers. On the surface of the longitudinal layer a few fluorescent nerve fibres are detected Nerve fibres penetrate into the muscle layer 80 ×

Fig. 3. Same as Fig 2 The adrenergic nerve plexus is clearly seen between the two muscle layers. A few fluorescent mast cells can be seen the adventitia (left) 150 ×

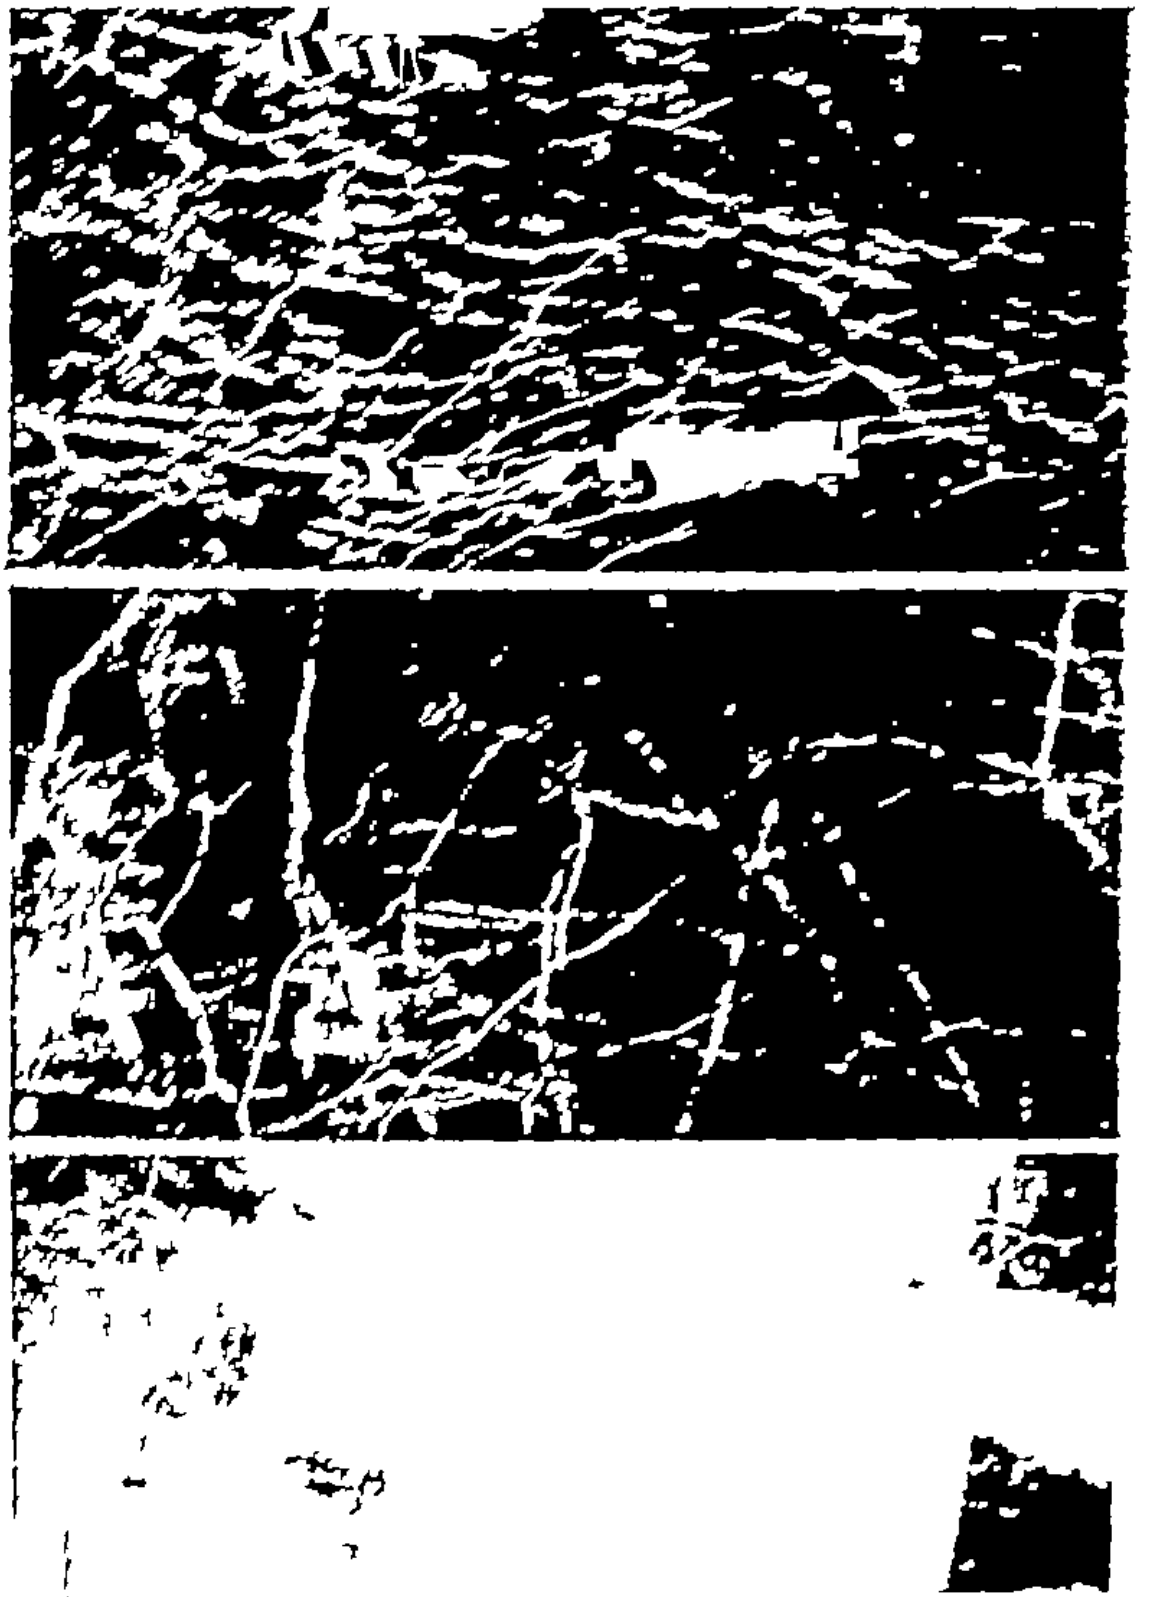

Fig 4 Tangential longitudinal section (10μ) of the portal vein. The longitudinal muscle layers can be seen on both sides of the tangentially sectioned circular layer The nerves located between the muscle layers (see Fig. 2) have tendency to accompany the circular layer A few nerve fibres can be seen on the outside of the longitudinal layer 120 ×

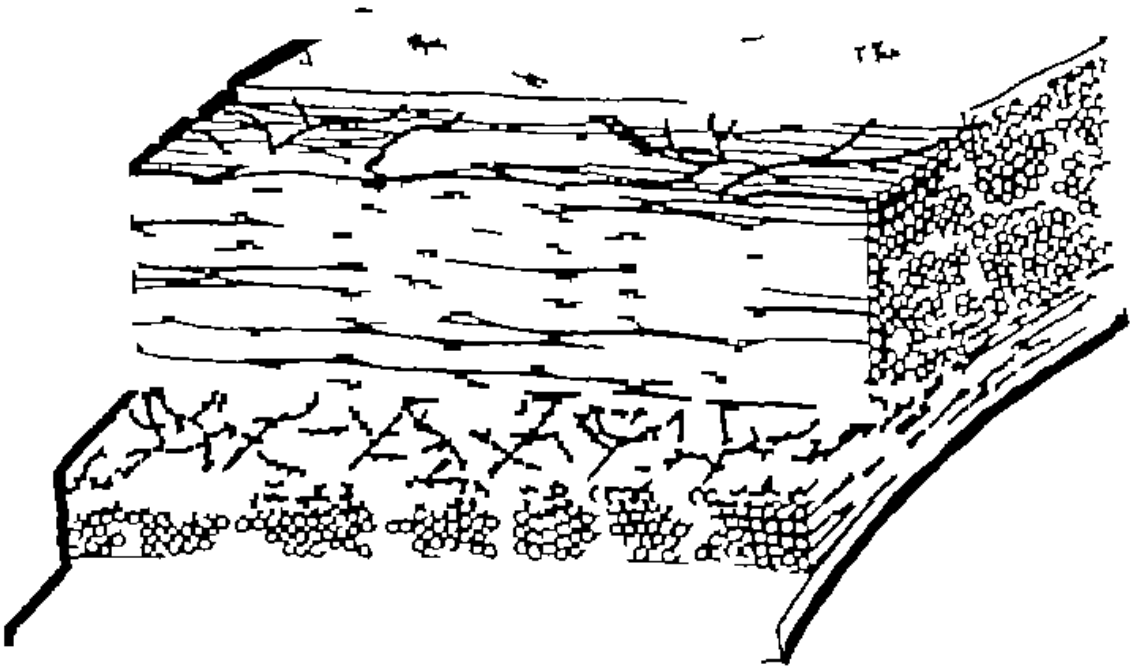

Fig. 8. Schematic drawing of the wall of the portal vein. Outer longitudinal muscle layer is 50–70μ thick, inner circular layer 10–20μ. Note main adrenergic plexus between the muscle layers and the scatt red nerves at adventitio-medial border

here a predominantly transverse orientation (Fig 5) In the region of the longitudinal muscle a more sparse and irregular adrenergic network was usually present (Fig. 6) which however again became somewhat denser near the liver (Fig 7) Mast cells and groups of small cells with intense green fluorescence were occasionally seen in the stretch preparations.

A schematic illustration of the morphological characteristics of the rat portal vein is shown in Fig 8

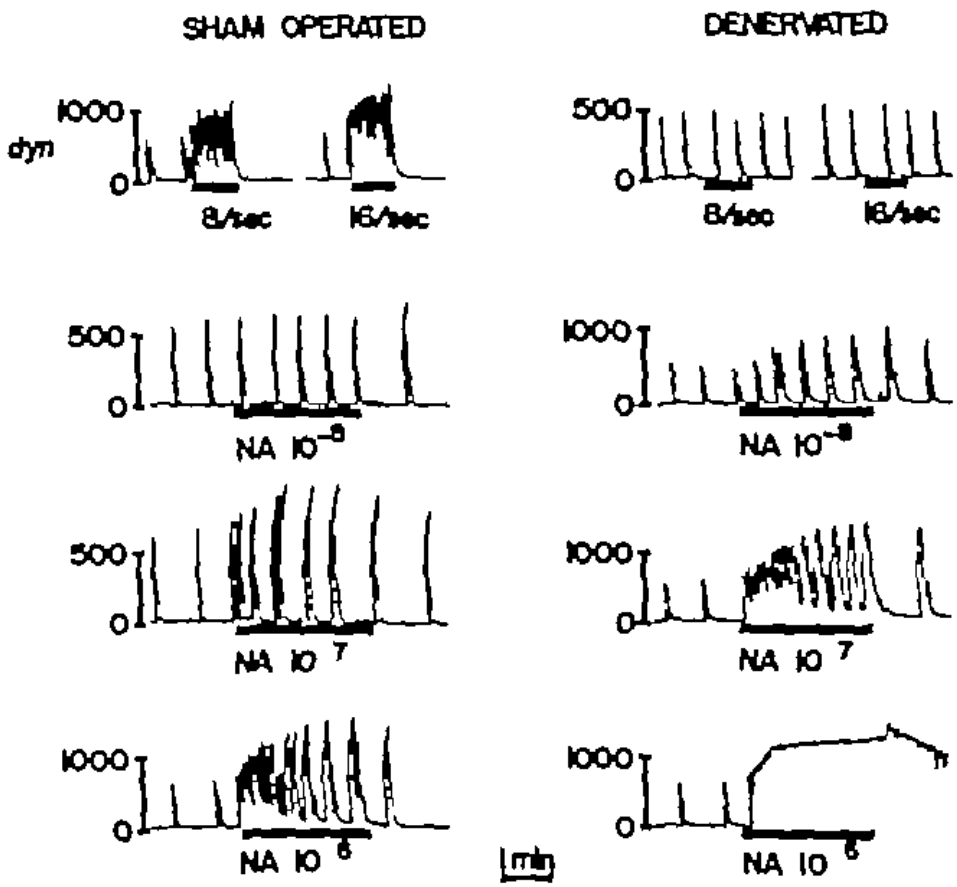

Fig. 9. Mechanical responses to electrical field stimulation (0.8 msec, 15 V) and to exogenous NA of the portal vein from one control (left) and one denervated preparation (right). Note absence of response to field stimulation and increased responses to NA after denervation.

Preparations from sham operated and non-operated animals did not differ in their responses to field stimulation or in histological appearance.

Fig 9 shows original recordings of mechanical responses to electrical stimulation and to three different NA concentrations in one denervated preparation and its sham operated control. The spontaneous myogenic activity typical of the portal vein is seen in both preparations during the control periods. Electrical field stimulation at 8 and 16 imp/sec elicited excitatory responses in the preparation from the sham operated but not in the one from the ganglionectomized animal. The denervated muscle showed a greater responsiveness to NA at all three levels illustrated.

The mean NA dose-response curves obtained in the present series of experiments are illustrated in Fig 10 The curve for six denervated vessels, examined 3 to 17 days after operation, is displaced to the left of that for the control group which consisted of 11 preparations from sham operated and four preparations from non operated rats (the two latter subgroups did not differ significantly from one another) In order to quantitate differences in NA responsiveness, values for ED_{50} were calculated by means of the computer program referred to under "Methods The

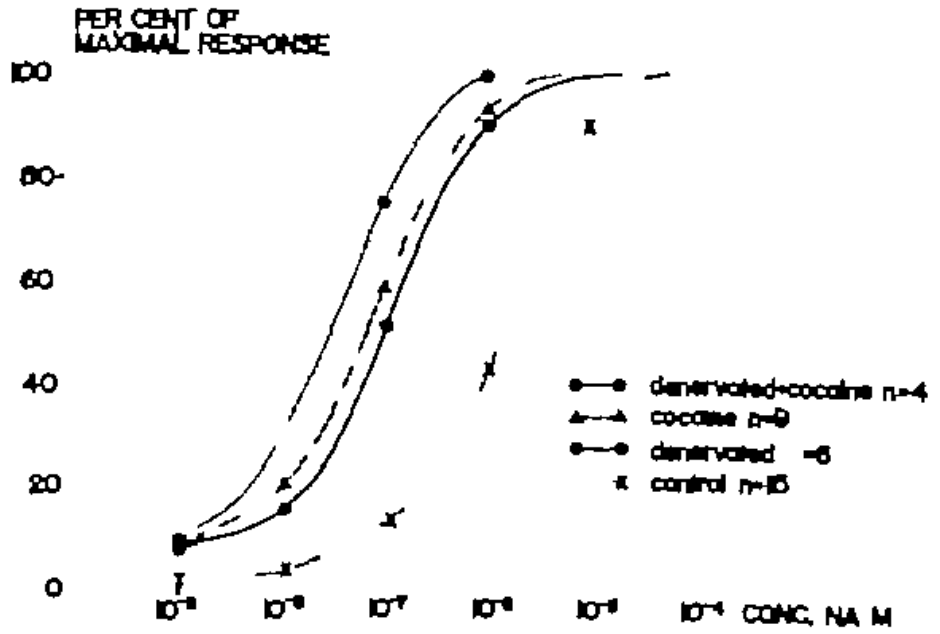

Fig. 10. Excitatory responses of the rat portal vein to NA under various experimental conditions, expressed in per cent of maximal response. Continuous β-receptor blockade. Least squares fit for a hyperbolic dose-response function calculated in each experiment (see "Methods"). The points in the figure represent mean values from number of experiments indicated.

ED_{50} for the control preparations was $(1.2 \pm 0.03) \times 10^{-}$ M (mean ± S.E.M.) and the corresponding figures for the denervated ones $(0.9 \pm 0.04) \times 10^{-}$ M. To give comparable responses normally innervated portal veins thus required 13 times higher NA concentrations in the bath than did the denervated muscles.

The individual values for ED_{50} in the denervated group indicated that the supersensitivity was already fully developed on the third postoperative day and no evidence was obtained of a further increase in responsiveness up to the 17th day. Some muscles from ganglionectomized animals were studied after longer intervals (20 to 35 days) but these preparations responded to field stimulation and showed fluorescent nerve terminals when examined microscopically, suggesting that reinnervation from remaining ganglion cells may have occurred.

The early onset of supersensitivity following denervation indicates that it is prejunctional in nature i.e. due to elimination of the neuronal NA uptake (see Trendelenburg 1966). To further elucidate this question, experiments were performed with cocaine which is considered to block the membrane uptake mechanism (for ref. see Iversen 1967). The mean NA dose-response curve of nine innervated portal veins treated with cocaine (10^{-6} M) is shown in Fig. 10. The ED_{50} of this group was $(0.4 \pm 0.02) \times 10^{-7}$ M. Fig. 10 also shows the mean dose-response curve of four denervated preparations treated with cocaine. ED_{50} for which was $(0.3 \pm 0.02) \times$ $\times 10$ M.

The difference between the mean ED_{50} of the control group and that of any of the three other groups is highly significant ($p < 0.001$). Cocaine treatment apparently results in a somewhat greater degree of supersensitivity than denervation as judged

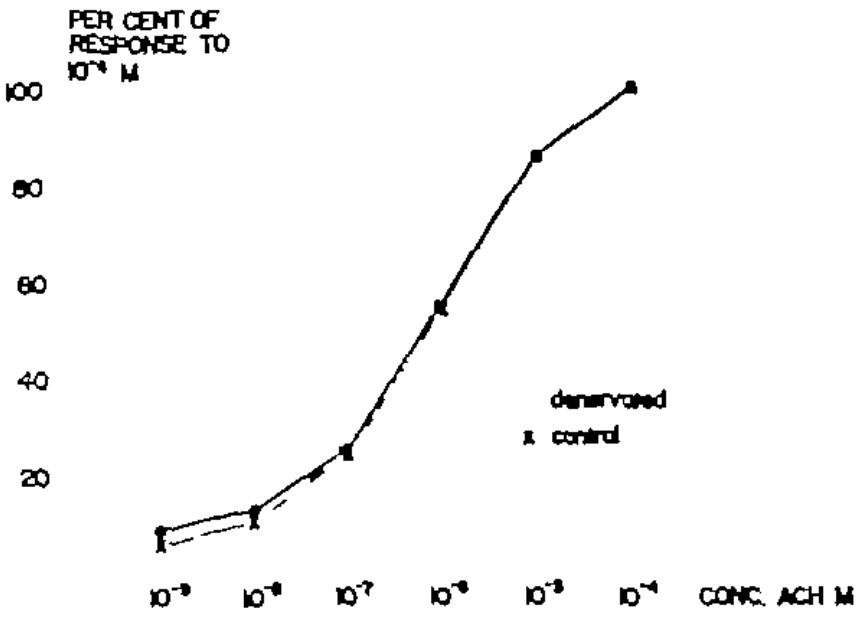

Fig 11 Excitatory responses to acetylcholine of the rat portal vein after denervation (●——●) as compared to control (× – – – ×). The points represent mean values from four experiments.

by the difference in ED_{50} ($0.05 > p > 0.01$) and the combination of the two procedures may accentuate the increased responsiveness in comparison with cocaine alone ($0.05 > p > 0.01$)

To investigate whether denervation of the portal vein also results in supersensitivity to non-adrenergic agents a series of experiments was performed with acetylcholine This substance produces excitatory responses of the portal vein which are blocked by atropine Acetylcholine dose-response curves for four preparations from sham operated and four preparations from ganglionectomized rats were obtained 8 to 20 days after operation. The results, illustrated in Fig 11 did not indicate any difference in responsiveness between the two groups.

Discussion

Chronic denervation of the rat portal vein caused a 13-fold increase in the sensitivity to exogenous NA in the present study Evidence that this supersensitivity was of the prejunctional type (i e due to elimination of the neuronal uptake mechanism) was given by the observation that it was fully developed already three days after the operation at which time the degeneration of nerve terminals is completed (Malmfors and Sachs 1965) and that cocaine treatment of normally innervated preparations caused a comparable or even greater supersensitivity The fact that cocaine caused a further shift of the NA dose-response curves to the left than did chronic denervation alone may suggest that cocaine also exerted some postjunctional

effect (Maxwell, Wastila and Eckhardt 1966 Bevan and Verity 1967 Kalsner and Nickerson 1969) No indication of development of unspecific postjunctional super sensitivity was obtained as no further increase in NA sensitivity was detected after the third postoperative day and as th responsiveness to acetylcholine was not altered after denervation. This is possibly due to the fact that the isolation procedure for *in vitro* studies may abolish the labile postjunctional supersensitivity (see Green and Fleming 1968)

Elimination of the neuronal uptake mechanism has been found to cause a more than 20-fold increase in sensitivity to NA in non vascular smooth muscle such as the nictitating membrane (Trendelenburg 1965) In most previous studies on blood vessels little or no supersensitivity has been obtained after denervation (see further below)

It is reasonable to seek the explanation for such differences in the extent of prejunctional supersensitivity in the organization of the sympathetic innervation The possible implications of the confinement of the adrenergic nerve terminals to a two-dimensional plexus in the arterial walls, as opposed to the dense three-dimensional distribution within the smooth muscle of the nictitating membrane have been discussed in a recent study by Haeusler and Haefely (1970). They concluded that these morphological differences in sympathetic nerve supply could explain their findings that neuronal uptake blockade produced a 15-fold increase in sensitivity of the nictitating membrane compared to only a 3-fold increase for an isolated mesenteric artery preparation. Further the distance between the nerve terminals and the nearest smooth muscle cells has been considered to be of importance for the degree of prejunctional supersensitivity This factor was discussed by Bevan and Verity (1967) as an explanation for the absence of denervation supersensitivity in isolated strips of elastic arteries where the neuro-muscular gaps exceed 4000 Å. This figure is smaller (about 1000 Å) in the peripheral vessels (see Lever Graham and Spriggs 1967) but it still exceeds values reported for densely innervated organs such as the vas deferens (Merrillees, Burnstock and Holman 1963)

The present data on supersensitivity in the portal vein indicate that th neuronal uptake mechanism in a control preparation so reduces the average NA concentration at the receptor sites, that the exogenous NA concentration in the medium has to be increased at least 13 times to compensate for the activity of th membrane pump.

The present histochemical analysis showed that the adrenergic nerve terminals are arranged in two-dimensional plexuses also in this vessel. Most of the cells in the longitudinal muscle layer which is 50 to 70μ thick, are thus widely separated from the nervous elements and it seems impossible that the NA concentration in their surrounding fluid should be directly influenced by the neuronal uptake It should be mentioned however that isolated perfused blood vessels have been found to be less sensitive to NA applied from the outside than to NA administered inside the lumen (Gillespie 1966, de la Lande Frewin and Waterson 1966, Crotty *et al.* 1969). De la Land Frewin and Waterson (1967) working with the central ear artery of

the rabbit, ascribed this difference to uptake of NA into the adrenergic plexus of nerve terminals at the adventitio-medial border On the other hand Crotty *et al.* (1969) found that this mechanism could not explain the differences in the sensitivity of the lateral saphenous vein of the dog to external and internal administration of NA. The existence of neural elements on both sides of the longitudinal muscle layer in the portal vein may seem to offer a possibility for a reduction of the NA concentration in the biophase below the bath concentration by a mechanism of the kind proposed by de la Lande and co-workers. Quantitative considerations of the rate of NA diffusion through vascular walls using the diffusion coefficient obtained by Török and Bevan (see Bevan Cheaher and Su 1969) and of the uptake capacity of adrenergic neurones (Trendelenburg, Draskóczy and Pluchino 1969) respectively show that the latter factor is *not* capable of reducing the mean tissue concentration in the portal vein sufficiently to explain the degree of supersensitivity This is also unlikely simply because of the scarcity of the outer nervous network (Fig. 2–4). Reduction in NA concentration corresponding to the degree of prejunctional supersensitivity can prevail only in the immediate vicinity of the adrenergic terminals *i.e.* at the very nearest layer of smooth muscle cells. Holman *et al* (1968) found that the terminal nerve structures were separated from the closest muscle cells by a distance of the order of 1500 Å in the rabbit portal vein.

The marked prejunctional supersensitivity obtained after denervation in the present study then seems to imply that the muscle cells which lie closest to the nerve terminals have a key function in eliciting the response also when the tissue is exposed to *exogenous* NA. These cells may function as pacemakers, they may have a more abundant supply of adrenergic a receptors or their receptors may have a greater affinity to NA. Once activity has been induced in these "key cells it can spread to the remainder of the media, so that forceful contractions ensue, due to the propagating ability of this vascular muscle (Johansson and Ljung 1967 1968, Ljung and Stage 1970) In view of the pattern of innervation such key cells controlling the longitudinal muscle layer may be located at its adventitial border in the innermost cell layers of this sheath or even in the circular muscle. In the latter case the longitudinal muscle would be activated by myogenic spread of excitation from the circular layer which in fact seems to receive the densest innervation.

In conclusion, the longitudinal smooth muscle of the portal vein develops a considerable prejunctional supersensitivity to NA despite the fact that nervous elements are found only at the borders of the muscle layer This pattern of innervation which characterizes most blood vessels has been held responsible for the low degrees of supersensitivity observed in arteries. Our results indicate that the *a*-adrenergic receptors which determine the response to exogenous NA are located *mainly* on the "innervated effector cells of the portal vein and from these cells the excitation spreads to the rest of the muscle by myogenic mechanisms. This situation may also prevail and give rise to high degrees of prejunctional supersensitivity in peripheral vessels with sparsely innervated but propagating smooth muscle

Correlation between Noradrenaline Release and Effector Response to Nerve Stimulation in Rat Portal Vein in Vitro

By

JAN HÄGGENDAL, BÖRJE JOHANSSON JAN JONASON and BENGT LJUNG

Abstract

HÄGGENDAL, J B JOHANSSON J JONASON and B LJUNG *Correlation between noradrenaline release and effector responses to nerve stimulation in the rat portal vein in vitro* Acta physiol scand. 1970 Suppl 340 17–3..

The purpose of the present study was to quantitate the release of adrenergic transmitter during sympathetic vasoconstrictor fibre stimulation as function of impulse frequency and to correlate this release to the magnitude of the contractile responses of the vascular smooth muscle. All experiments were performed *in vitro* using the neuroeffector system of the isolated rat portal vein. The preparations were first incubated in radioactive noradrenaline (³H NA) and during this 30 min uptake period the tracer equilibrated with an intraneuronal pool of NA corresponding to about 12 per cent of the total endogenous store, which was found to be approximately 2.2 μg NA/g tissue. In the subsequent phase of the experiments the tissue was superfused with Krebs solution, contractile activity was continuously recorded and the effluent from the muscle chamber was collected and analysed by liquid scintillation counting. In some experiments ³H NA and its main metabolites were separated and determined. The slow spontaneous release of radioactivity appearing in the absence of nerve stimulation consisted mainly of metabolites of ³H NA. The increased release obtained during electrical stimulation consisted almost exclusively of ³H NA itself The amount of ³H NA, released per impulse, was calculated as a fraction of the actual total content of radioactivity in the tissue At 4 imp/sec this fraction was 9.9×10 This could be estimated to correspond to total transmitter release per impulse of about 10 of the entire endogenous NA store. The fractional release of ³H NA per impulse seemed t be somewhat lower at 8 and 16 imp/sec and was significantly reduced at 32 imp/sec (3.9×10) The relat ve values obtained for total transmitt release at different frequencies and for the corresponding contractile re sponses could be summarized as release-response curv It indicated that the maximal con tractile response f the portal vein as determined in the first hand by postjunctional mechanisms and not by failure of the nerves to increase transmitter release at high frequencies.

For all parts of the vascular syst m the curves, relating th impulse rate to the effector response during vasomotor nerve activity are steep at low frequencies (1–8 imp/sec) Furthermore maximal constri tion is generally obtained at impulse

rates between 10 and 20 imp/sec (*e g* Folkow 1955[a] Celander 1954 Mellander 1960) As the mean impulse frequency in the vasomotor fibres under physiological conditions rarely seems to exceed 8–10 imp/sec (Folkow 1955[a]) the full range of nervous control of the blood vessels can be exerted by adjustments of the discharge rate within the steep part of the frequency response curve. A detailed understanding of the frequency response relationships in vascular neuroeffector systems requires knowledge of quantitative data for transmitter release from the vasomotor nerves at different impulse rates and the correlation between these amounts and the contraction of the vascular smooth muscle

Quantitative studies of vascular response and transmitter release under *in vivo* conditions are complicated by numerous factors. The vasoconstrictor response recorded as a change in pressure flow or volume can be affected by local metabolic influences and by geometrical factors involving differences in the wall to lumen ratio of the vessels. Furthermore, the amount of transmitter appearing in the venous blood varies with the flow rate which alters the conditions for diffusion (see *e.g* Rosell Kopin and Axelrod 1963 Carlsson Folkow and Häggendal 1964) *In vitro* preparations make it possible to study directly the contractile response of the vascular smooth muscle with well standardized conditions of diffusion However the amounts of endogenous noradrenaline (NA) released by nerve activity from a small strip of vessel are difficult to quantitate biochemically This problem of transmitter determination may be circumvented by studying the release of radioactive NA and this technique also permits analysis of ^{3}H metabolites of NA (for ref see *e.g* Jonason 1969 c) An important question is however to what extent the quantitative release of ^{3}H NA reflects the magnitude of the release of endogenous transmitter

The aim of the present study was to investigate the NA release in isolated preparations of the rat portal vein as a function of impulse frequency during electrical nerve stimulation and to correlate the amounts of released transmitter to the effector responses. The mechanical activity of the longitudinal muscle layer of the portal vein can directly be recorded (Axelsson *et al* 1967) and the intramural nerves of the preparation can be activated by electrical field stimulation (Johansson *et al* 1970) The rat portal vein is only about 100μ thick (Johansson *et al* 1970) and thus offers good possibilities for diffusion of liberated substances. In the present study the tissue was preincubated in ^{3}H NA before it was placed in a superfusion system which allowed recording of mechanical activity and continuous collection of released ^{3}H NA and its metabolites (*cf* Su and Bevan 1967 Hughes and Roth 1960)

Methods

I Procedures used for studying contractile responses and release of total radioactivity during field stimulation

Portal vein preparations from rats of the Sprague-Dawley strain, weighing 250–350 g and of either sex, were used in this part of the study The animals were killed by a blow on the neck.

The portal vein was isolated, cut open longitudinally and mounted in an organ bath for isometric recording of the mechanical activity as described previously (Arrhenius et al. 1967). A modified Krebs solution was used in all experiments. It had the following composition in mM: NaCl 123; KCl 4.73, $NaHCO_3$ 15.5; KH_2PO_4 1.19; $MgCl_2$ 1.19; $CaCl_2$ 2.49; glucose 11.5 and ascorbic acid 1.13 and was continuously bubbled with 4% CO_2 in O_2 at 38°C. After an accomodation period of about one hour dl-^3H-NA (specific activity 7.45 C/mmole; Radiochemical Centre, Amersham, England) was administered to the bath giving a NA concentration of 10^{-7} M. After 30 min incubation this organ bath was lowered, the muscle was rinsed for about 1 sec in non radioactive medium and a 1.5 ml bath was put in position. This small muscle chamber was continuously perfused at constant rate (approximately 1.3 ml/min) by pre-warmed and bubbled Krebs solution. Mixing of the fluid was obtained by bubbling the gas also through an inlet in the bottom of the chamber. The muscle chamber was supplied with a pair of platinum electrodes at a distance of 5 mm which allowed electrical field stimulation of the intramural adrenergic nerves as described elsewhere (Johansson et al. 1970).

The outflow from the perfusion system was continuously collected throughout the experiment according to the following time schedule. Sampling periods of 5 min duration were used in the initial 30 min of the wash-out. Following this, 1 min samples were taken for the first min before until the fifth min after each stimulation period which itself lasted for 2 min. The wash-out was then collected over two 5 min periods before the next cycle began (cf. Fig. 2 below).

The contractile activity of the portal vein was recorded continuously throughout the experiment. An integrating device was used to quantitate the force development during spontaneous activity and in response to nerve stimulation (see Fig. 1).

At the end of the experiment the muscle preparation was blotted between two layers of filter paper and weighed on a Cahn electrobalance. The tissue was homogenized in 1.5 ml of 0.4 N perchloric acid (PCA). Krebs and the extract was centrifuged for 20 min at 2000 rpm. For liquid scintillation counting 1.1 ml of the supernatant was taken. Further 0.1 ml of the ^3H-NA incubation medium and 1.0 ml of each wash-out sample, respectively, were diluted with PCA in Krebs to a final volume of 1.1 ml and a PCA concentration of 0.4 N.

The samples were counted in a liquid scintillator spectrometer after addition of 17 ml of scintillation fluid made up by 1 part methanol and 16 parts of a solution containing 120 g naphtaline; 7 g PPO (2,5-diphenoxyloxazole); 0.05 g POPOP (1,4-bis-2-(5-phenyloxazolyl)-benzene) in 1000 ml of dioxane. Quenching was corrected for by the use of internal or external standards.

II. Determination of radioactive NA and its metabolites

Some modifications of the wash-out procedure were introduced in experiments aiming at a differentiation between NA and its major metabolites. Three portal veins were mounted on the same muscle holder. One of them was connected to the transducer for recording of mechanical activity and the other two were merely stretched to their approximate in vivo length. During the 30 min uptake period the muscles were incubated in dl-^3H-NA as above or in l-^3H-NA (10^{-7} M with a specific activity of 2.34 C/mmole; Radiochemical Centre, Amersham, England). In the subsequent phase of the experiment, stimulation periods of 5 min duration were used and the perfusion fluid was collected over periods of 5 to 10 min in flasks containing 2 ml of 2 N HCl.

The samples were divided into two aliquots, one for determination of NA, deaminated metabolites and deaminated 3-O-methylated metabolites, and the other for the determination of normetanephrine (NM). Carrier substances were added (see Rutledge and Jonason 1967) and the samples were filtered and stored at −20°C.

The procedures used in this part of the study have been described in detail in previous publications (Rutledge and Jonason 1967, Jonason and Rutledge 1968) and will be presented here only in general terms. NA was adsorbed out and then eluted from Dowex-50 columns, by

acid and neutral metabolites passed through in the effluent The Dowex effluents were then passed over lumina columns and the effluents from these columns, containing the deaminated, 3-O-methylated metabolites were collected. Those products which were only deaminated were then eluted from the alumina columns by 0 2 N HCl. The metabolites from the acidified alumina effluents and eluates were extracted with ether the volumes were reduced under vacuum, scintillation fluid was added and radioactivity determined in a liquid scintillation counter

For determination of NM the neutralized samples were first passed over alumina where NA was adsorbed The alumina effluents, containing NM were then passed over a Dowex-50 column and eluted from the columns by N HCl. The amine eluates (NA and NM) were freeze-dried and the radioactivity was measured by liquid scintillation. Recoveries of the amines were determined in each sample by quantitating fluorimetrically the amount of carrier substance remaining in the eluate after the separation procedures. The values of the amines were calculated by correcting for efficiency recovery aliquot factors and the specific activity of the precursor The values of acid and neutral metabolites were calculated in the same manner except that no recovery values were assessed in these experiments.

III Determination of endogenous NA in the portal and mesenteric vein

Three experiments were performed in order to determine the total content of endogenous NA in the portal and superior mesenteric veins. Pooled preparations from 20 rats were used in each of these three experiments. The portal vein from the entrance of the gastro-splenic vein to the bifurcation at the hepatic hilus was dissected, cut open longitudinally rinsed in normal Krebs solution, blotted on filter paper and weighed on the electrobalance. A corresponding length of the adjacent superior mesenteric vein was treated similarly The tissues were homogenized in 10 ml ice-cooled 0.4 N PCA containing 20 mg ethylenediamine tetra acetate (EDTA) and 10 mg ascorbic acid. After the samples had passed columns of a strong cation exchange resin the NA was estimated fluorimetrically according to the modified trihydroxyindole reaction (Haggendal 1963). The recovery throughout the estimation procedures was determined by adding 100 pg NA to control samples. The recovery value, being about 70 per cent, was used for correction.

Results

I Endogenous NA levels

The endogenous NA levels in the portal vein were found to be 2.2 ± 0.24 μg/g wet weight (mean $\pm$ S.E.M.) and in the superior mesenteric vein 5.7 ± 0.13 μg/g

II Contractile responses and release of total radioactivity during field stimulation

The primary data obtained in this part of the study are exemplified in Fig. 1 The middle tracing illustrates the original recording of mechanical activity which demonstrates the typical spontaneous activity of the rat portal vein and the excitatory contractile responses to electrical field stimulation (0.8 msec; 15 V) at 4 and 16 imp/sec. The continuous integration of the mechanogram (upper recording in Fig 1) represents the accumulated area (dyn $\times$ min) under the curve of active force between each resetting As the integrator resets every 60 sec the tracing directly gives the mean force developed during each minute However as apparent in the stimulation periods, resetting also occurred when the integrator output reached full scale, which

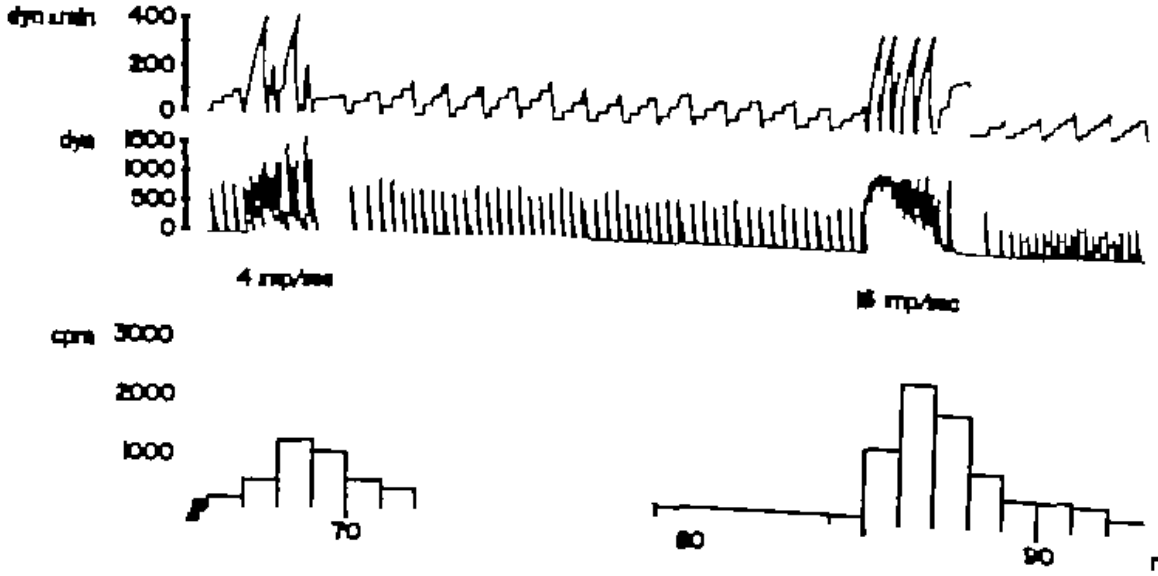

Fig 1. Mechanical activity of the portal vein, directly recorded (middle panel) and integrated (upper panel). Columns in lower panel indicate number of cpm and time for collection of each perfusate sample. Note increase in contractile activity and in output of radioactive tracer in response to electrical field stimulation (signal).

means that the average force then equals the sum of the deflections per min. The net mechanical response during nerve activity was calculated as the mean force developed during the stimulation period minus the mean force during the preceding two minutes of spontaneous activity. The absolute values of the neurogenic responses varied markedly between preparations. Therefore their magnitudes were in each experiment expressed in per cent of the initial response to 4 imp/sec, the frequency always used in the first stimulation period.

The lower part of Fig. 1 illustrates the total counts per minute (cpm) appearing in the perfusate collected over respective sampling periods. A low amount of radioactivity was present in the wash-out from the control state. During nerve activity this amount markedly rose to reach a maximum during the second minute and upon cessation of stimulation it returned to control values in 3–5 min.

The time course of the elimination of tracer from the tissue during the experiment could be reconstructed in detail by adding in the reverse order the total radioactivity of the different fluid samples to the number of cpm obtained in the ultimate muscle extract. Fig. 2 in this way illustrates the results of an experiment in which the effects of different impulse frequencies were studied.

A rapid fall in tissue radioactivity is found in the beginning of the wash-out period, most probably representing elimination of tracer from the extracellular fluid and perhaps, from other extraneuronal compartments. The subsequent slow phase has been interpreted to represent disappearance of tracer which, during the uptake period, has been incorporated into the intraneuronal "pool" of endogenous NA. A zero time value for this slow component was obtained by extrapolation, assuming an exponential decay (dotted line in Fig. 2). This figure, the weight of the tissue

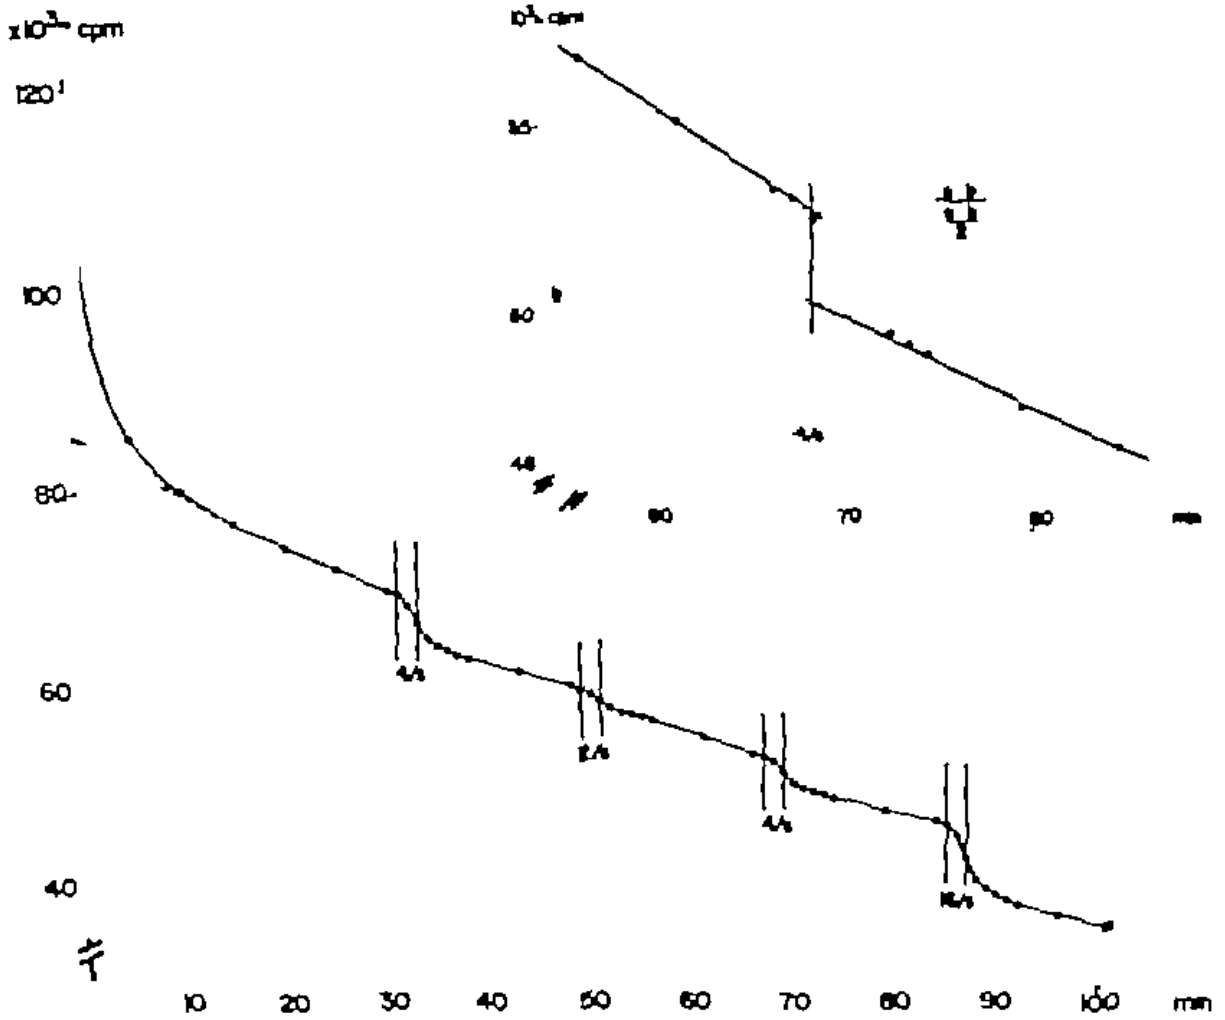

Fig. 2 Time course of the elimination of tracer from portal vein. The curve was constructed by adding, in reverse order the radioactivity of the perfusat samples t the cpm values for the ultimate muscle extract (open square symbol at the ight end) Release of tritiated transmitter in response t nerve stimulation was quantified as fraction (K) of the mean tissue content prevailing at the respective stimulation period. The magnified section of the curve illustrates how this calculation was done. For further details see text.

and the specific activity of the incubation medium made it possible to calculate the amount of labelled NA in relation to the endogenous NA store. In the experiment of Fig the zero time intercept was 85,200 cpm the muscle weight was 4.37 mg and the NA concentration of the medium 15.2 ng/ml giving 2,2*4 000 cpm/nl. This would correspond to a NA pool of 133 ng/g tissue. Since the determinations of total endogenous NA in portal veins indicated a content of 2.2 μg/g the specific activity of the NA n the tissue store in the particular case was only some 6 per cent of that of the incubation medium This figure is one of the lowest obtained the mean value for the whole group of 36 experiments was 1..3 per cent (±0.8 S.E.M.)

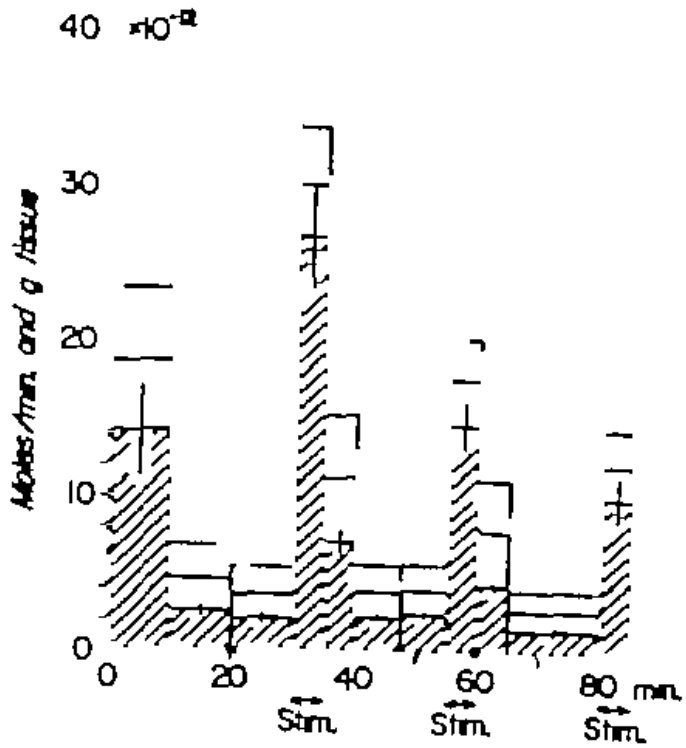

Fig. 3. Distribution pattern of radioactive *l*-NA and its metabolites in the perfusate. Filled bars represent labelled *l* NA; open bars represent the sum of *l* metabolites (calculated from *Fig. 4*) Experimental values of *l*-NA and NM corrected for recovery Within dotted lines, the calculated loss of acid and neutral metabolites through the separation procedures is given Mean values of two experiments (±S.E.M.) shown for noradrenaline. Stimulation at 4 imp/sec indicated.

Returning to the elimination curve of Fig * it can be seen that nerve stimulation was associated with an accelerated decrease of tissue radioactivity corresponding to the higher cpm values of the fluid samples obtained during and immediately after the stimulation period (*cf* Fig 1) This accelerated fall of tissue radioactivity is taken to represent transmitter release elicited by the nerve impulses, an interpretation which is supported by the results presented in section III We have chosen to quantitate this release in proportion to the actual total tracer content of the muscle (see further below) The procedure used in curve analysis and calculation is exemplified by the magnified section of the plot in Fig 2 The spontaneous wash-out rates preceding and following the nerve activity were extrapolated to the middle of the 2 min stimulation period (levels *a* and *b*) The number of cpm released by the train of impulses is then *a* minus *b* and the mean tissue content of radioactivity may be represented by the arithmetic mean of a and b The tracer release as a fraction of the total content is then given by *K* in Fig 2 Dividing by the total number of impulses during the stimulation period gives the fractional release per impulse

III Levels of labelled NA *and its metabolites in the perfusates*

The results presented in this section were obtained with labelled *l* NA. One control experiment with labelled *dl* NA showed the same general pattern The quantitative

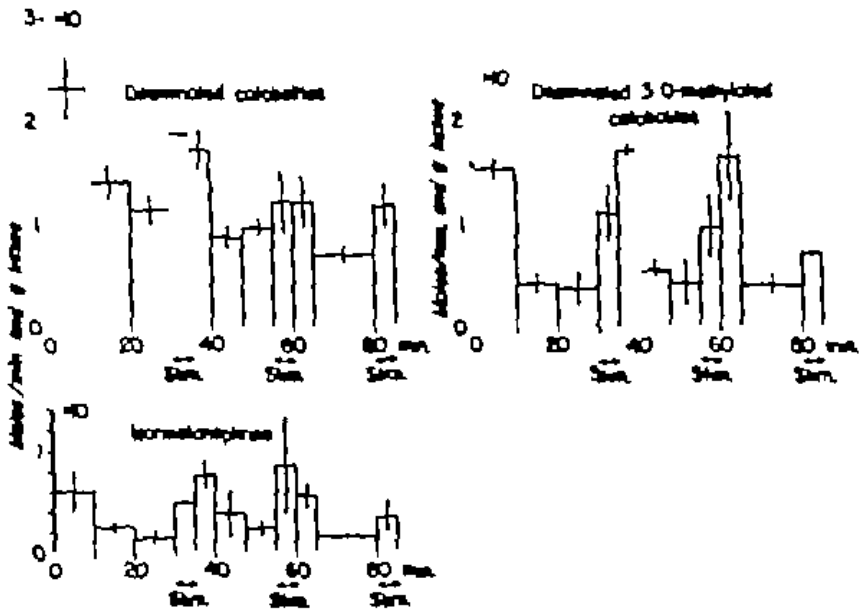

Fig. 4 Distribution pattern of the metabolites of radioactive *l* NA in the perfusate. Only NM corrected for recovery Mean values (±S.E.M.) of two experiments. Stimulation at 4 imp/sec indicated.

relationship between ^{3}H NA and its metabolites in perfusates from the stimulation and wash-out periods is demonstrated in Fig 3 The amount of ^{3}H NA (corrected for recovery) and the sum of the determined metabolites is presented. The dotted lines represent correction for loss of acid and neutral metabolites assuming a recovery of about 45 per cent on the basis of previous data (Jonason 1960 a, b) The major part of th radioactivity washed out during the first 10 min consisted of H NA During the following 20 min considerably smaller amounts of radioactivity were obtained the major part now being metabolites of labelled NA. During the three periods of field stimulation at 4 imp/sec there was a four to six fold increase in the release of total radioactivity and 70 to 80 per cent of this consisted of ^{3}H NA itself. In the samples taken immediately after the stimulation periods the total radioactivity was about 50 per cent of that obtained during stimulation and more than half of this activity emanated from metabolites. In the following wash-out fractions only small amounts of radioactivity were present, the major part being metabolites of NA

The pattern of th metabolites of labelled NA is presented in Fig 4 Only small amounts of NM were detected. The relative changes in the levels of NM during the different phases of the experiment were similar to the changes in NA The levels of the deaminated metabolites were higher than those of NM but the relative increase observed during stimulation was less pronounced (30 to 60 per cent) The levels of those products which were both deaminated and 3-O-methylated were in general higher than those of NM, but lower than those of the deaminated products.

However the increase of the amount of deaminated 3-0-methylated metabolites caused by electrical stimulation was relatively large (four to five times) and was maximal in the sample obtained immediately after stimulation.

In summary the results reported in this section have shown that the radioactivity of the perfusate in the absence of stimulation mainly consisted of metabolites of ^{3}H NA. The increased radioactivity associated with nerve stimulation is mainly in the form of ^{3}H NA proper If one assumes that an unchanged spontaneous leakage continues during stimulation (as has been done in the calculations of release exemplified in Fig 2) the present results imply that about 85 per cent of the increase during stimulation is constituted by ^{3}H NA. Furthermore, a large part of the remaining 15 per cent probably represents metabolites formed from ^{3}H NA after its release. In the following the increase in the output of total radioactivity caused by nerve stimulation will therefore be referred to as transmitter release.

IV Transmitter release and mechanical response at different impulse frequencies

Fig 4 showed that the H content in the tissue decreased rather rapidly with time and also that this decrease was influenced by the number of stimuli given. Furthermore, when the tissue contained less ^{3}H the absolute amount of radioactive transmitter released at stimulation also decreased (by about 70 per cent over 90 min) It might be more appropriate therefore to express transmitter release as a fraction of the prevailing tissue content of radioactivity as described in connection with Fig 4 A series of experiments was performed in order to elucidate whether this fractional release would vary in the course of the experiment as a function of time. Repeated stimulations at 4 imp/sec were given following the general schedule illustrated in Fig 2 The cumulated data indicated some tendency of the fractional release to decrease with time (about 20 per cent in 90 min) There were however relatively large variations between experiments so that no significant correlation between time and fractional release could be obtained. The mechanical responses showed some tendency to decline with time, on an average by about 25 per cent in 90 min. This fall was thus of about the same magnitude as the per cent decrease in fractional release of transmitter but considerably smaller than the decrease in absolute cpm values for release It is likely therefore that variations in the fractional release of H NA will reflect changes in the release of endogenous transmitter

The relatively large number of data ($n=45$) obtained with 4 imp/sec gives a value for fractional release per impulse of $(0.8\pm0.04)\times10^{-2}$ (mean$\pm$S.E.M.).

The dependence of the mechanical response on the amount of transmitter released was studied in experiments where different stimulation frequencies were used. The stimulation periods were arranged in such a way that the various impulse rates appeared in random order so as to minimize any possible effects of time and preceding impulses. For the same reason the results from the initial stimulation at 4 imp sec was only used as a reference and was not included in the comparison. Fig 3 illustrates

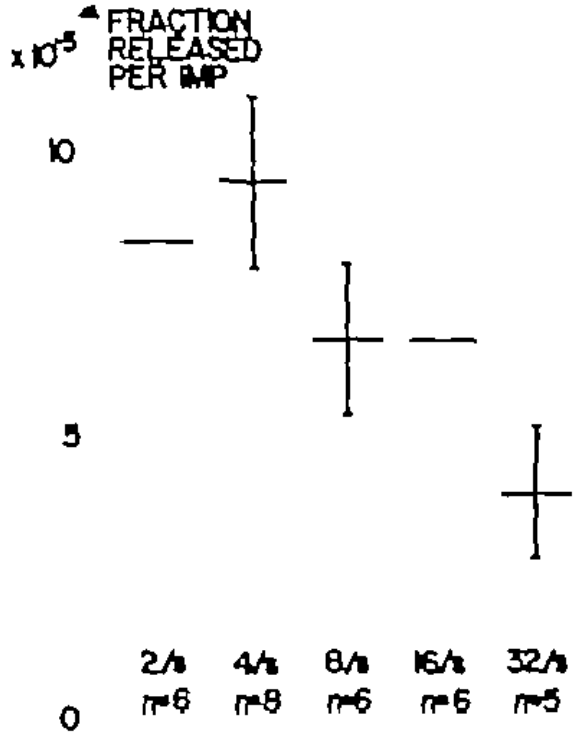

Fig. 5. Fraction of tissue radioactivity released per impulse at different frequencies of electrical field stimulation. Means ±S.E.M. indicated.

the fractional release per impulse at different frequencies of stimulation. The results suggest a moderate decrease in the transmitter release per impulse at 8 and 16 imp/sec compared to 4 imp/sec but the difference is not significant ($0.5>p>0.1$). A clear-cut decrease is found at 32 imp/sec when related to 4 imp/sec ($p<0.05$).

The quantitative data obtained at different impulse frequencies made it possible to analyse the contractile response as a function of the amount of labelled transmitter released. In the individual experiments relative values for the amount of liberated radioactivity and the mechanical response during each stimulation period have been expressed in per cent of the corresponding values obtained during the first period of stimulation as mentioned above this was always performed at a frequency of 4 imp/sec The results of this initial stimulation have thus been used as a reference for the subsequent stimulation periods in which different impulse rates were used in random order Thirty-one such randomized periods of stimulation have been obtained in 11 experiments and are represented in Fig 6 where the relative data for release and contractile response are plotted against each other

The total release of transmitter increased with frequency but not in proportion to the impulse rate obviously as a result of the variations in NA output per impulse indicated in Fig 5 The magnitudes of the mechanical responses in the frequency range of 2 to 8 imp/sec were closely related to the total amounts of NA released. At 16 and 3 imp/sec however the responses were only slightly enhanced despite the continued increase in transmitter liberation.

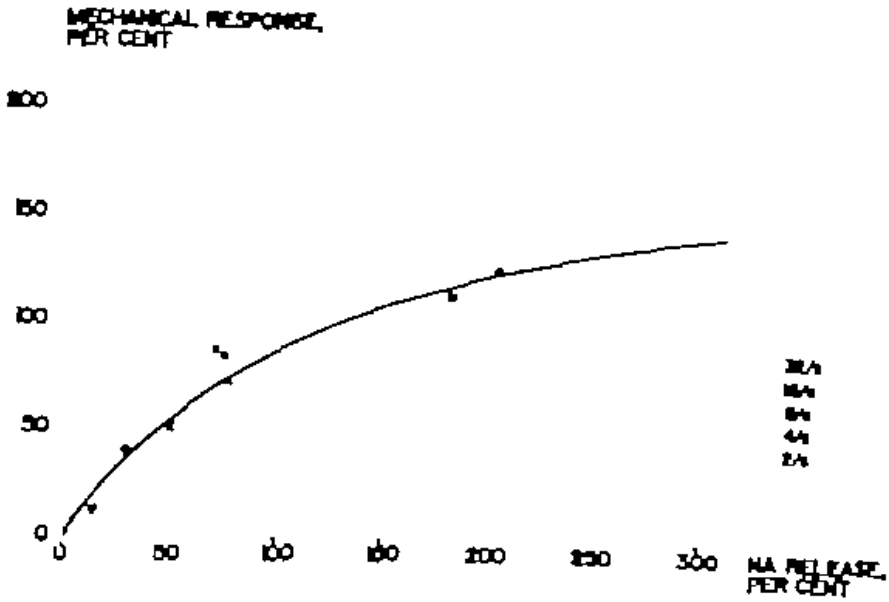

Fig 6. Relative data for ^{3}H NA release and mechanical activity in response to 2 min electrical field stimulation at different impulse frequencies. Same material as in Fig. 5. Line represents the best fit hyperbola. For further details see text.

Discussion

The NA content per unit tissue weight in the portal and mesenteric veins of the rat were rather high 2.2 and 5.7 μg/g respectively in comparison with values previously reported from several other but more thick walled blood vessels, which have ranged between 0.1 and 1.3 μg/g (von Euler and Lishajko 1958 Burn and Rand 1958 Mayer *et al.* 1968, Genest *et al* 1969) Since the innervation of most vessels, including the portal and mesenteric veins is arranged in an essentially two-dimensional way an expression of NA content per unit area may better correspond to the density of the adrenergic plexus. Considering the thickness of the portal and mesenteric veins which is about 100 and 30μ respectively and assuming a specific gravity of 1.0 both vessels contain approximately 20 ng/cm^2 vessel wall

It is now generally accepted that exogenous NA, both under *in vivo* and *in vitro* conditions, is taken up into the nerve terminals by the so-called membrane pump mechanism and stored there in the intraneuronal amine storage granules (*e.g* Hillarp and Malmfors 1964 Carlsson 1965, Malmfors 1965 Hamberger 1967) The characteristics of this uptake as studied by the use of ^{3}H NA have widely been analysed for different tissues (see *e.g* Iversen 1967 for review)

In the present experiments on the rat portal vein, uptake of H NA was obtained by 30 min incubation in 10 M labelled NA. Recent *in vitro* studies of the rat iri by Jonsson *et al* (1969) have shown that with such low concentrations of exogenous NA, tissue radioactivity reaches a relatively steady lev l within 30 min. The amount of ^{3}H NA remaining in the tissue after wash-out of the extracellular space did not change significantly when the uptake period was increased from 30 to 60 min in

their experiments. Evidence was presented that the labelled pool of NA was essentially intraneuronal but its size was considerably smaller than the total store of endogenous NA. The fact that a reasonably constant level of uptake was reached suggests, however that a subcompartment of the *total NA store had* been *equilibrated with* the extracellular tracer The calculations described in connection with Fig 2 above indicate that in the present experiments this subcompartment was about 12 per cent of the total endogenous NA content of the portal vein.

After ^{3}H NA has been taken up into the adrenergic terminals it can be released by direct stimulation of the nerves or by field stimulation as shown in a number of studies *in vivo* and *in vitro* respectively (*e g* Hertting and Axelrod 1961 Rosell, Kopin and Axelrod 1963 Gillespie and Kirpekar 1966 Baldessarini and Kopin 1967 Su and Bevan 1967) Electrical field stimulation of smooth muscle preparations has been shown to activate selectively the intramural nerve fibres (*Paton 1958* Paterson 1965) provided that impulse duration is kept low as in the present experiments.

Quantitative data on the release of labelled transmitter have been expressed above as a fraction of the actual tissue content of radioactivity and not as the absolute cpm values obtained in response to stimulation in the different stages of the experiment. The reason for doing this was that in control experiments with repeated stimulation at 4 imp/sec, the changes in the mechanical response seemed to correlate better with the changes in fractional release than with the changes in absolute ^{3}H release the latter decreasing markedly with time. If changes in the mechanical response at this physiological impulse rate signify variations in the total release of transmitter the latter variations should be reflected in the fractional release of ^{3}H NA. The fall in absolute release of ^{3}H NA in the course of the experiment is apparently compensated for by a corresponding increase in the release of endogenous transmitter probably as a result of new synthesis of NA (*e.g* Sedvall and Kopin 1967 Kopin *et al.* 1968) This may be associated with a redistribution of ^{3}H NA within the neuron However such redistribution appears to be of minor importance in the present experiments since the decrease in fractional release was small and comparable to the decrease in mechanical response

The fraction of the total tissue radioactivity which was released per impulse at a frequency of 4 imp/sec was found to be about 0.8×10^{-4} If this had originated from tracer which was evenly distributed in the entire store of endogenous NA the release of NA per impulse would also have been 0.8×10^{-4} of this total endogenous store. *In view of the above arguments that the* ^{3}H NA *is practically confined to a* smaller pool of NA, constituting some 1.. per cent of the total store there are reasons to believe that the total transmitter release per impulse is closer to 10^{-5} of the endogenous store This reasoning obviously rests on the prerequisite that released transmitter essentially comes from the pool of NA which was equilibrated with exogenous ^{3}H NA during the uptake period It is interesting to note that the figure for total release per impulse estimated in this way comes close to the value of 2×10^{-5}

for fractional endogenous release per impulse obtained by Folkow Häggendal and Lisander (1968) A figure of 5×10^{-4} for fractional endogenous release can be calculated from data obtained by Bevan, Chesher and Su (1969) in experiments on isolated pulmonary arteries treated with phenoxybenzamine which is known to increase overflow of transmitter

The overflow of radioactivity during stimulation measured in the present experiments may lead to an underestimation of the "true release because an unknown amount of released ^{3}H NA may have been reabsorbed into the nerve terminals by the "membrane pump Substances like desmethylimipramine and Lu 3-010 (1 phenyl 1 (3-methylaminopropyl) 3,3-dimethylphthalane) have been used experimentally to block this mechanism (*cf* Carlsson *et al.* 1969) Preliminary experiments with Lu 3-010 10^{-7} g/ml, using the present technique, did not result in any significant increase in the fractional release With a higher concentration (10^{-6} g/ml) there was even some decrease in the release per impulse, a phenomenon which is subjected to further analysis. Farnebo and Hamberger (personal communication) did not find any increase of the impulse-induced ^{3}H NA release from the isolated rat iris after treatment with desmethylimipramine at different concentrations. It appears that the so-called membrane pump blockers may influence also other mechanisms in the adrenergic neuroeffector system such as the suggested mechanism for variable transmitter release (Häggendal 1969 1970)

The present experiments concerning the pattern of H NA metabolism in the portal vein under the *in vitro* conditions showed that the major portion of the spontaneous release consisted of metabolites of NA, whereas ^{3}H NA itself was responsible for at least 85 per cent of the increased output of radioactivity during nerve stimulation Similar results were obtained by *e g* Rosell, Kopin and Axelrod (1963) studying the catecholamine release from th dog gracilis muscle *in vivo* Beside H NA the predominant compounds obtained in the perfusates from the isolated portal vein in the absence of nerve stimulation were deaminated metabolites. These probably reflect the action of th intraneuronal monoamine oxidase on ^{3}H NA which has leaked out into the axoplasm from the storage granules or been taken up by the membrane pump after primary spontaneous release into the neuromuscular gap (see *e.g* Jonason 1960 c) Metabolism by extraneuronal catechol-0-methyl transferase and extraneuronal monoamine oxidase is apparently of little importance during the spontaneous release, as suggested by the low lev ls of normetanephrine and deaminated, methoxylated products. Those latter compounds are, however responsible for the major part of the increase in metabolites obtained in connection with nerve stimulation It is likely that the NM originates from extraneuronal breakdown of released ^{3}H N A and that part of it has been further metabolized by tissue monoamine oxidase (*cf* Rutledge and Jonason 1968) It is worth noticing that deaminated 3-0-methylated products always reached their highest levels in the sample period immediately following nerve stimulation. This may suggest that they represent decomposition of H N A which has reacted with

the smooth muscle receptors before being 3-O-methylated and then deaminated (*cf* Eisenfeld *et al* 1967)

A major aim of the present investigation was to quantitate the transmitter release in the isolated portal vein as a function of stimulation frequency and to correlate these results to the simultaneously recorded effector responses. Such a correlation should help to explain the characteristics of the frequency response curves for adrenergically innervated effector systems

The amount of NA released per impulse did not change markedly when the adrenergic nerves were stimulated with frequencies in the range of 2 to 16 imp/sec. In conformity with previous studies (*e.g* Brown and Gillespie 1957 Kirpekar and Misu 1967 Davies and Withrington 1968) the output of NA fell at higher impulse rates. The mechanism of this decrease and the one also reported at frequencies of less than 2 imp/sec (Haefely Hürlimann and Thoenen 1965 Davies and Withrington 1968) does not seem to be known in detail Folkow (1952) demonstrated that normal vascular resistance is maintained at a discharge rate in the vasomotor fibres corresponding to 1–2 imp/sec and that during intense reflex vasoconstriction this discharge rate would rarely exceed 8 imp/sec. In this physiological range the total transmitter release thus seems to be proportional to the impulse rate.

As indicated in Fig 6 the contractile response of the portal vein is well correlated to the total amount of transmitter released by nerve stimulation at 2–8 imp/sec. Therefore, it is evident that the impulse frequency of vasomotor nerves very directly controls the state of contraction in the vascular smooth muscle within the physiological frequency range. At higher impulse rates, however the mechanical response does not increase much further in spite of continued increase in the total NA release. This implies that the limit for the maximal vasomotor response to nerve stimulation of moderate duration, as in the present experiments, is determined by some link of the effector system The levelling off of the frequency response curve above the physiological impulse rates therefore seems to be in the first hand a postsynaptic phenomenon.

This investigation was supported by grants from the Swedish Medical Research Council (B70-14X 23-06A, B70–14X 166-06B, B70–14X 2868-01), from the Medical Faculty University of Gothenburg from Wilhelm and Martina Lundgren Vetenskapsfond, from the Air Force Office of Scientific Research through the European Office of Aerospace Research, OAR, United States Air Force under Contract F6105–68-C-0044 and from US Public Health Service (HE-05678-08).

Introduction

The regional blood flow resistance as well as other vascular functions in the peripheral circulation are determined by the state of constriction, or tone of smooth muscle in the various types of blood vessels, and this tone is regulated by vasomotor nerves by circulating vasoactive hormones and by local factors (for ref see the recent review by Mellander and Johansson 1968) It is known that acute elimination of the nervous influence results in decreased resistance to blood flow in most vascular beds (for ref. see *e.g.* Folkow 1955) However after acute denervation some vascular tone persists in arteriolar resistance vessels, in precapillary sphincters and, to some extent in small veins. On the other hand, large arteries and veins and arterio-venous anastomoses may become fully dilated after the vasomotor nerves have been cut. The vascular tone that does prevail after acute denervation can only to a limited extent be ascribed to humoral vasoconstrictor agents but appears to reflect inherent myogenic activity in the smooth muscle (*e.g.* Folkow 1962 1964 a)

Direct microscopic observations on the vascular bed of suitable structures, such as the rat mesoappendix and the bat wing, have shown that the diameter of small arteries and veins and their branches rhythmically increases and decreases (for ref see *e.g.* Wiedeman 1963) Chambers and Zweifach (1944) coined the term vasomotion to describe this activity Vasomotion has been shown to persist in the distal arterial and venous vessels after acute denervation (*e.g.* Wiedeman 1963) whereas the major vessels then markedly increase in diameter Considerable evidence has thus accumulated from studies with haemodynamic approaches and vital microscopy that the smooth muscle in several sections of the peripheral circulatory system maintains basal vascular tone by spontaneous synchronized contractions. Such rhythmic behaviour requires that both initiation of activity and cell to cell propagation occur within the muscle tissue. This tissue then would belong to the single unit type of smooth muscle according to Bozler's classification (Bozler 1948) Myogenic tone in some vascular sections may be based on similar fundamental characteristics of the smooth muscle without giving rise to easily observable rhythmic contractions simply because the activity is asynchronous or of a tetanic type.

Much earlier work on isolated preparations of vascular smooth muscle has been performed on strips or segments of large arteries and veins and the lack of myogenic automaticity in such vessels lead to the conclusion that vascular muscle in general would belong to the multi unit type (Bozler 1948) a view which seemed deeply rooted as late as in the beginning of the sixties.

This summary is based on results reported in the following papers.

I. Sympathetic control of rhytmically active vascular smooth muscle as studied by a nerve-muscle preparation of portal vein. Johansson, B and B Ljung Acta physiol scand. 1967 *70* 299–311

II Spread of excitation in the smooth muscle of the rat portal vein Johansson B and B Ljung Acta physiol. scand. 1967 *70* 312–322.

VII Correlation between noradrenaline release and effector response to nerve stimulation in rat portal vein in vitro Häggendal, J B Johansson, J Jonason and B Ljung Acta physiol scand 1970 Suppl. 340 17–32.

The papers are referred to in the text by their Roman numerals.

transmitter may spread by cell to cell propagation to deeper portions of the media

The aim of this article is to summarize the results and conclusions presented in papers I to VII and to discuss the relative importance of these two mechanisms during vasomotor nerve activity in the portal vein. Possible implications of the present results for the control of vascular muscle in other parts of the circulatory system will also be discussed briefly

The separate studies have aimed at a stepwise analysis of the properties of this neuroeffector system. In paper I methods for direct recording of the mechanical activity of nerve-muscle preparations of the portal vein *in vivo* and *in vitro* were described and the adrenergic nerve supply was identified by pharmacological analysis. The importance of myogenic mechanisms for the synchronisation of the spontaneous activity (II) and of the excitatory neural responses (III) were then studied qualitatively Further aspects on pacemaker function and synchronization during adrenergic excitatory responses were elucidated in V A study on the development of prejunctional supersensitivity to noradrenaline (NA) after chronic denervation (VI) yielded information regarding the distribution of the adrenergic α receptors that are of importance in producing the response to exogenous NA. In the same study a description of the morphological characteristics of the rat portal vein and its innervation was included Quantitative studies on the release and stimulating effects of the adrenergic transmitter substance, NA, were performed in IV and VII.

Methodological considerations

Studies of intact vascular beds with methods for recording of pressure flow volume capillary exchange etc have greatly deepened our knowledge of the dimensions and the control of the circulatory system. In view of this wealth of information it may seem that experiments on isolated vascular preparations would involve a step in the direction of a more unphysiological approach with little prospect of bringing useful contributions to cardiovascular physiology The virtue of the *in vitro* system is, however that it permits analysis of cellular mechanisms behind observed phenomena to an extent which is not always possible *in vivo* and also that it permits quantitative studies under strictly standardized conditions. It is obvious that data from experiments on isolated vessels are more valuable if some evidence can be mustered to show that the principles revealed are applicable also to the intact circulation. An attempt was made to base the present studies of the neuro-muscular function of the isolated portal vein on the *in vivo* situation by comparing the responses of the isolated preparation to those of the portal vein *in situ* (I) The subsequent investigations dealing with propagation, electrophysiology morphology of innervation, transmitter release etc in the portal vein, have not aimed at a detailed analysis of each of these different aspects but have intended to clarify their respective roles in the primary function of the effector ... in the contractile response

The various experimental procedures employed in the individual studies have been described in detail in the respective papers. Here only some general methodological aspects will be discussed.

Animals As to the choice of species cats and rabbits were used in I for studies on the portal vein *in situ* and for the development of the technique for isolation of the nerve-muscle preparation. In papers II to VII *in vitro* studies of portal veins from rats have been performed. No qualitative dissimilarities between the mechanisms controlling the activity of this vessel in the different animals have appeared However species variations in the quantitative effects of nerve stimulation and of exogenous NA may exist. All quantitative data discussed in relation to release and effects of NA (IV VI VII) refer to the conditions in the rat.

Recording of contractile activity The mechanical activity has been recorded isometrically in the direction of the long axis of the vessel as the majority of the muscle cells are longitudinally arranged. As demonstrated in paper VI however an inner thin layer of the media consists of circular muscle The contractions of this layer have not been considered in those experiments.

The phasic contraction pattern constituting the spontaneous activity and remaining also at low and moderate degrees of induced excitation seemed to create some problems with regard to the quantitation of excitatory responses. However integration of the mean force development per unit time was of great help in this respect and was accomplished either by a gravimetric method (I) or by the use of an electronic integrating device (IV VI VII) When responses to nerve stimulation and to exogenous excitatory agents were measured, the mean spontaneous force developed in the preceding control period, was always subtracted, thus allowing estimations of net excitatory effects. Variations in the spontaneous activity may obviously lead to inaccuracies in the measurements of weak responses. However in the present studies quantitative comparisons between excitatory responses under varying experimental conditions (IV VI) have not been based on differences in threshold values but on relative changes of moderate and strong responses (in IV) or on shifts in dose-response curves (ED_{50} calculated in VI) Under these circumstances it is improbable that variations in spontaneous activity could have influenced the results and conclusions.

Recording of electrical activity Extracellular recordings of electrical activity have been performed simultaneously with registration of mechanical activity in II and V

In the former study the sucrose-gap method was applied in order to analyse qualitatively the effects of a hyperosmotic solution on the vascular muscle The sucrose gap method first utilized for recordings from nerve by Stämpfli (1954) was modified for studies on smooth muscle by Burnstock and Straub in 1958 More recently the technique has widely been used for investigations on effects of ions and drugs on membrane phenomena in vascular smooth muscle The experimental

procedure as applied to the portal vein has been described in detail by Axelsson *et al* (1967)

In V the main purpose of recording electrical activity was to provide a means of detecting the sequence of excitation in different parts of the preparation Recordings were made between a common electrode and each of three glass pipettes filled with Krebs solution and placed in contact with the portal vein preparation By correlating the temporal relationship between the activity recorded via the three electrodes, initiation and spread of activity in the smooth muscle could be analysed Similar techniques have been used in studies on electrical activity of gastro-intestinal muscle (see Prosser and Bortoff 1968) The recorded electrical activity represents volume-conducted potentials which are known to reflect the time course of membrane current flow under the electrode when this is close to the tissue (*e.g* Medrano *et al* 1967) The configuration of the potential changes in the electrograms were not analysed in detail in V since the purpose of the study was merely to elucidate the pathways of propagation of the electrical activity and this could be done by observing the sequential appearance of activity in the three leads.

Electrical stimulation of vasomotor nerves in vitro Two different methods were applied for electrical stimulation of the sympathetic postganglionic nerve supply of the isolated portal vein. In I, III and IV a nerve-muscle preparation was studied which consisted of the portal vein and the bundle of nerve fibres running towards it from the right coeliac ganglion. The nerves were directly stimulated in these experiments via a fluid electrode (see I) based on the principles described by Garry and Wishart (1951) Such a nerve-muscle preparation allows a safe analysis of the selective influence of nerve activity upon the effector organ However the delicate nerve fibres are inevitably subjected to some trauma during the dissection and in the course of an experiment. Therefore, this method would be less suitable for quantitative studies regarding the effects of nerve stimulation on transmitter release and effector responses which have been performed in VII. Instead the method of transmural electrical field stimulation was employed in VII and as a control of nerve degeneration, in VI (*cf* Paton 1955 Paterson 1965 Hughes and Vane 1967). Control experiments demonstrated that stimulation with pulses of 0.8 msec duration and 15 V in amplitude were supramaximal for nerve activation and that responses to such stimuli could be blocked by guanethidine, phenoxybenzamine or chronic denervation (see Fig. 9 in VI) The smooth muscle was comparatively insensitive to direct stimulation, less than 10 per cent of the neurogenic response was obtained when the preparation was stimulated after adrenergic blockade with pulses of 10 times longer duration (8 msec) It is thus safe to conclude that the intramural nerves were selectively activated by electrical field stimulation at the low impulse duration used in VI and VII.

Estimation of transmitter release. An indirect pharmacological analysis of the effect of transmitter concentration during nerve activity was performed in IV

Some aspects of methodological interest will be considered below in the discussion of the functional implications of the results of this study

Experiments aimed at direct quantitation of NA release from the adrenergic nerve terminals were done in VII. As shown in that study the total endogenous NA content in one rat portal vein (weighing 3 mg) is only about 6 ng. In view of the limited amounts thus available for release, labelled NA was studied as an indicator of the endogenous amine Quantitative conclusions regarding the release of endogenous NA based on data from such experiments are, of course, only justified if a relationship can be established between tracer release and release of endogenous NA. This matter will be considered below in connection with a discussion of the results and conclusions attained in VII

Results and conclusions

The main results and conclusions presented in I to VII will be summarized and discussed here in four subsections. The first part (A) deals with the functional characteristics of the smooth muscle of the portal vein. In section B the organization of the vasomotor nerves in the vascular wall will be described and their primary function during activity *i.e.* the release of transmitter will be discussed quantitatively In the third part (C) the distribution of the transmitter within the effector and the kinetics of transmitter receptor interaction are considered. In the final section (D) the results presented in the foregoing subsections are correlated quantitatively to the effector response so as to give an integrated picture of the function of the neuroeffector system in the portal vein.

A. Properties of the smooth muscle in the portal vein

Morphology Some histological data were presented in VI *The media of the vessel* was shown to consist of two muscle layers. The inner one which is about 15μ thick is arranged in an approximately circular fashion and appears to be a continuation of the media of the more thin walled mesenteric veins The outer media layer of the portal vein approximately 60μ thick is composed of bundles of muscle fibres arranged longitudinally It thus forms a comparatively heavy coat which extends from the liver hilus to the proximal part of the superior mesenteric vein (Fig 1-4 in VI) Assuming an average cell diameter of 4μ (*cf* Rhodin 1959 1967) and considering the large extracellular space (45 per cent of the wet tissue weight, determined with ^{14}C-sucrose by Arvill, Johansson and Jonsson 1969) it can be estimated that the longitudinal muscle sheath will contain 10 to 15 layers of cells

Electron microscopic studies of rat portal vein have shown regions of fusion between adjacent muscle cell membranes, nexuses" (Barr personal communication, Funaki 1967 See also Dewey and Barr 1968)

The rabbit portal vein has been shown to have morphological characteristics similar to those found in the rat (Holman *et al* 1968)

Spontaneous activity The portal vein contracts spontaneously both *in vivo* (I) and *in vitro* (I to VII) In the isolated preparation from the rat the automaticity is characterized by 3 to 8 phasic contractions per min and these have been shown electrophysiologically to be associated with bursts of action potentials (Funaki and Bohr 1964, Axelsson *et al.* 1967 see also II and V) Between these excitation periods there is electrical and mechanical inactivity The peak tension of the phasic spontaneous contractions often corresponded to more than half of the maximal tension obtainable in response to exogenous vasoactive agents (see *e.g* Fig 9 in VI) This indicates that the majority of the muscle cells become activated during each spontaneous contraction.

The presence of this spontaneous phasic activity indicates very strongly that excitation. I is rhythmically induced in some part of the muscle and 2. becomes propagated within the tissue.

Initiation of activity The frequency of the spontaneous contractions was not markedly affected by adrenergic neuron blockade (I) adrenergic α and β-receptor blockade (I, IV) or by chronic denervation (VI). This demonstrates that the vascular smooth muscle has an inherent ability to discharge rhythmically The membrane potential of cells in the portal vein has been shown to undergo gradual depolarization which seems to lead to rhythmic firing of bursts of action potentials (Funaki and Bohr 1964 Axelsson *et al* 1967) In view of the conducting properties of the muscle (see below), areas where the cells discharge simultaneously may serve as "pacemakers" for the entire preparation. From the results reported in V it appeared that the functioning pacemaker could be located in any part of the preparation and that shifts of pacemaker area frequently occurred during the spontaneous activity The pronounced synchronization of the spontaneous activity implies that the area which at a given moment has the most rapidly "sliding" membrane potential will elicit the excitation in the muscle.

Results from a set of unpublished experiments also illustrate this principle. Fig. 1 shows the mechanical activity of the hepatic (h) and mesenteric (m) ends of the rat portal vein when recorded separately with the middle part of the vessel immobilized (*cf* II and III). The polygraph channel recording activity in (m) had been reversed The two ends of the strip resulted in different fluid compartments utilizing the experimental arrangement described in III. In the upper panel of Fig. 1 the two ends of the preparation contracted synchronously in normal fashion. By local inspection at high paper speed (right part) the hepatic end could be seen to begin to contract slightly before the mesenteric one indicating that the actual pacemaker was located in (h). When the local calcium concentration was increased on the hepatic side the pacemaker with lower frequency located in the mesenteric end, gradually took over control of activity while the mesenteric half of the preparation was also exposed to the same increase in calcium concentration (panel C), the hepatic end regained control but

elements and that the concentration then rapidly declines so that it does not exceed 10^{-8} M at a distance corresponding to the diameter of one muscle cell.

Interaction between transmitter and adrenergic α receptors The concentration of transmitter which interacts with the adrenergic α receptors to produce the excitatory response to nerve stimulation was analysed using an indirect approach in IV. In principle this estimation was based on the finding that the degree of reduction of responses to exogenous NA produced by partial α receptor blockade with low concentrations of phenoxybenzamine was inversely related to the level of NA in the bath. Responses to nerve stimulation at 4 and 16 imp/sec were less reduced than were responses to exogenous NA at concentrations of 10^{-6} M or lower. However the neural responses were relatively more affected than the responses to 10^{-6} M exogenous NA. The per cent response remaining after partial phenoxybenzamine blockade was graphically represented as a function of the concentrations of exogenous NA in each experiment. By interpolation to these curves it was possible to deduce the NA concentrations which would be blocked to the same extent as were the responses to nerve stimulation. The values obtained 8×10^{-8} M at 4 imp/sec and 2×10^{-8} M at 16 imp/sec, were interpreted to represent the transmitter concentrations which had been reacting with receptors initiating the neural effector responses. It appears that the only factor which could make this value erroneously *high* would be the neuronal uptake mechanism which was not blocked in these experiments. It was later found in VI that chronic denervation of the portal vein caused a supersensitivity of the prejunctional type corresponding to a 13-fold decrease in ED_{50}. This implies that when the adrenergic nerves are intact the uptake mechanism reduces the NA concentration at the α adrenergic receptors to such an extent that the NA concentration in the bath has to be increased 13 times to give a response comparable to that of a denervated vessel. Therefore the local concentrations of exogenous NA at the receptors were below those in the bath when the effective transmitter concentrations were determined in IV. However at high exogenous NA levels the limit of the capacity of the uptake mechanism is reached and therefore the concentration in the entire biophase approaches that in the bath (see Fig. 10 in VI and also Langer and Trendelenburg 1969).

It thus seems safe to conclude that the actual transmitter concentration which activates the receptors during nerve stimulation at 4 imp/sec is, at least 10^{-8} M. Returning to the calculated concentration values presented in Fig. 2 it can be seen that NA levels of this order of magnitude only prevail for short periods at distances from the site of release which seem to include only one single layer of muscle cells. Although this reasoning is based on a number of assumptions which still remain to be experimentally verified in the portal vein it is evident that during nerve activity a very limited portion of the muscle cells of the media in this vessel can be directly activated by the transmitter.

It is striking that the effective transmitter concentration as determined in IV

corresponds rather closely to the peak values of the transmitter concentration (see Fig 2) despite the fact that the concentration peaks are of very short duration This indicates that the stimulating action of the transmitter is prolonged at the postjunctional level, so that its effectiveness in producing the contractile response to nerve stimulation is increased The time constants characterizing many of the links in the series of events leading to the contractile response may contribute to this enhancement. However the process of interaction of NA with the α receptors is of particular interest and will be discussed in detail in a later publication (Johansson, et al., to be published) The characteristics of the hyperbolic function relating the concentration of exogenous NA to the contractile responses of the denervated portal vein presented in VI imply that the process of formation of NA—α receptor complexes is about 10^7 times faster than the reverse reaction leading to the breaking of the complexes.[1]

Receptor kinetic reasoning (modified from Waud 1968) [ ] symbolizes concentration; k association rate constant; k_d dissociation rate constant.

$$\underset{[D]}{NA} + \underset{[R]}{\alpha\text{-receptor}} \underset{k_d}{\overset{k}{\rightleftharpoons}} \underset{[DR]}{NA-\text{receptor complex}} \tag{1}$$

$$[DR]+[R]=[R]_t = \text{total receptor population} \tag{2}$$

According to the law of mass action, (1) and (2) give at equilibrium.

$$\frac{[DR]}{[R]_t} = \frac{1}{1 + \frac{k_d/k}{[D]}} \tag{3}$$

Assuming that the mechanical response is proportional to the fractional receptor occupancy the ED_{50} for the denervated portal vein, approximately 10^{-6} M, gives 50 per cent receptor occupancy

$$\frac{50}{100} = \frac{1}{1 + \frac{k_d/k}{10^{-6}}} \qquad k_d/k_1 = 10^{-6} \tag{4}$$

The equation characterizing the drug receptor interaction can be given in the following general form:

$$\frac{d[DR]}{dt} = k_1[D][R] - k_d[DR] \tag{5}$$

replacing k with k_1 10^{-6} (4) gives

$$\frac{d[DR]}{dt} = k_1([D][R] - [DR]\ 10^{-6})$$

During rising and high concentrations of NA the rate of [DR] formation thus is high and roughly proportional to the NA concentration whereas the rate of [DR] dissociation at any moment is about 10^6 times slower and proportional to the concentration of the drug receptor complex.

In view of the rapid rate of binding of NA to the receptors, a high degree of receptor occupancy can develop despite the short duration of the peak concentrations of transmitter in the neuro-muscular gaps following the nerve impulses. Dissociation of the receptor-agonist complexes in the intervals between the peaks will lead to a gradual decrease in occupancy but the rate of this decay will be much slower than the fall of transmitter concentration calculated by the diffusion equations. It is evident that the use of partial α-adrenergic blockade to estimate the concentration of transmitter as done in IV will give a mean effective concentration which is more closely related to receptor occupancy than to mean concentrations of free transmitter" in the extracellular fluid phase. The fact that this effective transmitter concentration comes close to the peak values obtained in the left panel of Fig 2 can be understood from the above considerations of the kinetics of the receptor-agonist reactions. During repetitive stimulation receptor occupancy seems to be determined mainly by the peak concentration of the transmitter at the nearest muscle cells and by the time interval between pulses.

D Transmitter release and effector response at different impulse rates

The frequency-response curve The consideration of the release of the transmitter and its reaction with the α receptors, in the foregoing section, was mainly based on data pertaining to nerve stimulation at 4 imp/sec. The relationship between impulse rate and mechanical response has been presented in I for the cat portal vein *in situ* (Fig 5 in I) and for the rabbit portal vein *in vitro* (Fig. 7 in I) and in IV for the isolated nerve-muscle preparation of the rat portal vein.

In a series of unpublished experiments the responses of the isolated portal vein to stimulation of the intramural nerves were recorded. Electrical field stimulation with pulses of 15 V amplitude and 0.3 msec duration was used to selectively activate the intramural nerves (see VI for details in method) Each preparation was stimulated periods of _ min at different impulse rates ranging from 0.5 to 32 imp/sec applied in random order The resulting mean increases in force, expressed as a per cent of the response to 10 M exogenous NA, are illustrated in Fig 3.

The pattern of the effector response to nerve stimulation (*cf* section A) was similar in the various preparations and under the different experimental conditions The shapes of the frequency response curves likewise were in good agreement although the relative magnitude of the maximal response to nerve stimulation (that obtained at 16 imp/sec in most experiments in each series) varied with the technique used In all different *in vitro* preparations the delicate postganglionic nerve fibres have been subjected to some trauma but the functional consequences of this should be greatest in those experiments where the nerves were actually dissected and pulled into the fluid electrode This is the most likely reason for the smaller maximal response to nerve stimulation (in per cent of the maximal NA response) in these preparations. Electrical field stimulation should be more effective for activation of

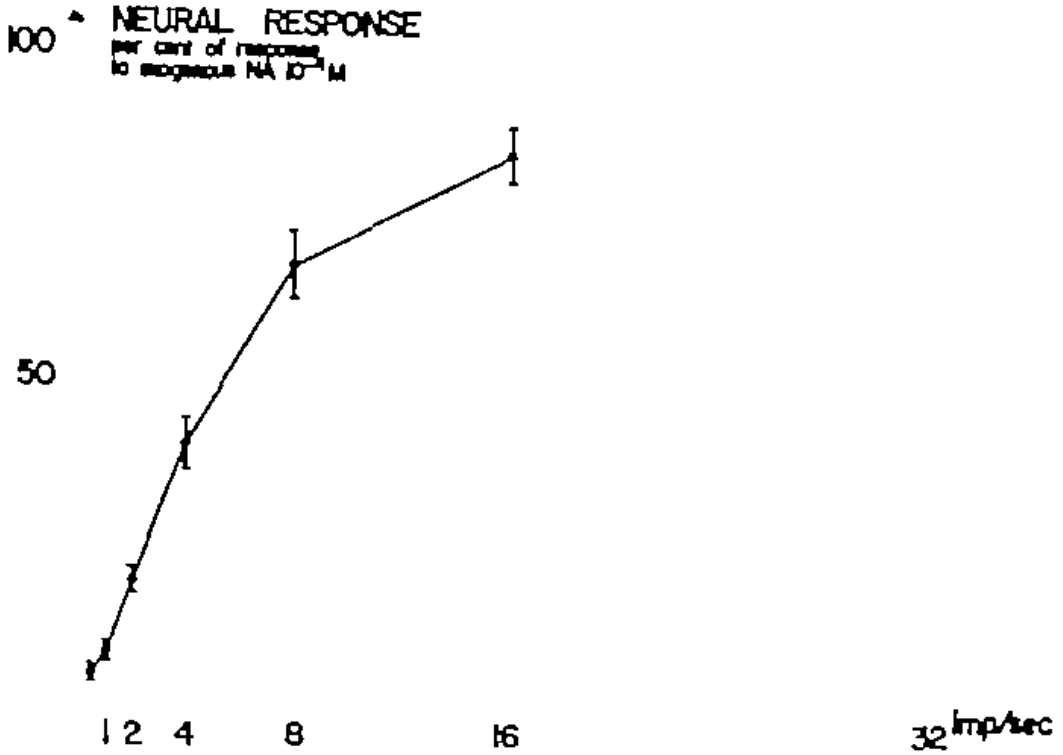

Fig. 3. Excitatory responses of rat portal vein to electrical field stimulation (0.8 msec 15 V) for 2 min at graded impulse rates. Frequencies applied in random orders in different experiments. Responses expressed as a per cent of responses to exogenous NA 10⁻⁴ M. Mean ± S.E.M. from 20 experiments.

all th nerve fibres supplying the vessel and the results obtained with this technique (Fig 3) will therefore be considered representative of the optimal neural control of the portal vein

The maximum response to nerve stimulation in the portal vein is obtained at 16 imp/sec and consequently the frequency response curve is steep at low frequencies. As a rule, no detectable contraction was produced by one single impulse of supra maximal intensity but repetitive stimulation at 0.3–0.5 imp/sec was required to obtain a measurable increase in contractile activity (unpublished results) Thus the full range of nervous control of the effector system can be exerted by varying the impulse rate by a factor between 30 to 50 times. For comparison, the rat o between the threshold concentrati n of exogenous N \ and the concentration necessary for maximal response is about *10 000 This principal difference between the frequency*-response and the dose-response relationships is often found in sympathetically innervated *effector* organs. In both cases the final common path in the production of the effector response starts with the NA–α receptor reaction. Th hyperbolic dose-response function obtained when N \ is exogenously administered to the portal vein (VI, IV) can be accounted for on the basis of current theories of drug receptor int raction (see review by Waud 1968, and footnote above) It seems reasonable also to seek the explanation for the shape of the frequency response curve in the kinetics of the reactions between the α receptors and the local concentration of transmitter during nerve activity at different impulse rates.

As to the amounts of transmitter released per impulse in the portal vein the experiments with ^{3}H NA in VII did not show any statistically significant variations when the impulse rate was altered between 2 and 16 imp/sec. In some previous studies on the perfused spleen of the cat a clear-cut decrease in the NA output per impulse has been observed at the lowest impulse rates, 1–3 imp/sec and at supra physiological frequencies (Brown and Gillespie 1957 Gillespie and Kirpekar 1966 Haefely Hürlimann and Thoenen 1965 Kirpekar and Misu 1967 Davies and Withrington 1968) Considering the obvious difficulties involved in quantitative collection and determination of the minute amounts of NA released at the lowest impulse rates, it appears that the transmitter release per impulse might be constant at all frequencies within the physiological range over short periods of stimulation.

It is a common feature of all the frequency response functions obtained for the portal vein (I, IV VII, Fig 3 above) that an approximately linear relationship exists in the frequency range of 1—8 imp/sec. Consequently the mean receptor occupancy during stimulation with these impulse rates *should* increase in proportion to the change in frequency Further the responses to 1 and 8 imp/sec correspond to about 10 and 70 per cent, respectively of the maximal response to exogenous NA (Fig 3) which shows that the mean level of receptor occupancy indeed rises very steeply over this frequency range This in turn can be understood in the light of the discussion in the last paragraph of section C When the interval between impulses is gradually reduced below say 1 sec the foot of the curve representing receptor occupancy *due to a subsequent impulse will climb higher and higher up on the* decay of the curve originating from the preceding impulse. The top values for the concentration of NA receptor complexes will not increase markedly since they are determined by the amplitude of the brief peaks of transmitter concentration (Fig 9 A) which seems to remain reasonably constant during repetitive stimulation. Furthermore the characteristics of the agonist-receptor association at these high NA levels imply that moderate changes in the absolute value of the peak NA concentration would only very slightly affect the resulting degree of receptor occupancy

At impulse rates above 8/sec the frequency response curves level off in spite of the continued increase in total transmitter release demonstrated in VII It may be tempting to ascribe this phenomenon to a decrease in the amount of NA released per impulse which appears to occur at high frequencies in the portal vein (VII) as well as in other effector organs (Brown and Gillespie 1957 Gillespie and Kirpekar 1966 Kirpekar and Misu 1967 Davies and Withrington 1968) However the high effective transmitter concentration 2×10^{-5} M obtained for 16 imp/sec in IV suggests that postsynaptic mechanisms may be responsible for the levelling off and the subsequent fall of the response at high frequencies As judged from the dose-response relationships published in VI, an effective transmitter concentration of 2×10^{-5} M appears to be sufficiently high to produce maximal excitation of those *effector* cells which become directly activated by the transmitter An optimal excitatory influence upon the innervated muscle cells may thus be reached at

the summit of the frequency response curve *i.e.* around 16 imp/sec. The tendency of the neurogenic responses to decline at supra-optimal impulse rates (*see IV*) also has its correspondence in the responses to exogenous NA, which decrease if the NA concentration is markedly increased (VI).

Localization of action of transmitter and exogenous NA. It can be seen from Fig. 3 above that during vasomotor nerve stimulation at 16 imp/sec the response constituted on an average 85 per cent of that to 10^{-4} M exogenous NA which could be considered maximum under the actual experimental conditions. The method of field stimulation appears to effectively activate the intramural nerve fibres but it is inevitable that some of these may have become injured during the isolation procedure and in the course of the experiments. It seems likely therefore that under ideal conditions responses of similar magnitude could be obtained by nerve stimulation and by administration of exogenous NA. This supports the above conclusion that during the maximal response to nerve activity an optimal NA concentration prevails at those effector cells which become directly activated by the transmitter. It also indicates that a comparable mass of muscle is excited by nerve activity and by exogenous NA.

It was demonstrated in a previous section that the transmitter can only reach one or two out of the 10 to 15 layers (see above) of muscle cells in concentrations which are compatible with the magnitude of the effective transmitter concentrations observed in IV. Furthermore, it was concluded from the results of VI that those receptors which initiate the response to exogenous NA must be close to the nerve terminals, suggesting that the primary action on the effector system is located at the same sites whether NA is released from nerve terminals or administered exogenously.

This conclusion was based on an analysis of the development of supersensitivity to NA after denervation of the rat portal vein. Chronic denervation by bilateral removal of the coeliac and mesenteric ganglia caused a 13-fold increase in sensitivity to NA as revealed by a parallel shift of the dose-response curve. The supersensitivity was found to be of the prejunctional type *i.e.* due to elimination of the neuronal uptake mechanism which thus normally reduces, by a factor of 13, the average concentration of exogenous amine in the extracellular fluid surrounding those effector cells which become primarily affected by NA. Considering the spatial relation between the two-dimensional adrenergic plexuses and the muscle cells of the media, also studied in VI and regarding the capacity of the NA uptake process in adrenergic nerves, it was concluded that a reduction in NA concentration corresponding to the degree of prejunctional *supersensitivity could prevail only in the* immediate neighbourhood of the nerve structures (for details and references see VI).

From this reasoning it follows that the same small portion of the muscle cell becomes primarily excited both when endogenous NA is released during nerve-

activity and when exogenous NA is administered In the former case this restriction in NA influence is apparent from the dynamics of transmitter distribution during nerve activity whereas in the latter it is a consequence of the properties of the effector As mentioned in VI the particular properties of the innervated cells may involve quantitative or qualitative aspects of receptor supply or functional membrane characteristics manifesting themselves as differences in excitability Since the high effective concentrations can occur only at very short distances from the sites of release (Fig _) and since the cells directly responding to NA are close to the nerve plexuses it seems justified to speak of the neuro-muscular junction as a functional entity in this type of vascular smooth muscle. A similar specialization of the innervated" cells in smooth muscle from other organs has been suggested by Burnstock (1968)

Myogenic spread of adrenergic excitation In spite of the limited portion of the effector cells which primarily become activated by nerve impulses or exposure to exogenous NA the magnitude of the tension response indicates that the entire effector system is engaged, a conclusion which is supported by comparison with responses to other means of excitation (K^+ hypotonicity etc.) Consequently the *majority* of the muscle cells of the longitudinal layer appears to become secondarily excited by myogenic spread of electrical activity This is possible by virtue of the conducting properties of this smooth muscle as described previously Myogenic spread of adrenergic excitation was shown to occur over considerable distances in the experiments reported on in III and in Fig 6 of V In the former series of experiments excitatory responses were induced by nerve stimulation or by administration of exogenous NA to one half of a portal vein preparation, the two ends of which resided in different chambers of the organ bath. After treating the other half of the vessel with phenoxybenzamine so as to exclude any direct stimulation of its receptors, it was demonstrated that part of the adrenergic response induced on the non treated side was propagated to the other side, so that forceful, synchronous contractions of increased frequency occurred in both parts of the preparation. Application of hypertonic sucrose to the central section of the vessel was used to support the myogenic nature of this propagation (Fig 3 in III) The conduction distances involved in these experiments are obviously many times greater than those which are relevant in the transmural spread of excitation through the media.

In conclusion it seems likely that the majority of the smooth muscle cells in the portal vein become secondarily affected during responses both to nerve stimulation and to exogenous NA. Those cells where the membrane potential primarily becomes reduced under the NA influence seem to be rather densely distributed along the vessel and therefore these graded potential changes have to spread over only short distances to be of importance for the recruitment of the remainder of the muscle during vasomotor nerve activity (*cf* section A above)

General discussion

The aim of the preceding section was to unify the results obtained in the present series of studies into an overall view of the neural and myogenic mechanisms which operate in the portal vein. In this section the emerging picture of the functional properties of this neuroeffector system will be summarized and its general implications on the control of the system will then be briefly discussed.

The vascular smooth muscle of the portal vein displays spontaneous phasic contractions both *in vivo* and *in vitro*. The mechanical activity is closely associated with electrical spike discharge. Initiation of this activity is due to rhythmic excitation of muscle cells in pacemaker areas, the discharge rate of which can be considerably increased by NA either after its release from the adrenergic vasomotor nerves or when exogenously administered. The muscle cells fire bursts of spike potentials which can spread over the entire length of the preparation by virtue of low resistance connections between the muscle cells, the so called nexuses. The latter allow conduction of individual action potentials over the bundles of smooth muscle. Nerve stimulation and the influence of exogenous NA improve the conditions for propagation.

During nerve activity NA is released from the varicosities of the terminal adrenergic axons which are arranged in two-dimensional plexuses and do not penetrate into the bundles of smooth muscle cells which constitute the effector. As a consequence of this geometrical arrangement and of the amounts of NA released per impulse during nerve stimulation the released transmitter primarily activates only the very nearest muscle cells. This however is accomplished by exposure of these cells to short lasting high concentration peaks which give rise to rapid formation of transmitter receptor complexes causing an immediate high degree of receptor occupancy. In contrast to the swift dilution of NA in the fluid surrounding the innervated effector cells, the breaking of the drug receptor complexes is a slow process implying a prolongation of the stimulating effect of the quantity of transmitter released per impulse. For this reason the mean receptor stimulation obtained during repetitive nerve activity becomes comparatively high and roughly proportional to the impulse rate in the physiological frequency range (1–8 imp/sec).

The sensitivity of the effector to exogenous NA seems to be essentially confined to those muscle cells which are reached by the transmitter in effective concentrations during nerve activity. This differentiation of the muscle cells indicates a specialized postjunctional link in the neuro-muscular connections of this vessel. Because of electrotonic coupling between the muscle cells the direct neural influence on the limited portion of the effector cells becomes conducted so as to affect the entire media.

This organization of the neuroeffector system resembles in many respects that described in other organs supplied with smooth muscle of the single unit type such as the gastro-intestinal tract although the excitatory nerves in the

course are cholinergic in nature (*cf* Gillespie 1962 a, b see also reviews by Holman 1968 Bennett and Burnstock 1968)

As to the nervous control of other blood vessels Bevan and co-workers have performed a thorough analysis of the neuro-muscular mechanisms operating in an isolated preparation of a large elastic vessel, the rabbit pulmonary artery (see Bevan 1962 Su Bevan and Urquilo 1964 Bevan and Verity 1966 Verity and Bevan 1968 and Bevan *et al* 1969) In brief, that particular vascular effector was shown to respond very slowly to stimulation of the adrenergic vasomotor nerves and after a relatively long latency The induced contractile activity seemed to be independent of electrical changes in the muscle membrane and consequently myogenic conduction should not occur The average neuromuscular distance was found to be very large (19000 Å) and the transmitter seems to activate the muscle cells gradually by diffusion into the media from the terminal adrenergic plexus located at the adventitio-medial border The muscle layers throughout the media of elastic arteries have been shown to be supplied with α receptors (Bevan and Verity 1967) which would make it possible for diffusion of transmitter to recruite the deeper layers of the media in the neural response

Experiments under *in vivo* conditions have also led to the conclusion that diffusion *of transmitter is of importance for activation of the media in large conduit arteries* (Gerová *et al* 1967 Gerová and Gero 1969)

The fundamental discrepancies between the present findings regarding the nervous control of the smooth muscle in the portal vein and those mentioned here for elastic arteries probably reflect true differences in the functional organization of the neuro-effector systems in respective sections of the vascular system. It is conceivable that the portal vein with its pronounced single-unit behaviour and discrete neurogenic influence enforced by the myogenic conduction of activity on one hand and the pulmonary artery with multi unit type of smooth muscle and more diffuse spread and action of the transmitter on the other represent the extremes in a spectrum of vascular neuroeffector organization. Between these ultimate types, most vessels may occupy intermediary positions with regard to rhythmicity propagating ability receptor distribution and intimacy of neuro-muscular connecti (*cf* Bohr 1965 Furchgott 1964 Rhodin 1967 see also reviews by Holman Somlyo and Somlyo 1968)

The extent of nervous influence in the parallel-coupled vascular circuits different tissues shows variation which seem purposeful in meeting the demands of the respective organs as well as the cardiovascular homeos whole organism (see review by Mellander and Johansson 1968) Su differences in the control of circulatory functions apparently reflect rather than qualitative dissimilarities in the neuro-muscular organi the individual vascular circuits Each of the latter however is form of series-coupled sections of widely different morphological and f teristics. As pointed out in the Introduction" above the present ex

the portal vein was prompted by the expectation that this neuroeffector might serve as a model of the nervous control of haemodynamically more important sections of the peripheral circulation where the vessels are less accessible to direct studies. It therefore seems appropriate to conclude this summary by considering the applicability to different sections of a vascular bed of the principles presented with respect to the portal vein.

There are several reports on the functional properties of large and medium sized arteries i.e. those with "Windkessel" and distributing functions. The results are to some extent contradictory which may reflect variations between different vessels within this group. The large arteries from most species generally show no spontaneous myogenic activity and action potentials have but rarely been recorded in response to exogenous NA or nerve stimulation (for ref. see Holman 1969). Evidence has been presented that transmitter diffusion within the media is responsible for spread of activity during vasomotor nerve stimulation (Bevan *et al.* 1969, Gerová *et al.* 1967, for further ref. see above). However, it cannot be excluded that myogenic spread of excitation could play a role also in large arteries since conduction of electrical activity has been demonstrated in strips of rat aorta (Biamino and Kruckenberg 1969) and since morphologically regions of membrane fusion between the muscle cells have been shown to exist in this vessel (Cliff 1967). Further, it is known that vasodilatation in the peripheral resistance vessels of skeletal muscle is associated with an ascending dilation of the cognate conduit arteries (see Hilton 196..) and inhibition of myogenic propagation might be a likely explanation (*cf.* Folkow 1964 b). It is probable that the smooth muscle in vessels within the Windkessel and conduit sections shows regional individualities in function but in general they lack inherent activity and are predominantly controlled by extrinsic nervous influences.

In contrast, the precapillary resistance vessels, *i.e.* small arteries and arterioles and to some extent also the postcapillary resistance vessels, *i.e.* venules and small veins, are known to possess considerable myogenic activity which haemodynamically manifests itself as a basal vascular tone which persists after acute denervation but can be inhibited by vasodilator agents (see Folkow 196.. 1964 a and b). Vital microscopic studies have revealed rhythmic calibre changes both on the arterial and venous side in these sections although the contraction waves seem to fuse into a less phasic pattern of activity as the muscle mass increases in the more proximal resistance vessels (Wiederman 1968, for further ref. see Wiederman 1963). Johansson and Bohr (1966) demonstrated phasic contractions in isolated strips from arteries with an outer diameter of 200 to 500 μ. It is thus established that the smooth muscle in the resistance sections possesses ability to initiate and conduct activity. Electrophysiologically spontaneous action potentials have been recorded from small arteries and arterioles (Funaki 1961, Steedman 1966). Further, as the density of nexuses has been demonstrated to increase with decreasing vessel diameter (Rhe... 1967) it is reasonable that the smooth muscle in the peripheral resistance v... functional characteristics similar to those of the portal vein. Folkow has

functional importance of myogenically active vascular smooth muscle in the resistance vessels, in view of its sensitivity to stretch in explaining the cellular mechanisms contributing to blood flow autoregulation (Folkow 1962 1964 a, b) In the present series of studies another important functional aspect of the electrotonic coupling between the effector cells is indicated, that of myogenic spread within the media of neurogenically induced activity The adrenergic nerve terminals are confined to the adventitio-medial border of the resistance vessels which again, implies that only a limited portion of the effector cells are in close connection with the muscle cells (Ehinger *et al* 1967 Rhodin 1967) The minimal neuro-muscular distances in these peripheral vessels appear to be less then those considered above for the portal vein (Appenzeller 1964 Matthews and Gardner 1966 Lever Graham and Spriggs 1967) In fact, the neuro-muscular relationship seems to become increasingly intimate with decreasing vascular size at least on the precapillary side (Rhodin 1967) Further some studies indicate that prejunctional supersensitivity after denervation can develop in the resistance vessels in contrast to the large elastic arteries (*cf* VI and Reynolds and Imig 1963 Haeusler and Haefely 1966 Palmer and Norberg 1969) This also supports the idea that the general neuroeffector organization in the resistance vessels may closely correspond to that described in the portal vein. It thus seems that also in resistance vessels myogenic conduction in the smooth muscle contributes to the effectiveness of the neural influence. In this connection it deserves mention that the myogenic enforcement of the nervous response does not require that electrotonic conduction occurs over great distances in order to synchronize the electrical activity in large sections of the vasculature It may also be operating in vessels which do not show phasic contractions as the only prerequisite is electrotonic coupling between the muscle cells.

The vessels in the precapillary sphincter section regulate the number of patent capillaries. Their smooth muscle usually is circularly oriented and consists of only a few interconnected muscle cells (Rhodin 1967) which show inherent rhythmicity and vasomotion before and after acute denervation (for ref see Wiedeman 1963) Due to the limited muscle mass it appears that myogenic conduction may be of little importance for the magnitude of the neural influence. As in the arteriolar resistance vessels the activity in the precapillary sphincters seems to be profoundly affected by local vasodilator factors formed in the tissue. In the precapillary sphincter section this influence also seems particularly strong in counteracting the neurogenic constriction This illustrates the role played by myogenic automaticity in providing the background activity on which excitatory and inhibitory influences act in a competitive way (see Mellander and Johansson 1968)

In the cutaneous arterio-venous shunts involved in thermoregulation, and also in the large veins with predominant capacitance function, the smooth muscle does not show spontaneous activity with the exception of the large splanchnic veins. There appears to be little experimental evidence available which would allow direct evaluation of the importance of myogenic conduction in arterio-venous shunts and

capacitance vessels. It seems safe to conclude however that extrinsic nervous influences are very dominant in the regulation of the contractile activity in these vessels. They respond to nerve stimulation at very low impulse rates and in fact one single impulse in the vasomotor nerves causes a clear-cut reduction in cutaneous blood flow due to constriction of the arterio-venous shunts (Sivertsson 1970) The frequency response curves for both arterio-venous shunts (Folkow and Sivertsson 1964) and capacitance vessels (Mellander 1960) are very steep in the low frequency range.

The low impulse rates required for threshold responses in these vessels and the steep frequency response curves in the low frequency range resemble in many respects the frequency response relationships described for the sympathetically innervated, non vascular smooth muscle of the multi unit type for instance in the nictitating membrane and the dilator muscle of the iris (Celander 1954) In these organs the adrenergic innervation is very dense and appears to directly reach most of the individual muscle cells (Malmfors 1965 1968) and this can account for the characteristics of their frequency-response relationships. The data available at present concerning the pattern of innervation of arterio-venous shunts and capacitance vessels do not seem to justify the conclusion that the vasomotor nerves directly influence all effector cells of the media. The frequency response curves of these vascular sections may also be explained in the face of an adrenergic nerve supply restricted as in most blood vessels, to the outer layers of the media.

The fact that these blood vessels respond to nerve stimulation at very low impulse rates could be a consequence of a multi-unit arrangement with limited electrotonic interconnection between the effector cells In such muscle the depolarization induced by the transmitter can only affect the individual unit. Due to the absence of a large current sink in non-conducting muscle the local depolarization caused by a certain degree of receptor occupancy for a limited period of time, would be greater than in single-unit smooth muscle If such a mechanism contributes to the low threshold frequency in the cutaneous arterio-venous shunts and the capacitance vessels, another consequence of such multi unit behaviour would be that only muscle cells activated by the transmitter would participate in the contractile response. It is well known that the range of variation in regional flow resistance obtained by nervous activation of the cutaneous arterio-venous anastomoses is extremely great, but this could be compatible with activat on of muscle cells only in the outer media as the wall t lumen ratio in these vessels is high (Folkow and Sivertsson 1964).

The steepness at low stimulation rates of the frequency response curves for the comparatively thin walled capacitance vessels has to be explained by other mechanisms. Several factors may contribute. In some large veins adrenergic nerves are found within the media indicating that also its deeper layers of muscle cells in fact receive some innervation (Ehinger et al 1967) Further when expressed as a per cent of maximum th apacitance responses, recorded as changes in blood volume will appear exaggerated in comparison with resistance

Introduction

During the last decades there has gradually emerged an increased knowledge concerning the "anticipatory" visceromotor adjustments that are elicited *e g* in situations of challenge or manifest threat. With respect to the cardiovascular system these adjustments, often initiated by telereceptors and calling for corticohypothalamic integration, include an augmented heart activity and an increased muscle blood supply as combined with blood flow restrictions in most other tissues. It was, no doubt, evident already from the classical studies of Hess, Bard, Ranson and their groups (see *e g* Bard 1960) that the response patterns characterizing *e g* rage or fear are associated with widespread and intense sympathetic discharge. However most of our present knowledge concerning the complex cardiovascular adjustments, associated with the so called *defence reaction*, has gradually developed from studies concerning the sympathetic cholinergic vasodilator fibres and their functional significance, since they appeared to be involved only in the defence reaction. It was therefore initially often taken for granted that these fibres represented the most dominant and essential link of this reaction but, interestingly enough dilator fibres are now known to be present only in some species (see below) but nevertheless, powerful and efficient defence reactions seem to exist in virtually all mammals.

The existence of a sympathetic vasodilator fibre system suggested already in 1880 by Dastre and Morat but clearly demonstrated first by Bülbring and Burn (1935) has aroused much interest and debate during the last few decades. Further studies by Folkow and Uvnäs (1948 1950) and Folkow Haeger and Uvnäs (1948) suggested that such fibres were distributed to the skeletal muscles only that their transmission was uniformly cholinergic and that they were not involved in the steadily operating reflex homeostasis of the circulatory system. Earlier speculations that sympathetic dilator fibres might be supplied to the coronary vessels as well (see *e g* Uvnäs 1960 a) have recently been challenged (Feigl 1967). However the vagal nerves seem to convey dilator fibres to the coronaries of the dog but their functional significance is still unknown (Feigl 1969)

It now appears clear from many studies that the sympathetic cholinergic vasodilator fibres impinge upon precapillary resistance vessels only and

have no direct effects on the precapillary "sphincter" sections or on the capacitance vessels. Thus, the clearance of ^{131}I and the uptake of oxygen did not increase in muscles in association with activation of their vasodilator fibres (Hyman *et al* 1959 Rosell and Uvnäs 1962) and studies of the filtration process and of the pre- and postcapillary responses in connection with activation of the dilator fibres indicated a distribution confined to the precapillary resistance vessels (Folkow Mellander and Öberg 1961) The finding that the clearance of radioactive tracers from the muscle tissue did not increase in connection with the cholinergic dilatation led first to a discussion whether the dilator fibres might open shunt vessels (Uvnäs 1960 b) However other studies, including those mentioned above and experiments where the transit of microspheres was determined (Piper and Rosell 1961) indicated that no true shunts were involved but that the restriction of the dilator fibre impact to larger precapillary resistance vessels only could, in fact, cause "functional shunting" by creating uneven capillary perfusion. Moreover acetylcholinesterase-rich terminals, in all probability belonging to the sympathetic vasodilator fibres, were recently demonstrated in the precapillary vessels of skeletal muscles in cats and dogs (Bolme and Fuxe 1970). These axon terminals were indeed restricted to arterial vessels 30—100 μ in diameter in contrast to the adrenergic nerve terminals that are known to be spread over a

ly wider spectrum of vessels on the arterial as well as the venous

1951 it was shown by Eliasson *et al* that the sympathetic dilat
could be activated from a restricted "centre" in the anterior h
thalamus of the cat, as part of a characteristic and powerful re
pattern involving intestinal and cutaneous vasoconstriction heart
ation and usually a blood pressure rise. Later vasodilator ne
ways have been traced from the amygdala (Hilton and
and from the motor cortex, to descend via the hypothalar
centre and a mesencephalic synaptic relay station to the
neurons in the spinal lateral horns (Eliasson, Lindgren
Lindgren 1955 Lindgren *et al* 1956, Abrahams, Hilton
1960) The cholinergic vasodilator fibres may also be
epithalamus (Reinert 1964)

Thus the cholinergic vasodilatation, as evoked from
"defence area" forms part of a characteristic
that involves adrenergic excitation of most vascular
as combined with an activation of the adrenal medull
1951 Rosén 1961 Feigl Johansson and Löfving 1964

1964). Further there seems to be a concomitant activation of the adrenal cortex (Folkow *et al* 1967) Also the sympathetic supply to the gastrointestinal tract proper is excited inducing a prompt suppression of this organ system, mainly by means of an adrenergic inhibition of the intramural cholinergic ganglion cells (*e g* Folkow and Rubinstein 1965 Jansson, Lisander and Martinson 1968). Piloerection, pupillary dilatation, *etc.* are other signs of this widespread but well-coordinated sympathetic discharge pattern.

As to the functional significance of the sympathetic cholinergic dilator fibres, it was suggested already in the thirties by Bülbring and Burn (1935) that they might be activated in connection to muscular activity They are not engaged in the steadily operating homeostatic reflexes emanating from the baro- and chemoreceptors (see Uvnas 1960 a) although it has recently been reported that they may be activated from intrathoracic receptors (Bergel and Makin 1967 Bevan 1968) When the hypothalamic representation of the sympathetic vasodilator fibres was shown, their role in "emergency situations" and perhaps also in the initiation of exercise, was suggested (Eliasson *et al.* 1951). It was further shown that hypothalamic stimulation in awake cats evoked the mentioned visceromotor changes which were then found to be regularly linked to an arousal reaction that escalated into flight or attack if the stimulation was intensified (Abrahams, Hilton and Zbrozyna 1960) Based on these as well as on subsequent observations (Abrahams, Hilton and Malcolm 1962, Abrahams, Hilton and Zbrozyna 1964) Hilton and associates proposed that the autonomic changes form a preparatory cardiovascular reflex, activated already in the alerting stage of the defence reaction. Further Bolme and Novotny (1969) showed that the cardiovascular components of the defence reaction can be elicited as an orienting reflex or as a conditional reflex to either painful cutaneous stimulation or to exercise on a treadmill. These results are, in general terms, in agreement with the results and ideas of Hilton and his group, as outlined above. Bolme (1969) suggested that "the sympathetic vasodilator nerves play a role in the cardiovascular homeostatic mechanisms to regulate the arterial pressure prior to exercise" Recently however the concept that vasodilator fibres are activated as part of the alerting response and manifest "emergency situations" was challenged by Adams *et al* (1969) who found no evidence for a vasodilator fibre activation during fighting in cats. It should perhaps in this context be stressed that several autonomic response patterns of perhaps somewhat different organization might be elicited from diencephalic levels, each coupled to particular and partly

different types of emotionally charged" situations. If so, there might be no true controversy between these apparently different results.

Marked species differences appear to exist with regard to the supply of sympathetic vasodilator fibres. These fibres have been shown in cats, dogs, sheep, goats and foxes but not, for instance, in rats nor in different kinds of monkeys (see Bolme *et al* 1970) As far as man is concerned, the question is not definitely settled. However cholinergic nerve terminals could not be found around the vessels in human skeletal muscle (Bolme and Fuxe 1969) On the other hand, during mental arithmetics an increased blood pressure, heart rate and cardiac output, associated with an increased muscle blood flow and a reduction of renal and cutaneous blood flows, have been observed (Fencl *et al* 1959) Moreover Blair *et al* (1959) observed a prompt and marked increase of muscle blood flow in acutely alarmed human subjects, a response that seemed to be considerably reduced after atropine. In fact, in 1945 Barcroft and Edholm suggested that sympathetic dilator fibres might be involved in man in situations of vaso-vagal syncope produced by bleeding. In any case, in species lacking or having a poor supply of cholinergic sympathetic vasodilator fibres, such as the rat, a closely similar cardiovascular pattern nevertheless appears to be evoked in stressful situations (Folkow and Rubinstein 1966) The increase in muscle blood flow seems here to be caused by a selective and regional inhibition of vasoconstrictor fibre tone, perhaps reinforced by the vasodilator action of bloodborne adrenaline.

The aim of the present series of studies has been to elucidate *how the cardiovascular component of the defence reaction, as induced by hypothalamic stimulation is altered by some influences of local reflex and central nervous origin* In paper I the interest was focussed upon the changes in cardiac output and its preferential distribution to the skeletal muscles. It was observed that, in spite of continuous hypothalamic stimulation, the cholinergic vasodilatation tended to fade away rapidly ("escape ') and, along with this the increase of cardiac output as well.

This escape was subjected to further analysis in paper II. It appeared to be due to a purely *local* "autoregulatory response" of the precapillary vascular smooth muscles that efficiently curtailed the neurogenic blood flow increase within the skeletal muscles.

Further during a defence reaction the heart rate as well as mean arterial and pulse pressures almost invariably increase and the question arose as to what extent the consequent baroreceptor activation is able to reflexly counteract the defence reaction. This question was investigated in paper III. Evidence was here obtained suggesting a differentiated interaction between

the defence reaction and the baroreceptor reflexes which could have interesting consequences for cardiac output.

For such reasons, the effects of this interaction with particular regard to the cardiac output was studied in detail in paper IV Because of this differentiated interaction, the reflex inhibitory response from the baroreceptors appeared, in fact, to act in "haemodynamic synergism" with the excitatory defence reaction, if anything bolstering the cardiac output increase for a given neurogenic drive and load on the heart.

Finally in search for neurogenic influences that might have a purely suppressing effect on the defence reaction and on the vasodilator fibre activity it was found that stimulation of parts of the cerebellar cortex exerted such an overall inhibitory influence (paper V) markedly contrasting to that elicited by the inhibitory baroreceptor reflex.

Methods

General considerations In the present series of studies anesthetized animals, often under the additional influences of muscle-paralyzing drugs and hence artificially ventilated, were used to examine how some factors of local, reflex and central nervous origin influence the hypothalamically induced defence reaction.

It might appear that studies of such a type would be better performed in awake animals with implanted devices for recording and stimulation. It is, for example, obvious that neuronal excitability and synaptic transmission, especially of cortical and diencephalic structures, are markedly affected even by superficial anesthesia, implying that brain stem mechanisms may be secondarily depressed, or conversely released by the elimination of tonic excitatory and inhibitory influences from higher centres. Too deep an anesthesia will also markedly suppress the activity of such lower brain stem structures that directly control vascular tone and cardiac activity Further anesthesia may in other more indirect, ways affect the activity levels and responses of the different effector organs. For example, what might look like a differentiated autonomic discharge response to stimulation as judged from the effector adjustments, may in fact be a uniform one (or *vice versa*) depending upon the initial level of autonomic activity and the current state of the effectors. Thus, if autonomic nerve activity is initially very high, a further excitation, even if uniform may cause quite different degrees of effector responses than is normally the case. These different hemodynamic effects will be obtained, simply because the hyperbolic frequency response curves for resistance vessels, capacitance vessels and for the heart have different shapes. Lastly whenever artificial respiration is administered, care must be taken to adjust tidal volume and frequency to prevent hypo- or hyperventilation which, because of the consequent shifts in P_{O_2}, P_{CO_2} and pH, influences not only the cardiovascular effectors directly but also their nervous control.

Several reasons have, however contributed to the choice of the present experimental approach. In awake animals, autonomic nervous activity and cardiovascular homeostasis are subject to so many unpredictable influences that the mechanisms under study may be more or less masked in an uncontrollable way Further anesthesia tends to exclude such secondary

influences that can appear in awake animals in the form of conditioned reflexes. It should also be realized that topical stimulations of autonomic brain stem structures in awake animals are likely to excite *ascending* pathways in the reticular formation as well. These may *via* cortical or diencephalic structures, elicit secondary autonomic responses, masking those that were intended to be elicited by direct excitation of *descending* pathways or their relay stations. Besides, the present type of experiments permits an isolation of the autonomic nervous adjustments from somatomotor influences on the cardiovascular system by the use of curarization. Apart from the obvious ethical objections, the use of awake and curarized animals for studies of this type would only invite non-specific and unpredictable defence reactions that may well create more disturbances than the use of a well controlled light anesthesia. Attempts have also been made to minimize the adverse effects of anesthesia by using different anesthetic agents preferentially however chloralose was used since this drug appears to affect autonomic nervous control less than other types of anesthesia. As far as the recordings of the autonomic responses are concerned, a purely electrophysiological approach seems less feasible for the present problems, for reasons discussed in detail by Löfving (1961).

Material and anesthesia. The various experimental procedures used have been described in detail in the respective papers. In the present context only some general methodological aspects will be outlined. The investigations were carried out in a total of about 175 cats and 7 dogs, the latter reported in papers I and II. In one cat an electromagnetic flow probe had in an earlier operation under pentobarbital anesthesia been placed around the aortic root to permit a comparison of aortic flow in the awake, intact animal with that during anesthesia and following the various experimental procedures (see IV). All other experiments were performed on anesthetized animals, where in most cases chloralose, 30—60 mg/kg b.w. was used. In some animals chloralose-urethane (25—50 and 100—200 mg/kg b.w. respectively) or pentobarbital sodium 30—40 mg/kg b.w. was given instead. The anesthetic agents were usually administered intravenously following induction with ether but also the intraperitoneal route was used, or the drug was given to the awake animal *via* an injection into the cephalic vein.

Recordings of the cardiovascular parameters. Heparin was used as an anticoagulant. *Mean arterial blood pressure* was recorded continuously by a catheter in one of the brachial or femoral arteries by means of a Statham (P23AC) strain gauge pressure transducer or with a mercury manometer. *Central venous pressure* was followed by means of a catheter connected to a low pressure Statham (P23BC) transducer.

When recorded, *cardiac output* was in most cases determined with the thermodilution method (see Korner 1965) This has the advantage of leaving the central circulation undisturbed and at the same time permitting fairly frequent determinations. The tip of the thermistor was placed in the ascending aorta. Small slugs of saline at room temperature were injected *via* a cannula with its tip placed close to the right atrium The thermodilution curve obtained was plotted semilogarithmically and corrected for the slight recirculation after which the area under the curve was determined and cardiac output calculated. The thermodilution method has, however the disadvantage that cardiac output cannot be recorded continuously Therefore, an electromagnetic flowmeter Medicon 2000 was used in other experiments although the thorax had to be opened in a fairly traumatic operation. Each probe was calibrated by perfusion with saline. By this technique cardiac output minus the coronary blood flow was recorded.

Muscle blood flow was measured as the outflow from the deep femoral vein, mainly draining the calf muscles, by means of a drop recorder unit operating either an ordinate writer or a step recorder Circulation below the ankle was always occluded by a tight ligature and sometimes the calf was skinned, the bone marrow opened and plugged and all collateral veins at the knee level were ligated. *Skin blood flow* was recorded, by the same technique, as the venous outflow from the hind paw by means of a cannula inserted in the great saphenous vein, all other major collateral veins being ligated. *Intestinal blood flow* was measured as the venous outflow from a 20—30 g jejunal segment following laparotomy and exteriorization of other parts of the intestines. All drop recorders were initially primed with dextran-Tyrode solution, which was also administered if bleeding occurred.

In several experiments vascular flow resistance was directly recorded by means of an electronic device (for details see paper III) In a few control experiments these regional blood flows were also followed by an electromagnetic flow meter placed on the arterial side.

For calculation of the capillary filtration coefficient (CFC) in skeletal muscles, a method was used that enables simultaneous recording of arterial inflow pressure, venous outflow pressure, blood flow and changes of tissue volume in the calf (see Kjellmer 1964) The calf was placed in a saline-filled plethysmograph and CFC was determined by raising the venous outflow pressure abruptly by a known amount and noting the rate of outward filtration resulting from the increased capillary hydrostatic pressure. This value was expressed as the flow of filtrate across the

capillary membrane in 100 g of tissue per unit pressure change; ml/(min×100 g×mm Hg)

Stimulation techniques For topical stimulations in the central nervous system the animal's head was fixed in a modified Horsley-Clarke apparatus. The *defence area* was reached stereotaxically and stimulated by a thin monopolar electrode, isolated except for its tip. The *medullary depressor area* was sometimes reached stereotaxically through the cerebellum but more often the latter structure was gently lifted or completely or partly removed by suction. A similar type of electrode was used. The *anterior cerebellar lobe* was generally stimulated by unidirectional pulses between a pair of electrodes 2 mm apart, or sometimes by a concentric bipolar electrode.

All central nervous stimulations were performed by a Grass S5 stimulator or by a stimulator specially designed for these purposes (constructed by Erving Lars Stage), allowing for either constant current stimulation or constant voltage in the form of unidirectional rectangular pulses.

Following repeated defence area stimulations the responses sometimes tended to decay gradually. Signs of deterioration appeared first by the gradual elimination of the vagally mediated post stimulatory bradycardia and, later by a decline of the cholinergic muscle vasodilatation. As the cholinergic muscle vasodilatation was found to be resistant to the baroreceptor reflex influences and could only be depressed by cerebellar cortical stimulation, in contrast to most other components of the defence reaction, it was used as the criterion that the defence area was still largely intact after the various experimental procedures. As soon as the cholinergic vasodilatation showed signs of decaying rapidly upon repeated stimulations, the experiment was no longer used for "matching" the defence reaction against other influences.

During stimulation thermal and/or electrical injuries often occur and this, together with polarization phenomena, may lead to changes in resistance and capacitance in the electrode circuits. Such changes were, however often followed in the present experiments by the use of an oscilloscope and an unchanged cholinergic vasodilatation proved to be a sensitive criterion that the defence area was largely intact as changes in muscle vasodilatation as a rule paralleled changes in electrode circuit resistance. For such reasons defence area stimulations with constant voltage or with constant current yielded essentially similar results in the present experiments.

For baroreceptor stimulation a Moussejeff (1926) preparation, connected to a pressure reservoir containing oxygenated dextran-Tyrode solution was utilized. The artery transformed into a blind sac, could then be closed

towards the heart by a clamp on the common carotid artery so that the baroreceptor region was either exposed to any desired level of steady pressure by means of the pressure system or when the carotid clamp was removed, to the prevailing pulsatile arterial pressure. Other baroreceptor stations were in most experiments excluded. In some experiments the central end of the cut vagal nerve was stimulated in the proximal direction by a bipolar silver electrode using stimulation parameters that induced a well-graded and reproducible depressor response caused by generalized sympathetic inhibition and, in cases where the other vagus nerve had been left intact, vagal bradycardia.

Results and Comments

Changes in the central circulation caused by activation of the defence area as compared with depressor area stimulation.

In paper I the hypothalamic defence area, as well as the bulbar depressor area and related hypothalamic depressor (sympathoinhibitory) structures, were stimulated. Changes in cardiac output, heart rate, stroke volume, central venous and arterial pressures were studied. Muscle blood flow was recorded as well, partly to indicate an appropriate activation of the defence area. These two centrally elicited response patterns were chosen as they contrast in several respects (see *e g* Folkow Heymans and Neil 1963) the important defence reaction involving a widespread but differentiated sympathetic *excitation* while a generalized sympathetic *inhibition* is elicited from the mentioned depressor regions.

Defence area stimulation caused as much as a five-fold increase in skeletal muscle blood flow in the anesthetized, usually curarized animals. This flow increase often occurred in two steps with a fairly slight initial increase due to inhibition of vasoconstrictor fibre tone and a secondary usually far larger flow increase that was abolished by atropine (see also papers *III* and *IV*) As long as the adrenal medullae and their innervation were left intact the adrenaline release could somewhat prolong and occasionally even enhance the neurogenic muscle vasodilatation, as evidenced by its usually slight modification when the β-receptors of the muscle blood vessels had been blocked by administration of a β-adrenergic blocking drug In the majority of the experiments, however in which the adrenals had been denervated or eliminated to start with, the cardiovascular changes, including the muscle vasodilatation, were principally the same as when the adrenals were intact. This observation confirms earlier findings that the influence of circulating catecholamines is of fairly subordinate importance with respect to cardiovascular effector organs as compared with that of the direct nervous control, at least in the cat (Celander 1954 Mellander 1960) It was, on the other hand, noted that the cholinergic muscle vasodilation, though usually very intense to start with, was fairly transient even if prolonged stimulation of the defence area was performed. The

background of this "fading" effect of the cholinergic vasodilator fibres was separately studied in paper II (see below)

With respect to the central circulation, there was often a brief initial *decrease* in aortic flow at the onset of the defence area stimulation largely coinciding in time with a very prompt resistance increase in circuits like those of the skin, the kidneys and the intestines. This was made clear by some experiments where an electromagnetic flow meter was mounted on the arterial side of the mentioned vascular beds. An immediate vasoconstriction occurred in these circuits simultaneously with the initial, transient fall in aortic outflow (Lisander unpublished) and this vasoconstriction which could imply as much as a threefold increase in resistive load for the left ventricle, preceded the full onset of muscle vasodilatation by about 5—8 seconds. This sudden but transient resistive load, which seemed to be established even before the increased venous return and the neurogenic effect on the heart had become fully developed, probably explains the brief initial fall in left ventricular output. This fall might, however partly be due to relatively poor myocardial function, as it was seldom observed to any considerable extent in later experiments when more preparative skill was attained.

After this transient reduction and in phase with the onset of the muscle blood flow increase, cardiac output rose well beyond control and could at its peak increase twofold, coinciding with the maximal increase of muscle blood flow which could be fivefold. In this situation both stroke volume and heart rate were substantially increased and mean blood pressure was raised about 50 per cent. This means that total peripheral resistance fell by some 25—30 per cent despite the often extensive vasoconstriction in the skin, gastrointestinal tract and the kidneys. It also means that the left ventricle within a few seconds could be faced by roughly a threefold increase in work load, due to the twofold increase in output combined with the 50 per cent pressure increase. Central venous pressure could either rise or fall slightly but stroke volume increased independently compatible with a considerable inotropic effect on the heart of neurogenic origin. Apart from the somewhat larger increase in heart rate due to the decreased vagal influence on the heart, when the vagal nerves were intact, the response pattern was in principle the same after vagal section as long as one or both of the carotid baroreceptor areas were left intact.

However after administration of a β-adrenergic blocking drug (alprenolol Aptin® Hässle) the response pattern was changed in some functionally important respects. In animals with intact vagi there was still a slight

or moderate tachycardia but this was now entirely dependent upon an inhibition of prevailing vagal tone as it was absent after vagotomy. Cardiac output nevertheless rose to some extent as the result of an increase in stroke volume which was regularly related to a rise in central venous pressure. Evidently the stroke volume increase was in this situation partly or mainly a consequence of the Frank Starling relationship. Again, the substantial rise in central venous pressure, which was now seen, may be due to several factors. It is clear from other studies (*e.g.* Folkow, Mellander and Öberg 1961) that a considerable venoconstriction forms part of the defence reaction as does contraction of the spleen, both factors that *will enhance venous return. Moreover it is possible that the marked* cholinergic vasodilatation in the skeletal muscles might *per se* raise central venous pressure to some extent, in a similar manner as is seen upon opening of an artificial arteriovenous shunt. Whichever the case, in the intact animal such effects appear to be well balanced by the prompt onset of an increased sympathetic influence on the heart so that only slight shifts in central venous pressure occur in this situation.

It is of interest to note that for comparable excitations of the defence area the increase in the load on the left ventricle was reduced by approximately 50 per cent as a result of the β-adrenergic blockade on the heart. The increase of cardiac output *per se* was reduced to less than half of that present before the β-adrenergic blockade. This illustrates the extent that the central nervous drive on the heart directly contributes to the cardiac changes.

These effects of defence area activation should be compared with those produced by stimulation of the medullary depressor area and related hypothalamic structures, from which inhibition of sympathetic activity and activation of the vagal heart fibres is induced. Such stimulations were carried out on animals that were "curarized" and artificially ventilated, vagotomy was performed in the course of the experiments. As a rule the common carotid arteries were occluded during some of a series of central stimulations to create a high initial level of sympathetic activity.

When the depressor area stimulation was started, arterial blood pressure fell rather abruptly to begin with. Simultaneously muscle blood flow and cardiac output exhibited transient and usually slight *increases* that were both unaffected by atropine. Also heart rate, central venous pressure and total peripheral resistance fell during this phase. All these events must be ascribed to a generalized inhibition of sympathetic activity, the result of which becomes particularly striking with respect to muscle blood flow resistance since sympathetic constrictor fibre tone is usually most intense

in this vascular bed in the actual experimental situation (see e g Löfving 1961) For these reasons a sudden generalized inhibition of sympathetic tone can lead to such a drastic fall in flow resistance within the skeletal muscles that their blood flow *increases* transiently despite the concomitant fall in perfusion pressure. Simultaneously with this phasic muscle blood flow increase, cardiac output could exhibit a slight but transient increase, which, however was effectively curtailed when central venous pressure fell and the sympathetic inotropic effect was withdrawn Soon therefore, a gradual fall in output below control ensued which first after a minute or two of stimulation reached a stable and often very low level. Sometimes this fall in output could be further enhanced by tilting the animal with the hind legs down. An even more powerful influence in this respect, sometimes causing acute cardiovascular collapse, could be obtained by so adjusting the respiration pump as to increase intrathoracic pressure moderately Also bleeding, so small that it hardly influenced "resting blood pressure, was found to intensify the decrease in cardiac output caused by depressor area stimulation. All these maneuvers tend to reduce venous return and are normally compensated for by a reflexly increased sympathetic activity Due to the centrally induced sympathetic inhibition the animals were, however largely unable to perform such reflex compensation *for a peripheral pooling of blood.* — *The hypothalamic depressor (sympathoinhibitory)* area was stimulated instead of the bulbar one in a few experiments. The changes were essentially the same but usually less pronounced in extent.

In general, therefore, the influences on the central circulation caused by depressor area stimulation were in direction "mirror images" of those induced by defence area stimulations, while both exhibited a muscle vasodilatation which, however had a different background in the two situations.

The "escape" from the vasodilator fibre influence

In paper I was observed that increases in muscle blood flow and in cardiac output showed a close syncronicity during defence area stimulation, both tending to fade away despite continued hypothalamic stimulation. In paper II this "escape" of the muscle resistance vessels from the dilator fibre influence was subjected to further study

Irrespective of whether the cholinergic vasodilatation is elicited centrally or peripherally there is usually a rapid return of vascular resistance during continuous stimulation (Lindgren 1955 Folkow Mellander and Öberg 1961 Renkin and Rosell 1962 Dorr and Brody 1965 Bolme 1969) Some

of the possible mechanisms that might explain this escape seem to be *a priori* unlikely. Thus it cannot be due to compensatory reflexes in the isolated vascular bed studied as it occurs also when the cut sympathetic trunks are stimulated directly. Furthermore, it appears to take place irrespective of the method used for elimination of the vasoconstrictor fibre influence and can therefore hardly be ascribed e.g. to insufficient α-receptor blockade. Neither is it likely to be due to smooth muscle tachyphylaxis to acetylcholine since prolonged infusion of this agent results in a fairly sustained vasodilatation (see *e.g.* Mellander and Johansson 1968). Moreover, the escape can hardly be ascribed to transmitter depletion at the nerve endings because acetylcholine can be detected in considerable amounts in eserinized perfusates even after several minutes of sympathetic stimulation (Folkow, Haeger and Uvnäs 1948). Lastly, local damage to the stimulated sympathetic nerves seems to be ruled out, first by the fact that well sustained vasoconstrictions are obtained by the same type of stimulation when no α-adrenergic blocking drugs are given and, second, by the fact that an escape takes place also when a cholinergic dilatation is elicited by hypothalamic stimulation.

In the present experiments, direct stimulation of the lumbar sympathetic chain was utilized in order to minimize the number of neuronal links involved. Further, the ability of the denervated vascular bed to autoregulate flow in the face of altered perfusion pressure was assessed by changing the arterial inflow pressure in a stepwise fashion. In this way the "reactivity" of the smooth muscle in the resistance vessels could be repeatedly tested. Thus, when perfusion pressure was suddenly returned to control after a brief and moderate lowering there was normally a brisk but transient reactive hyperemia, revealing the extent of the compensatory vascular relaxation that had taken place during the pressure reduction. However, it was observed that whenever normal blood flow autoregulation was impaired, the escape from sympathetic vasodilator fibre influence was less pronounced too. These two phenomena were so closely correlated as to strongly suggest that the escape phenomenon is simply due to a local myogenic response.

Measurements of the capillary filtration coefficient (CFC), reflecting the responses of the precapillary sphincter sections, were therefore performed to clarify where within the muscle vascular circuit such a local counterregulation occurred. To allow for CFC measurements at the peak of the neurogenic vasodilatation, it was as a rule necessary to prolong the dilator response somewhat, which could usually be achieved by large administrations of phentolamine. This drug, when given, in doses supra

maximal for constrictor fibre blockade, directly to the vascular bed of the calf muscles, often proved to decrease markedly both flow autoregulation to pressure changes and the escape from the dilator fibre influence, without causing too drastic reductions in the tone of the resistance vessels and precapillary sphincters in the "resting" state. It remains unclear by what mechanism phentolamine acts in this respect. It was in any case not related to its blocking effect on the adrenergic constrictor fibres, as this was already achieved by the combined use of guanethidine and substantially smaller doses phentolamine. The completeness of the blockade of the α-receptors could be checked by supramaximal sympathetic stimulation after atropine administration. The large doses of phentolamine sometimes appeared to reduce smooth muscle reactivity in the resistance vessels to such an extent that autoregulation of flow was completely absent in some experiments, in which cases well sustained neurogenic vasodilatations could be induced during stimulation periods lasting 10 minutes or more.

CFC was found to *decrease* somewhat during the neurogenic vasodilatation. This is in contrast to the results obtained when acetylcholine was infused intraarterially when CFC increased along with the flow increase. However as soon as an escape from the dilator fibre influence occurred, CFC again returned towards control, in phase with the escape. Had a compensatory contraction of the precapillary sphincter sections been responsible for the escape, CFC would have become *reduced* in phase with, and in proportion to the escape. It further seems excluded that the escape occurs in postcapillary vessels since this would have led to a *rise* in capillary pressure during the escape, which certainly was not the case. Moreover veins in general exhibit only little myogenic automaticity (see e g Ljung 1970) and do not display any significant autoregulation to e.g. pressure changes (Folkow and Öberg 1961) Hence, by exclusion, the myogenic counterregulation responsible for the escape phenomenon must occur in essentially the same parts of the precapillary vessels where the *dilator fibres exert their action (see Introduction)*.

Based on these findings, the hypothesis was put forward that the sympathetic vasodilator fibres act by inhibiting the activity of only a limited number of precapillary smooth muscle cells along the precapillary resistance vessels that act either as "pacemakers" for the establishment of precapillary myogenic tone or/and are of importance for the upstream myogenic propagation of the pacemaker activity to the largest precapillary resistance vessels. Such a type of restricted dilator fibre action would be somewhat analogous to the vagal influence on the heart, which is obviously very efficient despite a vagal fibre distribution that is mainly

limited to a few key points in the myocardium. A profound and widespread dilatation of the precapillary resistance vessels would thus be possible by depriving those resistance vessels that are placed upstream to the pacemaker regions of the myogenically propagated excitation. Just as the heart may escape from a vagal inhibitory influence, an escape would also easily occur in the resistance vessels when their reactivity is pronounced, then induced from normally silent "ectopic" pacemakers located in such vascular sections that are not directly affected by the dilator fibres.

Interaction between the defence reaction and baroreceptor reflexes.

A defence area stimulation practically always elicits a prompt increase both in mean arterial pressure and in pulse pressure. The question then arises if and to what extent, the baroreceptor reflexes counteract the hypothalamically induced changes. Hilton (1963 1965) measuring blood pressure and heart rate in cats, found that a carotid sinus distension which normally caused marked bradycardia and blood pressure fall had no such effects when the defence area was stimulated simultaneously He concluded that the baroreceptor reflexes suffer a temporary abrogation during the defence reaction. On the other hand, in paper I it was observed that the blood pressure rise caused by a standardized defence area stimulation was almost the same after β-adrenergic blockade. Since the cardiac output increase was now considerably smaller total flow resistance must, in return, have contributed relatively more to the pressure rise, suggesting a reflex modulation. Moreover some earlier studies also indicate that the systemic vessels also during defence reactions can be affected by the baroreceptor reflexes (e.g. Feigl Johansson and Löving 1964 Folkow Öberg and Rubinstein 1964). These results together suggest the possibility of a modified operation of the baroreceptor reflexes during the defence reaction and this problem was further elucidated in III and IV

Experiments with standardized defence area stimulations were carried out where the animals had one carotid sinus prepared according to Moussejeff (1926) while other baroreceptor stations were excluded Blood flow was recorded in muscle, skin or intestine, together with heart rate and blood pressure. The conclusions drawn were as follows: If a baroreceptor reflex was elicited alone there was, as expected a fall in blood pressure and heart rate combined with systemic vasodilatation. If however a defence area stimulation was performed simultaneously the reflex inhibitory effects on the heart were almost completely suppressed, while those on the peripheral vascular beds were about the same as before. As

far as the muscle vessels were concerned, the conditions were here particularly complex. As earlier found by Folkow, Öberg and Rubinstein (1964) vasoconstrictor fibre tone had to be more or less eliminated before the cholinergic vasodilatation could be fully developed. This was achieved by means of a baroreceptor reflex inhibition of prevailing vasoconstrictor fibre activity initiated by the rise in mean and pulse pressures as a result of the defence reaction. Such a mechanism is quite effective because the vasoconstrictor fibres to the muscle resistance vessels do not appear to be significantly activated from the defence area directly.

In other experiments standardized defence area stimulations and baroreceptor fibre stimulations were matched against each other. In still other experiments the defence area stimulations were performed with and without the baroreceptors being activated in the normal way by the ensuing pressure rise. Broadly speaking, these results too suggested that the baroreceptor reflex effect on the heart was almost completely suppressed by the defence reaction, even when the vagal heart fibres had been left intact, in agreement with Hilton's results (1963, 1965), whereas the reflex modulation of the peripheral vascular beds remained largely unhampered. In other words, there appeared to be a *differentiated* interaction between the excitatory defence reaction and the secondarily involved inhibitory baroreceptor reflexes, where only the reflex inhibitory influence on the heart was suppressed centrally by the defence reaction. The consequences of this differentiated interaction on the cardiac output and the work load of the left ventricle were further explored in a preparation where aortic blood flow was also measured by means of an electromagnetic flowmeter applied around the aortic root (paper V). From these experiments it became evident that the efficiency of the heart as an "output pump" during a defence reaction was clearly *improved* by the action of the baroreceptor reflexes. Depending mainly on the intensity of the defence area stimulation a standardized activation of these reflexes could either decrease the load on the heart for a given cardiac output, or increase the output for a given load on the heart. It was further confirmed that the reflex inhibition of constrictor fibre tone to the muscle resistance vessels was a prerequisite for an efficient vasodilator fibre influence, at least in the cat. Therefore, the secondary involvement of the baroreceptor reflexes had also the important consequence that it helped to direct the major part of the output increase to the skeletal muscles.

In summary, the net hemodynamic result of the differentiated interaction between the defence reaction and the baroreceptor reflex was an undiminished central drive on the heart, while the vascular bed was still

reflexly modified. For such reasons a larger cardiac output could be achieved from a given drive and load on the heart and in such a way that the blood supply of the skeletal muscles was preferentially favoured.

Cerebellar modification of the defence reaction.

As it was found in IV and V that the differentiated interaction between the excitatory defence reaction and the inhibitory baroreceptor reflexes actually led to improved haemodynamic effects of the defence reaction, it was explored whether some other inhibitory influence might exert an overall suppressing effect on the defence reaction. It is known that cerebellar cortical stimulation can reduce the reflex responses induced by modulations of the baroreceptor activity (Moruzzi 1940), while cerebellectomy seems to exert opposite effects (Reis and Cuénod 1965) neither procedure influencing "resting" blood pressure significantly Furthermore sham rage, which can be induced by even trivial stimuli in the decorticate cat, can be inhibited both by cerebellar stimulation (Moruzzi 1947) and by baroreceptor activation (Bartorelli *et al* 1960)

For such reasons a series of experiments were performed in order to explore if and then in what way the cardiovascular components of the defence reaction induced by hypothalamic stimulation, were influenced by stimulation in the cortex of the anterior cerebellar lobe. The preparation was largely the same as in IV except for arrangements for topical cerebellar stimulation. Besides, in some experiments cross circulation of the skeletal muscle vascular bed was performed where adrenergic blockers could be given intra arterially to the cross-circulated calf muscle vascular bed.

Cerebellar stimulation, which alone had only insignificant cardiovascular effects, proved to reduce the increase in heart rate and in blood pressure as well as the muscle blood flow augmentation as elicited by defence area stimulation The interest was focused mainly upon the cerebellar suppression of the muscle vasodilatation. This phenomenon could *a priori* be due to a decreased activation of the cholinergic vasodilator fibres or to an impeded reflex inhibition of constrictor fibre tone in this vascular bed, which, as mentioned, seems to be a prerequisite for the full development of the cholinergic dilatation.

There was no evidence of any muscle vasoconstrictor fibre activation that could be ascribed to the cerebellar stimulation and which could have masked the vasodilatator fibre impact. On the other hand, the concomitantly decreased augmentation of mean arterial pressure and pulse pressure must imply a reduced stimulus for the baroreceptors. It therefore seemed

possible that the less pronounced pressure changes, induced by combined defence area and cerebellar stimulation, could cause a reduced reflex inhibition of vasoconstrictor fibre tone and for that reason lead to a decreased cholinergic dilatation. From experiments where baroreceptor activity could be "stabilized" it was, however evident that such a mechanism played no significant role for the decreased muscle vasodilatation.

The possibility remained, however that the reflex effect of a given baroreceptor activation might be diminished by the cerebellar stimulation. If so, the incomplete inhibition of vasoconstrictor fibre tone might have interfered with the cholinergic vasodilatation. In order to definitely exclude any involvement of adrenergically mediated phenomena in the cerebellar suppression of the muscle vasodilatation, the adrenergic system was *pharmacologically blocked, the vagi cut and the adrenals* eliminated in a series of experiments. Even under these conditions, however the atropine-sensitive muscle vasodilatation induced by defence area stimulation was markedly reduced by a concomitant cerebellar stimulation. Hence, the cerebellar suppression of the muscle vasodilatation involves a considerable suppression of the cholinergic vasodilator fibre activity *per se* Baroreceptor activation, on the other hand, had no such effects. Thus, when a cross-circulated calf region had been adrenergically blocked, even strong activations of the baroreceptors did not interfere with the vasodilator fibre influence evoked by hypothalamic stimulation.

To summarize, while the inhibitory baroreceptor reflex and the defence reaction by their differentiated interaction work in "haemodynamic synergism" (see III and IV) the cortex of the anterior cerebellar lobe appears to suppress in a generalized way the defence reaction by inhibiting essentially all its cardiovascular components, including the activation of the cholinergic vasodilator fibres.

General Discussion

Smooth muscle tone of the skeletal muscle vascular bed is determined predominantly by local myogenic mechanisms, as modified mainly by vasoconstrictor nerve activity The balance between these two factors varies, however considerably in the different series-coupled vascular sections. Further while the adrenergic vasoconstrictor fibres reach more or less all vascular sections where smooth muscle is present, the cholinergic vasodilator nerve endings seem to be confined only to the larger precapil lary resistance vessels of skeletal muscle (for ref see Mellander and Johansson 1968) The vasoconstrictor nerves, which in contrast to the vasodilator ones are tonically active, appear to affect the venous capacitance vessels and the larger precapillary resistance vessels to a relatively more dominating extent than is the case with the precapillary sphincter sections, even though adrenergic fibres can be traced in these sections too

In agreement with such findings in the muscle vascular circuit, microscopic observations concerning other vascular beds indicate that, following sympathectomy vascular tone is best retained in the immediate precapil lary sections (for ref see Wiedeman 1963) A recent study where intravital microscopy was combined with direct recordings of blood flow in skeletal muscle of the cat agrees with these findings (Eriksson and Lisander 1969) indicating also that the vasoconstrictor fibre impact is especially marked in somewhat larger precapillarly vessels with diameters that are about 50 microns in the denervated "resting" state.

Thus, sympathetic denervation leads to a considerable reduction in tone particularly in that variety of vascular smooth muscle that, according to Bozler's (1948) terminology may be called multi unit" type (mainly veins and larger arteries) whereas a considerable tone remains in the "single-unit" type of smooth muscle (mainly in arterioles, precapillary sphincters, in some venular sections and in the portal vein) In the latter type of muscle a "basal tone" seems to be generated by myogenically active "pacemaker" cells from which the activity is propagated in a cell to-cell fashion to myogenically less active regions largely in a similar way as impulse generation and propagation occurs in the heart. Thus, pacemaker activity seems to be especially well developed in vascular sections adjacent to the proximal end of the capillaries, from which it may be myogenically propagated

upstream with chances for fusion of activities where vascular branches meet. If so such a functional arrangement could explain the more steady tone in larger precapillary vessels (Folkow 1964) and also the occurrence of ascending dilatation in such vessels when e.g. vasodilator metabolites have suppressed pacemaker activity in more peripheral branches.

As to the detailed arrangement of the nervous supply to the muscle vessels, the adrenergic nerve terminals seem to be arranged in a two-dimensional plexus that does not penetrate the media but makes direct contact only with its adventitial layer (*e.g.* Bolme and Fuxe 1970). Recent *in vitro* studies of a "model" of single unit type of vascular smooth muscle (portal vein) indicate that the relatively sparse supply of adrenergic terminals in such vessels nevertheless allow for a very efficient nervous control. The reason is that the direct nervous influence, though exerted on only a fraction of the smooth muscle cells, by means of myogenic cell-to-cell propagation to non-innervated muscle cells "recruits" virtually the entire media to participate in the neurogenically induced activation (see Ljung 1970). It seems likely that a similar organization exists in the haemodynamically important precapillary resistance vessels.

As to the sympathetic cholinergic vasodilator fibres, haemodynamic experiments, briefly outlined in the introduction, indicate that they exert their action by dilating mainly or only the larger precapillary resistance vessels with no direct influence on *e.g.* the precapillary sphincter sections or on the postcapillary vessels. The experimental results presented in II lend further support to this view. Thus, the fall in blood flow resistance induced by activation of these fibres was accompanied by a constriction of the precapillary sphincter sections, as judged by a decrease in CFC. This latter response should probably be ascribed to a myogenic counter-regulation triggered by the neurogenically induced flow increase and the consequent rise in local transmural pressure. The evidently secondary nature of this oppositely directed response in the precapillary sphincter sections may explain some earlier observations where the diffusion events have been continuously followed during activation of the cholinergic vasodilator fibres. In the very earliest phase of the neurogenic dilatation there is evidence of an improved capillary exchange (Barlow and Walder 1965, Bolme and Edwall 1970), but it becomes reduced below the resting value during more prolonged dilator fibre activations (Rosell and Uvnäs 1962). Further evidence against any direct effect on the size of the perfused capillary surface area by the cholinergic dilator fibres is given by the fact that the ^{86}Rb clearance remains largely unchanged during dilator fibre activation if blood flow is kept constant throughout (Renkin and Rosell

1962) As a contrast to this evidently restricted effect of the cholinergic dilator fibres, infused acetylcholine increased both the blood flow and the number of perfused capillaries (II) in agreement with several other studies (see Mellander and Johansson 1968)

Recent morphological studies have further supported this view concerning a restricted dilator fibre impact as indicated by the mentioned physiological studies. Thus, in cat skeletal muscle the cholinergic sympathetic nerve endings, which like the adrenergic ones appear to be confined to the border between the media and the adventitia, are largely restricted to arteriolar vessels with diameters of 30—100 μ in contrast to the widespread supply of adrenergic fibres (Bolme and Fuxe 1969) Further the density of their terminals appeared to be considerably lower than that of the adrenergic nerves, also in the mentioned vascular sections.

Despite their evidently sparse and restricted distribution, the dilator fibres are nevertheless able to produce an almost maximal reduction of flow resistance in skeletal muscle at least in certain favourable situations (see *e g* Folkow Mellander and Uberg 1961) suggesting an impressive and widespread effect on virtually all the precapillary resistance vessels. This may be accomplished in two principally different ways Either the diffusion of transmitter is so extensive that almost all smooth muscle cells along the vascular arborization are reached, or the restricted supply of dilator fibres is concentrated to such smooth muscle sections that are particularly important for the establishment of myogenic vascular tone, *i.e* on pacemaker cells or/and on key points for the myogenic propagation of pacemaker activity

The first alternative seems highly unlikely both because the cholinergic transmitter is generally most efficiently destroyed at the site of release and, should it have a chance to diffuse away it would like the adrenergic transmitter (see Ljung 1970) become so rapidly diluted that it would probably be able to influence only closely adjacent muscle cells. In this particular case the transmitter would by diffusion have to also reach also larger precapillary resistance vessels situated several millimeters upstream from the site of release.

As to the other possibility *i.e* that the dilator fibres primarily interfere only with pacemaker cells or/and with some restricted key points for the myogenic spread of excitation from the pacemakers, such an explanation seems to best fit both the present and most earlier findings. Such a neurogenic suppression of the precapillary myogenic activity at, or near its normal source of origin would deprive more proximal vascular sections of their excitation. However in case usually silent "ectopic" pacemakers

upstream with chances for fusion of activities where vascular branches meet. If so such a functional arrangement could explain the more steady tone in larger precapillary vessels (Folkow 1964) and also the occurrence of ascending dilatation in such vessels when e.g vasodilator metabolites have suppressed pacemaker activity in more peripheral branches.

As to the detailed arrangement of the nervous supply to the muscle vessels, the adrenergic nerve terminals seem to be arranged in a two-dimensional plexus that does not penetrate the media but makes direct contact only with its adventitial layer (*e g* Bolme and Fuxe 1970) Recent *in vitro* studies of a "model" of single unit type of vascular smooth muscle (portal vein) indicate that the relatively sparse supply of adrenergic terminals in such vessels nevertheless allow for a very efficient nervous control. The reason is that the direct nervous influence, though exerted on only a fraction of the smooth muscle cells, by means of myogenic cell to-cell propagation to non innervated muscle cells "recruits" virtually the entire media to participate in the neurogenically induced activation (see Ljung 1970) It seems likely that a similar organization exists in the haemodynamically important precapillary resistance vessels.

As to the sympathetic cholinergic vasodilator fibres, haemodynamic experiments, briefly outlined in the introduction, indicate that they exert their action by dilating mainly or only the larger precapillary resistance vessels with no direct influence on *e g* the precapillary sphincter sections or on the postcapillary vessels. The experimental results presented in II lend further support to this view Thus, the fall in blood flow resistance induced by activation of these fibres was accompanied by a constriction of the precapillary sphincter sections, as judged by a decrease in CFC. This latter response should probably be ascribed to a myogenic counter regulation, triggered by the neurogenically induced flow increase and the consequent rise in local transmural pressure. The evidently secondary nature of this oppositely directed response in the precapillary sphincter sections may explain some earlier observations where the diffusion events have been continuously followed during activation of the cholinergic vasodilator fibres. In the very earliest phase of the neurogenic dilatation there is evidence of an improved capillary exchange (Barlow and Walder 1965 Bolme and Edwall 1970) but it becomes reduced below the resting value during more prolonged dilator fibre activations (Rosell and Uvnas 1962) Further evidence against any direct effect on the size of the perfused capillary surface area by the cholinergic dilator fibres is given by the fact that the ^{86}Rb clearance remains largely unchanged during dilator fibre activation if blood flow is kept constant throughout (Renkin and Rosell

fibre stimulation, it is not surprising that the cholinergic vasodilator fibres have never been shown to exert any *tonic* influence upon the cardiovascular system even in situations of *e g* sustained alarm etc. (see Uvnas 1960) Because of the escape phenomenon, an intermittent dilator fibre activity or a sudden increase of such activity would be needed to reveal any clearcut vascular effect. Conversely a prevailing tonic activity in the dilator fibres would hardly be revealed by such procedures as nerve section, atropinization or administration of eserine, again, due to the normally efficient escape phenomenon.

Thus, in several respects the sympathetic vasodilator fibres pose many interesting questions and their study has led to a greatly improved knowledge not only concerning the important cardiovascular changes taking place in alarm situations but has also helped to clarify intricate problems concerning precapillary vascular control It is then somewhat ironic that many species, perhaps including man, have a poor supply of these interesting fibres or even lack them entirely It has, however been suggested that such species, which nevertheless seem to display a characteristic and efficient defence reaction with increased muscle blood flow may do so by inhibiting the vasoconstrictor fibre tone in this vascular bed often reinforced by blood borne adrenaline and possibly facilitated by the presence of a relatively low myogenic tone in the muscle resistance vessels. Actually in case the adrenergically controlled vascular smooth muscle cells are in part responsible also for the generation in myogenic tone in such cases, pacemaker activity might be brought to a temporary quiescence by the sudden withdrawal of excitatory nervous impulses. Such a hypothetical mechanism would, in fact, haemodynamically function in a similar way as the vasodilator fibres do in species where the myogenic precapillary tone is pronounced in the skeletal muscles, as in the cat and the dog. However little is known about these problems but quantitative studies of muscle blood supply during alarm situations in species lacking sympathetic dilator fibres may be of considerable interest, considering the biological importance of the defence reaction.

According to Löfving (1961) depressor responses elicited from the cingulate gyrus and the hypothalamic sympathico-inhibitory area might be involved in emotional fainting in man and in the "playing dead" reactions of some animal species. Those structures, in turn, project upon the medullary depressor area from which a general inhibition of sympathetic tone is elicited (Löfving 1961 Porszasz 1964 Porszasz-Gibitzer 1965) In general agreement with these findings, inhibition of sympathetic tone appeared to be solely responsible for the

increase in muscle blood flow that took place initially when the medullary depressor area was stimulated (I) This flow increase could transiently even surpass that seen after sympathectomy which is seemingly suggestive of an active dilatation but it was completely unaffected by atropine. Further in the cross circulation experiments described in V in which the defence area was to be stimulated, the nearby hypothalamic sympathoinhibitory area was occasionally activated separately on insertion of the needle electrodes. This led to a depressor response in the recipient, but no vasodilatation was seen in its cross circulated calf muscles after that adrenergic blockers had been given to this vascular bed (Lisander and Martner unpublished)

Initial increases in muscle blood flow have been observed in man during fainting by Barcroft and Edholm (1945) and it was by them suggested that it might be due to an activation of cholinergic sympathetic vasodilator fibres in connection with the fainting response. Furthermore, it has been proposed that muscle vasodilator responses conveyed by the medullary depressor area have an active component, mediated by histaminergic vasodilator fibres in the sympathetic trunks (Beck 1961) In general, transient outflows of muscle flow beyond that present after acute sympathectomy have often been considered as strong evidence of vasodilator fibre activation. It is beyond the scope of the present survey to discuss at length the evidence for or against these views. It should, however be stressed that the muscle vasodilatations, seen upon depressor area stimulation or baroreceptor activation, were completely unaffected by atropine but were abolished in cross-circulated calf muscles after regional administration of adrenergic blockers. It is, moreover frequently seen that a sudden interruption of constrictor fibre activity is followed by a transient "reactive hyperaemic response, a type of reactive hyperaemia, simply as a result of the previous neurogenic flow restriction The fact that such transient dilatations can be abolished or reduced by antihistaminics (Beck 1961 1965) might after all be due to unspecific actions of the drugs used in analogy of the phentolamine effects described in II Doses of the latter drug, which exceeded those required for complete α adrenergic blockade, were sometimes found to abolish reactive hyperaemia by interfering with smooth muscle "reactivity Such an unspecific interference with phenomena like automaticity and myogenic propagation in blood vessels may well be exerted by several drugs it is, for instance, seen after administration of quinidine and urethane (Lisander unpublished)

Except for the initial increase in muscle blood flow the defence reaction and the depressor response are opposite to each other in virtually all re-

spects (see Introduction) The defence reaction comprises an increased discharge in virtually all adrenergic fibres, with exception of those to the muscle resistance vessels, where instead the cholinergic vasodilator fibres are activated, as combined with a central suppression of the vagal activity to the heart. The depressor response, on the other hand, consists of a generalized inhibition of sympathetic adrenergic fibre activity as combined with an increase in vagal tone to the heart.

Also the changes in cardiac output caused by these two centrally induced response patterns are each other s contrasts, to the extent that they are al most mirror images as described in I. Upon defence area stimulation a shortlasting fall in cardiac output preceded the often pronounced rise that characterizes this excitatory response pattern. Depressor area stimulation, on the other hand, led to an initial brief increase in output which was followed by an often profound reduction. The shortlasting initial fall in cardiac output observed upon defence area stimulation was synchroneous with the prompt vasoconstriction in several important vascular beds preceding the slightly delayed muscle vasodilatation. The heart is able to expel the same, or nearly the same, stroke volume against a wide range of resistances, due to the heterometric and homeometric autoregulation mechanisms (the Frank Starling effect and the Anrep effect, respectively see Sarnoff and Mitchell 1962) Both mechanisms may be expected to be involved after a sudden rise in peripheral resistance, the homeometric autoregulation, however first after a somewhat longer interval. During defence area stimulation there is, in addition, the increased sympathetic inotropic and chronotropic influence on the heart which is powerful and rapidly established (Rosén 1961) Under conditions of high inotropy in the myocardium a sudden rise in aortic resistance may cause a transient fall in output lasting a few beats, followed by a rise beyond the initial value, at an increased diastolic left ventricular volume (Bugge-Asperheim and Kiil 1969).

At the peak of the muscle vasodilatation, total systemic resistance returned to or below the resting value, with a maintained neurogenic drive on the heart. In addition to this direct excitatory influence on the myocardium, an increased venous return adds to the situation and is indeed a prerequisite for maintaining the output at a high level. Here the constriction of the spleen and of the systemic (Folkow Mellander and Öberg 1961) as well as of pulmonary capacitance vessels (Anderson and Brown 1967) are of importance, the former illustrated in the present experiments by the considerable rise in right atrial pressure seen when the defence area was stimulated following β-adrenergic blockade.

Observations on the control of cardiac output as exerted by cortico-hypothalamic structures are fairly scarce in the literature especially when compared to the amount of studies concerned with the central control of other facets of the circulation. Rushmer and Smith (1959) found that cardiac and peripheral circulatory changes mimicking those during exercise could be induced by stimulation in the fields of Forel in the diencephalon of the dog structures which seem to correspond to the defence area and/or its projections in the cat. Further the present finding (I) that cardiac output rises during defence area stimulation in the cat has been independently made by Anderson and Brown (1967)

The results obtained in III and IV suggest a differentiated interaction between the excitatory hypothalamic defence reaction and the inhibitory baroreceptor reflexes, with a selective suppression of the inhibitory reflex influence on the heart while the reflex modulation of vasoconstrictor fibre activity was little, if at all, affected. Contributing to this differentiated interaction, the different shapes of the hyperbolic frequency response curves, characterizing the neuro-effectors of the various cardiovascular compartments, may in some situations help to reinforce the differentiated influence by a peripheral action. Thus, the curves characterizing the adrenergic control of the heart and the capacitance vessels are decidedly more steeply hyperbolic than those of most resistance vessels (Folkow Löfving and Mellander 1956 Mellander 1960) If for example, a very intense vasoconstrictor fibre discharge is induced from the defence area and this is moderately inhibited to a uniform extent by the baroreceptor reflex, this reflex modulation will substantially damp the centrally induced constriction of the resistance vessels but hardly that of the capacitance vessels. The reason is that the reflex discharge modulation will in this latter case still be operating largely on the horizontal "plateau" level of the markedly hyperbolic frequency response curve characterizing the capacitance vessels. Such differences as to the frequency response curves must, incidently be of great importance for the efficient mobilization of the capacitance vessels for priming the heart and for the neurogenic activation of the heart as well. The particularly steep frequency response curves, which characterize the adrenergic control of both these cardiovascular compartments, will help to keep the heart well filled and also to keep the myocardium at an almost maximal degree of inotropy even in situations where the centrally induced sympathetic discharge is as moderate as 4—5 impulses/sec.

It is, however clear that the differentiated interaction between the defence reaction and the baroreceptor reflexes does not depend only on

peripheral factors such as the mentioned differences in the neuroeffector characteristics. It also involves a true nervous "occlusion" of the reflex cardiac control at some central level. It would otherwise be difficult to explain e g the virtual absence of any baroreceptor reflex activation of vagal heart fibres during the defence area stimulations. These results confirm those of Hilton (1963 1965) and are also in agreement with the recent findings of Gebber and Snyder (1970) Both these groups found that vagal bradycardia induced by baroreceptor activation was completely inhibited by hypothalamic stimulation Gebber and Snyder noted, in addition, that the baroreceptor modulation of the sympathetic outflow was still efficient during hypothalamic stimulation, in agreement with the present results concerning the blood vessels. They also recorded action potentials in the external branch of the superior cervical ganglion, the inferior cardiac branch of the stellate ganglion and in the splanchnic nerve. Hypothalamic stimulation caused a rise in activity in these nerves which was partially reduced by superimposed baroreceptor activation.

Hilton (1963 1965) recording only blood pressure and heart rate, found that carotid sinus distensions that under resting conditions caused a marked blood pressure fall and bradycardia had no detectable effects when performed during defence area stimulation, not even on the blood pressure. In this latter respect there is an apparent discrepancy between Hilton's data and those presented in III and IV It may however be explained by the fact that the baroreceptor activation described in IV did sometimes not reduce the pressure rise but could instead further enhance aortic blood flow particularly if the defence area stimulation was very pronounced. If only blood pressure and heart rate had been recorded in such experiments the mentioned baroreceptor reflex influence on the vascular bed would have passed unnoticed.

Since the baroreceptor reflexes do not interfere with the discharge of the cholinergic dilator fibres, but may instead greatly favour their impact on the muscle resistance vessels by inhibiting prevailing constrictor fibre activity these reflexes have also the important consequence that they particularly favour the blood supply to the skeletal muscles with respect to the *distribution* of the increased cardiac output. Haemodynamically therefore, the defence reaction and the baroreceptor reflexes may be said to act in synergism with respect to creating an appropriate enhancement of the nutritional supply during emergency situations at reasonable metabolic costs for the heart.

The inhibitory influence that can be elicited from the cerebellar cortex, on the other hand, was shown to interact with the defence reaction in a

principally different way by exerting an *overall* inhibitory influence, thus including the discharge of the cholinergic vasodilator fibres as well. For example, after complete pharmacological blockade of all adrenergic effects on the cardiovascular system defence area stimulation caused a marked, atropine-sensitive muscle vasodilatation and this dilatation could be considerably reduced by a concomitant cerebellar stimulation. No other type of neurogenic influence that specifically inhibits sympathetic vasodilator fibre activity appears to be known at present.

The only corticofugal neurons of the cerebellum emanate from the Purkinje cells and they convey only inhibitory impulses. Nevertheless, cerebellar cortical stimulation may cause not only inhibitory but also excitatory responses in the cerebellar nuclei and the nucleus of Deiters. These excitatory effects seem to be due to antidromic activation of afferent neurons which by means of collaterals reach both the cerebellar cortex and the mentioned nuclei (see Eccles, Ito and Szentágothai 1967) Hence, the studied cerebellar inhibition of the defence reaction may have been caused either by stimulation of Purkinje fibres or by antidromic activation of the mentioned afferents. It is, on the basis of the present experiments alone, impossible to exclude any of these alternatives as a possible mechanism for the inhibition of the defence reaction. One appealing possibility is, however that this effect is due to excitation of true Purkinje fibres exerting an inhibitory influence on cells in the fastigial nucleus, which, in turn, exert a tonic excitatory influence directly or indirectly on the hypothalamic defence area. It is, for example, known that sham rage can be facilitated by stimulation of the fastigial nucleus (Zanchetti and Zoccolini 1954) and other findings suggest that some of its neurons may have a tonic activity This cerebellar nucleus is further known to project upon the brain stem reticular formation (for ref see Eccles, Ito and Szentágothai 1967) According to Lindgren (1955) the descending axons from the neurons comprising the defence area, at least those controlling the vasodilator fibres, have synaptic relays in the mesencephalon and in the spinal cord. It is not unlikely that the cerebellar inhibitory action on the defence reaction is exerted on more than one of these three neuronal stations.

It has been reported that distension of the carotid sinus may inhibit sham rage in decorticate cats (Bartorelli *et al* 1960) It was therefore investigated whether baroreceptor reflexes exerted any direct inhibitory influence on the sympathetic vasodilator fibre connections when these are activated by topical stimulation of the hypothalamic defence area. However no such action could be found which emphasizes the suggestion

that the baroreceptor reflexes act in haemodynamic synergism with the cardiovascular defence reaction when they are secondarily excited in the natural way by the blood pressure rise (see III and IV) Thus, although both baroreceptor reflexes and cerebellar cortical stimulation may inhibit sham rage, only cerebellar stimulation interferes with the dilator fibre discharge, as elicited by topical stimulation of the hypothalamic defence area. The reason may be that the inhibitory influence of baroreceptor activation upon the sham rage response has its impact e.g on ascending pathways necessary for the activation of the hypothalamic defence area, which in the present experiments was directly activated.

Summary

1 Myogenic, reflex and central nervous modifications of the hypothalamically induced defence reaction have been analyzed in cats and dogs.
2 The effects of the defence reaction on the central circulation were explored, in comparison to the effects of an opposite type of centrally elicited response, the depressor reaction

Defence area stimulation induced up to twofold increases in cardiac output and about threefold increases in calculated work load for the left ventricle. β-adrenergic blockade could reduce this increase in left ventricular work load by almost 50 per cent. In skeletal muscle, active cholinergic vasodilatation increased flow up to fivefold whereas gastrointestinal renal and cutaneous blood flows were promptly reduced. Since these neurogenic flow reductions slightly preceded the muscle vasodilatation, the cardiac output increase could be preceded by a very brief phase of decrease.

Depressor area stimulation produced an often profound reduction in cardiac output, sometimes preceded by a brief increase. Flow resistance fell, especially in skeletal muscles, where an initial flow increase coincided with the transient increase in cardiac output- further there was a pooling of blood in the capacitance section. All these vascular effects appeared to be due to inhibition of vasoconstrictor fibre tone only Blood loss or raised venous transmural pressure greatly potentiated these effects of depressor area stimulation to the extent that acute cardiovascular collapse could ensue.

3 The cholinergic muscle vasodilatation, whether elicited centrally or peripherally tended to fade away rapidly despite continued dilator fibre stimulation. However this "escape" took place only when vascular smooth muscle reactivity" was pronounced, otherwise, sustained neurogenic vasodilatation could be obtained. Precapillary sphincter activity was secondarily increased as a result of the neurogenically reduced flow resistance, but returned to control when the escape developed, suggesting that this phenomenon takes place upstream to the sphincter sections of the precapillary vessels. A hypothesis was put forward that the cholinergic vasodilator fibres have a very restricted site of action, suppressing only "pacemaker" smooth muscle cells and/or key sites for the upstream myo-

genic propagation from such pacemakers. A neurogenic inhibitory influence at such sites would lead to widespread dilatation upstreams, but escape would ensue whenever latent pacemakers in these nonninnervated proximal sections of the resistance vessels become active, thus reestablishing myogenic tone.

4 The interaction between the hypothalamic defence reaction and the homeostatic baroreceptor reflexes was explored with respect to cardiac as well as to vascular effects. The results suggest that defence area stimulation suppresses the baroreceptor reflex inhibition of the heart while that influencing vasoconstrictor fibre discharge remains largely the same. As one of the consequences, skeletal muscle blood supply could be considerably enhanced since the reflex inhibition of regional constrictor fibre tone greatly facilitated the impact of the cholinergic vasodilator fibres. As to cardiac performance, the differentiated interaction between the defence area and the baroreceptor reflexes enabled the heart to deliver a given output at a lower load, or conversely a higher output for a given load on the left ventricle. Thus, the baroreceptor reflexes, rather than damping the defence reaction may be said to act in "haemodynamic synergism" with this central excitatory response, thanks to the mentioned differentiated interaction.

5 Cerebellar cortical stimulation, on the other hand, interacted with the hypothalamically induced defence reaction in quite a different manner. While cerebellar stimulation alone had only slight cardiovascular effects, it considerably reduced the increases in heart rate and blood pressure as well as the muscle blood flow increase as elicited by standardized defence area stimulations. The cerebellar suppression of the muscle vasodilatation was mainly due to an interference with the cholinergic vasodilator fibre activation as elicited from the defence area. Thus, the mentioned cerebellar structures appear to antagonize essentially *all* the elements comprising the reaction in contrast to the effects induced from the baroreceptors and with a markedly different net cardiovascular response as a result.

Acknowledgements

To professor Björn Folkow my teacher I wish to express my sincere gratitude for ardent advice and invaluable help throughout the study Thanks are further due to my co-authors and to my colleagues in the department.

Without the help of the departmental staff this series of experiments would not have been possible and I particularly wish to thank Mrs Barbro Johansson Mrs Birgitta Vallander and Miss Gunnel Andersson for skilful technical assistance. I am also most indebted to animal keeper Gösta Magnusson, photographer Tomas Palm and engineering. Lars Stage.

I am also most grateful to Mrs Helena Öberg and Mrs Kerstin Andreasson for typing the drafts. Dr Ed Kendrick has given me much appreciated help with the English text.

This study has been supported by grants from the US Public Health, (HE-05675-09) from the Swedish Medical Research Council (B70-14X 16-07A) and from the Faculty of Medicine, University of Göteborg.

AB Hässle, Göteborg, Sweden has generously covered the employment of a technician and supplied the β-blocking drug Aptin.

I. INTRODUCTION

Cell differentiation and growth are closely related to the transcription of the genetic code, that is, to RNA synthesis, and to the process of translation or protein synthesis (cf Mandel and Jacob 1970) Information concerning the cellular RNA and protein metabolism during development would thus appear essential for the understanding of the processes of growth and differentiation under both normal and pathological conditions. Obviously this also applies to the nerve cells.

The unique biological properties of the neurone, especially as regards the dynamics of that specialized cell (Weiss 1960), suggest that concepts based on observations of the development of other cell types need not be valid for nerve cells. The early ultraviolet spectrographic and volumetric studies of Hydén (1943) led to the conclusion that embryonal mammalian nerve cells, unlike most other somatic cells, pass through a second period of growth, characterized by continuous accumulation of nucleolar and cytoplasmic nucleotides and proteins. Similar observations were later made by Sourander (1953) and Hughes (1955) on the mass and nucleic acid content of the anterior horn neurones of chick embryos. Studies on rabbit retinal ganglion cells (Brattgård 1952) demonstrated that nucleoprotein and protein concentrations differed in young and adult or stimulated and unstimulated animals but because of discontinuous sampling, only very limited conclusions could be drawn as to the rate of change at various ages. The same applies to the study of Ringborg (1966) on the RNA content and base composition of the pyramidal cells of rat hippocampus.

The available information is not sufficient to create an integrated picture of the postnatal changes in the nucleic acid and protein content of the mammalian neurone For such a picture to emerge systematic quantitative cytochemical *information covering the whole period of postnatal development of the nerve* cell from birth to maturity is needed Such information concerning the basic structural and functional unit of the nervous system would be desirable both for a better understanding of the normal growth and maturation of the nervous system, and as a prerequisite for studies of neuronal development under experimentally *varied conditions.*

In view of recent systematic morphological and functional studies on the postnatal development of the mammalian motor neurones (cf Skoglund 1969) it would be of particular interest to study the chemical differentiation of these cells.

Since the function of these neurones is intimately connected with skeletal muscle (Eccles 1963, Guttman 1963) a major determinant of body mass (Donaldson 1924, Miller 1969), an understanding of the development of spinal anterior horn neurones in relation to somatic growth is also of interest.

Except for Brattgård's (1952) study little is known about the influence of environment on the postnatal chemical maturation of the neurone. During recent years increasing interest has been shown in the effects of early postnatal nutritional deprivation on the developing nervous system (e.g. Scrimshaw & Gordon 1968, McCance & Widdowson 1968). This interest has been largely stimulated by the realization that the incidence of protein-calorie deficiency (W.H.O 1962) in human infants is widespread and on the increase (Béhar 1968) and that it is apparently associated with impaired intellectual function (Cravioto *et al.* 1966, Stoch & Smythe 1963, Mönckeberg 1968) Experimental studies, on the other hand, have led to the formulation of a hypothesis of vulnerable periods in the development of the central nervous system during which unfavorable environmental conditions, e.g undernutrition, might be particularly harmful (Dobbing 1968). It has been shown in animal experiments that undernutrition during early postnatal period results in impaired behavioral characteristics. A number of physical, chemical and histological changes, such as reduced brain weight, reduced DNA-content of the brain and retarded myelination have also been observed in the central nervous system of human infants or animals subjected to undernutrition during early postnatal development. These changes were partly irreversible by rehabilitation (cf. Winick 1969). It is evident that the entire process of structural growth and chemical differentiation of the nerve cells as of any other cells must in some way depend on the nutrients available (Coursin 1968). Virtually no information is available, however on the effects of nutritional deprivation on the development of the neurone

The aim of the present study was to draw a coherent picture of the changes of the RNA and protein content of the nerve cell as a function of age and in relation to somatic growth during postnatal development. An attempt was also made to investigate the effects of caloric restriction imposed during the period of most intensive developmental change, and the effect of subsequent rehabilitation.

For this purpose, spinal anterior horn neurones were isolated from normal, undernourished and rehabilitated rats at frequent age intervals, and used for determinations of the neuronal dry mass after lipid extraction, reflecting the cellular protein content, and for determinations of the neuronal RNA content and composition. In these determinations, use was made of techniques allowing direct analysis of the absolute amounts of RNA and dry mass per cell.

II. MATERIAL AND METHODS

A. *Experimental animals*

The rat was chosen as the experimental animal because it offers several advantages from the point of view of the present study The rat is a spostnatal brain developers (Davison and Dobbing 1968) and can thus be easily subjected to varying experimental procedures during the most intensive period of development of its nervous system. Furthermore, since rats have been extensively used in studies of protein-calorie deficiency several methods for nutritional manipulation of even young rats have been devised (e.g. Sugita 1918, Stewart 1918, Kennedy 1957 Chow & Lee 1961, Miller and Dyrnza 1963). Finally early concepts concerning the nucleic acid and protein metabolism of developing nerve cells were largely based on observations of spinal neuroblasts of rat embryos (Hydén 1943).

Male albino rats of the Sprague-Dawley strain bred at the Department of Histology University of Göteborg, were used throughout the study Their parents were delivered by AB Anticimex, Stockholm, Sweden.

The animals were kept in metal cages on sawdust and soft shavings at a temperature of about 20° C. The pregnant rats were placed in separate cages four to five days before term. Fine wood wool was provided as nesting material. The animals were controlled twice daily to insure determination of the time of birth to within ± 12 hours. The gestation period for rats varies usually between 21 and 23 days (Porter 1967). On the day following birth the young rats were weighed and sexed (see Porter 1967) and the litter size was adjusted to eight pups. All abnormal pups and redundant females were discarded. The animals were weaned at 21 days of age. The rat mothers and young rats were given water and a standard diet *ad lib* The development of the rats was closely followed by inspection and weekly weighings, and the least suspicion of illness meant that the animal was immediately discarded.

Miller (1969) has discussed the significance of the discontinuous nature of many developmental processes in experimental design. Frequent sampling is mandatory during periods of rapid change. Thus, during the present study animals were sacrificed at eleven different ages for the cytochemical analysis of neuronal development in normal rats. The distribution of the animals in the various age groups is presented in detail in Table I The 6 rats in each age group were usually derived

from two different litters. Altogether 68 animals from 24 litters were thus used for studies of neuronal development in normal animals.

For cytochemical studies of the effect of undernutrition and subsequent rehabilitation on neuronal development an additional 32 rats were used, sacrificed at 4 different ages (see Table II and X for details of the experimental design)

B. Production of undernutrition and rehabilitation

1 Choice of method

As noted above, several techniques for producing undernutrition in infant rats have been described. Sugita (1918) and Stewart (1918) limited the daily suckling time of young rats. Based on the previous observations of Parkes (1929) on mice, Kennedy (1957) developed his »litter adjustment method« to produce undernourished rats, later extensively used by e.g. Widdowson & McCance (1960), Dobbing (1964) and Winick and collaborators (Winick and Noble 1966). More recently Chow and Lee (1964) described a method in which the rat mother was restricted to 50 per cent of her total calorie requirement. Finally Miller & Dyrnsza (1963) reported a more rigidly controlled technique for modifying the diet of the postnatal suckling rat. They fed the neonatal animals intragastrically using a specially designed needle. Their method also involved the use of nonlactating foster mothers. With this method a variety of diets can be fed to the neonate but the selection of diets is restricted, for example by the necessity of adjusting the osmolarity of the diet (Miller & Czajka 1967).

The advantages and drawbacks of the methods of Kennedy and Chow and Lee were discussed by Miller (1960). There are considerable difficulties in obtaining reproducible results with these methods as the extent of the undernutrition will vary a great deal depending e.g. upon such factors as the size and the aggressiveness of the individual pup. The method of Miller and Dyrnsza allows exact control of the quality and quantity of the diet ingested, but this technique is very laborious and is out of the question if a relatively large number of undernourished animals is to be produced.

In the present study it was important that the degree of undernutrition as reflected by body weight, could be exactly controlled, and that undernourished pups from several litters could be combined to make a uniform experimental group. The principle used by Sugita and Stewart appeared to allow direct and relatively easy control of the increase in body weight of each pup by regulating the daily suckling time. Furthermore control pups from the same litter can be fostered by the same mother. The rat mothers are not subjected to such untoward conditions as excessively large litters or dietary restrictions which might affect their ability to take care of the young. This principle was, therefore, adopted for the preliminary experiments.

After several trials the following procedure was finally accepted.

Before parturition the rat mothers were accustomed to daily handling. The time of birth was observed but the mother and pups were left undisturbed during the first day. At the age of one day the litter size was adjusted to 9. The pups were weighed and sexed and divided into an experimental and a control group consisting of 6 and 3 pups, respectively. Both groups were weighed daily.

The experimental animals were daily isolated from the mother and kept in conditions simulating those in a rat's nest (Gustafsson 1948). They were placed in a small plastic box with soft shavings as bedding material. This box was kept in an incubator with a relative humidity of approximately 60 to 70 per cent and a temperature of from 35° C to 22° C, depending on the age of the animals (Gustafsson 1948). The daily suckling time was adjusted so as to maintain a steady albeit very slow increase in body weight. In practice, this time varied from 6 to 9 hours daily. It was found that the body weight had to be allowed to increase at a rate of not less than 20 per cent of the control rate to assure acceptable survival at weaning. This meant that the undernourished rats weighed about 11 to 15 gms. at weaning. Some rat mothers showed inability or unwillingness to take care of the undernourished young and were discarded. »Good» mothers succeeded well with most of their litters, the survival rate being about 80 to 100 per cent. Only male rats from such litters were included in the actual experimental series.

After weaning at 21 days of age the undernourished rats were kept in metal cages on sawdust and soft shavings at about 20° C. They were given a defined, balanced diet in restricted amounts twice daily and water *ad lib*. The diet (for composition of diet see Table III) contained 20 per cent protein and all necessary minerals and vitamins in amounts exceeding the established minimum requirements calculated on a body weight basis (McCoy 1963). The amount of food was adjusted so as to allow a very slow increase in body weight. The undernourished rats used for the cytochemical analyses were allowed to reach the following body weights: about 10 g at 15 days of age, about 20 g at 30 days of age and about 30 g at 90 days of age. The total mean amount of diet consumed was 2.7 g *per* rat *per* day as compared with 11.2 g per rat and day for rats fed the same ration *ad lib*. The caloric intake of the undernourished rats was thus *restricted to about 24 per cent of that of control animals*.

Except for their small size and rather thin hair the undernourished animals did not show any obvious signs of disease, in particular no signs of any known vitamin deficiency. They were very lively with an apparently intact motor performance as also documented cinematographically (Fig. 1).

The control siblings (see table V) remained with the mother until weaning at 21 days of age. Thereafter they were given the experimental diet and water *ad lib*.

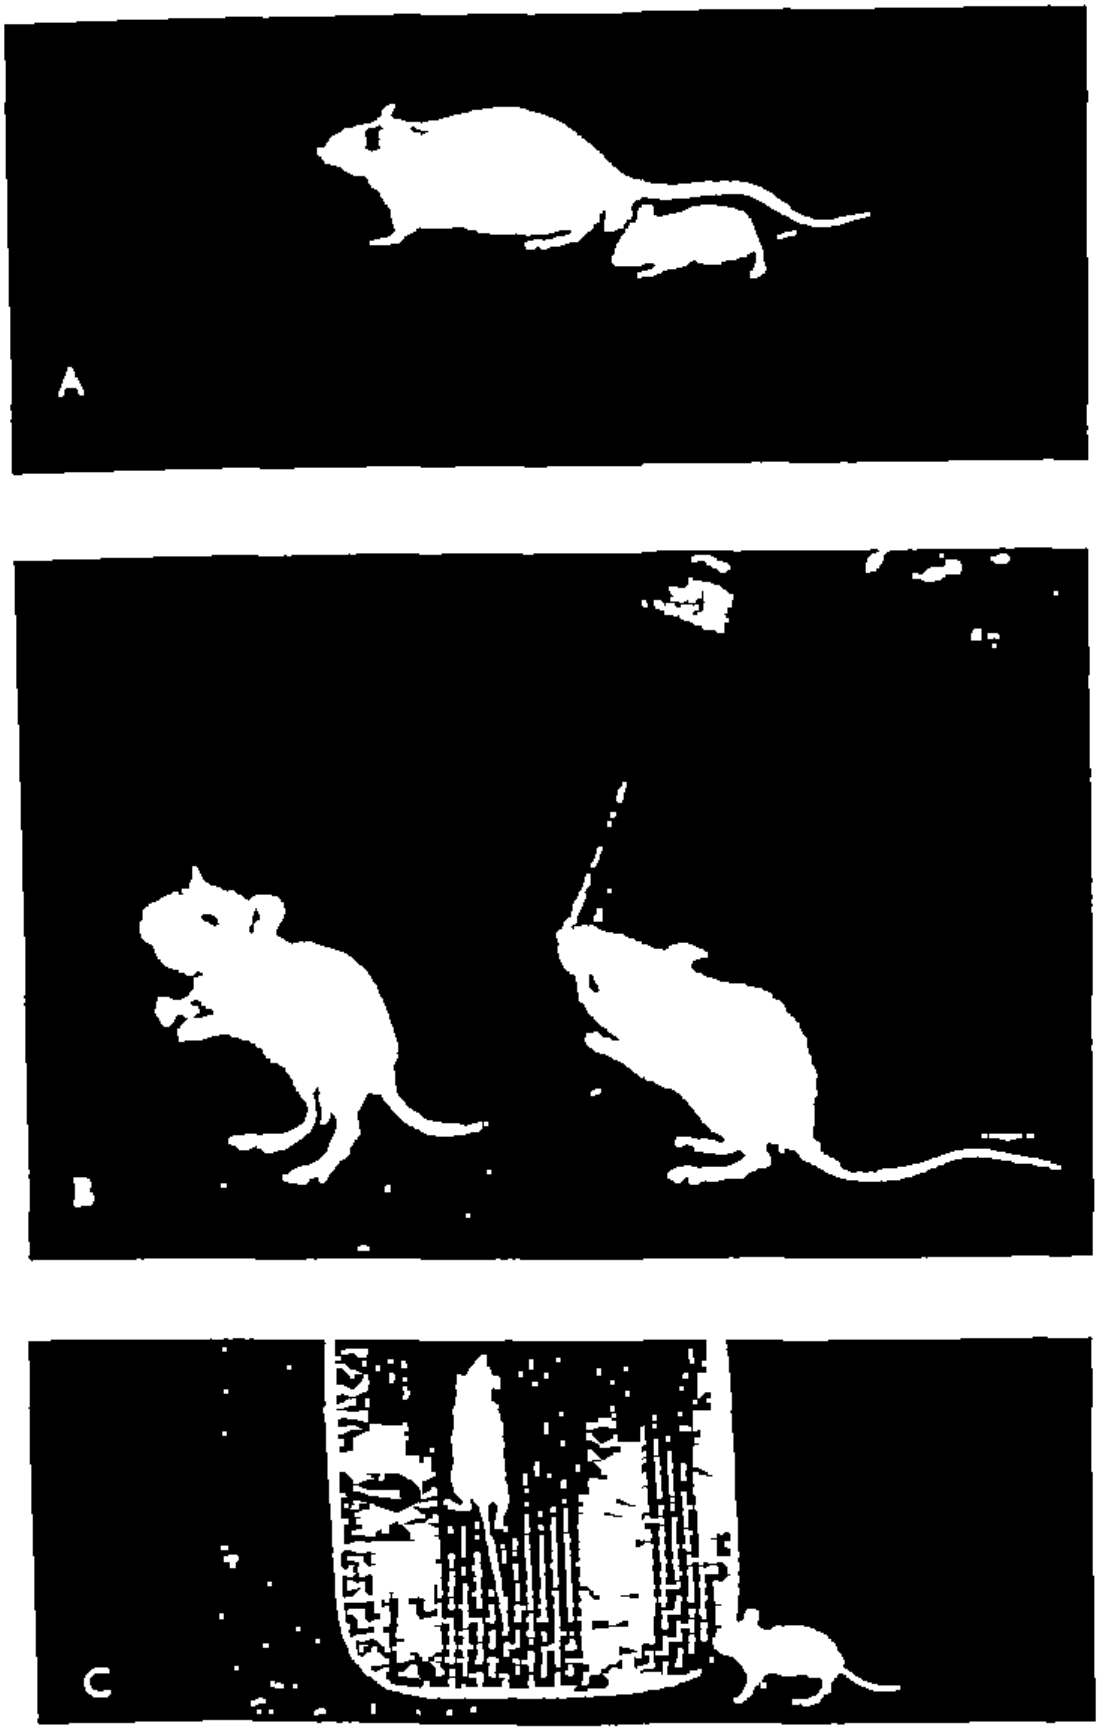

Fig. 1 a. A 3-month-old undernourished rat (body w ight 30 g; t the right) and control littermate (body w ight 380 g; t the l ft) b Two undernourished rats balancing on hind legs and drinking. An undernourished rat limbing on ertical rface.

5. Rehabilitation

For rehabilitation the previously undernourished rats were given the experimental diet and water *ad lib*. After a delay of a few days this resulted in a rapid increase in body weight, which however even after maximal rehabilitation, did not reach normal values for their age. In other respects the rehabilitated animals did not present any obvious abnormalities in appearance, motor performance, or behaviour at simple clinical inspection.

C. Cytochemical methods

1. Choice of methods

The purpose of the present study was to investigate variations in the RNA and protein content of nerve cells at various ages. An apparently simple and attractive way would have been to rely on various types of histochemical estimations in tissue sections (cf. Adams 1965) and calculate the relative changes in cellular RNA or protein content on the basis of measurements of cell volume. In a developmental series such an approach might, however, give rise to considerable difficulties.

As recently pointed out by Mellström and Skoglund (1969), the same histological treatment may cause markedly differing degrees of shrinkage in the nervous tissue from animals of different ages, thus distorting the results of the volume measurements. Furthermore, for calculation of volume of a large number of neurones, various mathematical idealizations would have to be developed for animals of different ages as the form of spinal anterior horn neurones obviously changes during development.

These difficulties and the errors associated with histochemical quantitation (Adams 1965 a) were avoided in the present study by the use of methods allowing direct measurement of the dry mass (reflecting the protein content) and absolute amounts of RNA *per* cell. Rosengren's direct X-ray absorption method (Rosengren 1950) was chosen for the mass determinations. This method allows a relatively large number of measurements to be done within reasonable time and with satisfactory accuracy (Rosengren 1959, Hallgrim 1969). Edström's microchemical methods were used for the measurements of neuronal RNA content and composition (Edström 1961). These methods necessitate the use of isolated neurones.

It was therefore necessary to evolve a procedure that would make it possible to isolate an anatomically well defined, comparable population of nerve cells from both newborn and adult rats under identical conditions. It was also imperative that the procedure should not affect the RNA or protein content of the nerve cells.

For the isolation of neurones free-hand dissection of fresh nerve cells (Hydén 1960) was first tried. These preliminary experiments showed, however, that it was very difficult or impossible to isolate the small and fragile spinal anterior

horn neurones in sufficient numbers from newborn and young rats by the free *hand dissection method*. On the other hand, such neurones were easily dissected out from fixed tissue sections with the aid of a pneumatic de Fonbrune micromanipulator (Edström 1961). This method also made it possible to select a three-dimensionally well defined anatomical area for dissection of nerve cells.

Since fixed tissue had to be used, a fixation procedure had to be chosen which would guarantee good preservation of nucleic acids and protein. Controlled immersion fixation with Carnoy's solution at room temperature up to 72 hours has been found to result in the quantitative preservation of the neuronal RNA (Edström 1961, Jarlstedt 1962).

The suitability of Carnoy-fixation for mass determination with methods based on X-ray absorption has been tested previously (Brattgård 1952) with special regard to the preservation of proteins. As the neurochemical analyses presented in Brattgård's study were made by Associate Professor Lars Swennerholm he was also consulted. He could confirm that fixation with Carnoy's solution and further histological preparation of nervous tissue resulted in a loss of 8.5 per cent of nitrogenous substances calculated as nitrogen, consisting mainly of low polymeric substances such as amino acids. Thus the protein content of the tissue was not essentially affected. In contrast, lipids were almost completely extracted with the exception of less than 5 per cent. These neurochemical observations were confirmed by X-ray microradiographical analysis; no significant difference in mass was found between nerve cells fixed in Carnoy's solution and cells frozen sectioned in the fresh state with subsequent extraction of the lipids with chloroform (Brattgård 1952). These observations appeared also to be valid for direct ray absorption analysis of isolated spinal anterior horn neurones, as no significant differences in the reduction in mass could be observed between cells dissected in the fresh state and subsequently treated with Carnoy's solution, or only with chloroform. The markedly reduced X ray absorption of nerve cell nuclei treated with Carnoy's solution (Brattgård and Hydén 1954) may thus be due to redisposition rather than actual loss of organic material other than lipids.

The effect of fixation on carbohydrates is of no importance as the amount of carbohydrates in nerve cell material is very low and can be neglected as a source of error in the determination of total cell mass. The same is true for a number of electrolytes which do not absorb X-rays at the wavelength employed (Brattgård & Hydén 1952, Brattgård 1952). The results of X-ray absorption analysis of material fixed in Carnoy's solution thus correspond to the mass of protein and nucleic acids added together. As the amount of nucleic acids in nerve cells is of the order of 10 per cent of the mass of protein, the values obtained reflect essentially the amount of protein per cell. Henceforth the mass of the isolated nerve cell body after Carnoy fixation and histological treatment will be referred to as neuronal dry mass.

2 Sampling

Large and small nerve cells occur intermingled in the anterior horns of the spinal cord (Rexed 1952, 1964, Schadé and van Harreveld 1961) The spinal anterior horn neurones are of varying size (Ngowyang 1930) and also have different RNA contents at various levels of the spinal cord (Edström 1956). It was thus essential that the nerve cells used for the cytochemical analyses always represented the same neurone population and were derived from the same precisely defined anatomical area. This was accomplished by using only large anterior horn neurones from the anterolateral nucleus (corresponding to Rexed s lamina IX) of the 7th cervical segment at the level of the attachment of the posterior root on the spinal cord.

The 7th cervical segment was chosen because some systematic developmental data were available on this segment (Donaldson & Nagasaka 1918). The most cranial attachment of the 7th posterior root on the spinal cord was regar ded as the cranial limit of the segment, according to Thomas and Combs (1962).

12 large anterior horn neurones from each of six subsequent sections, six cells from each side, altogether 72 cells per animal, were used for the cytochemical analyses. 36 cells from three sections were used for the RNA determinations, and 36 cells from alternating sections for mass determinations.

To compensate roughly for the changes in the size of the nerve cells and length of the spinal cord segments during postnatal development, 40 μ sections were used for newborn and up to 8-day-old rats, 60 μ sections for 10 to 15-day-old rats, and 80 μ sections for older rats.

3. Preparation of material for cytochemical analysis

On the basis of the reasoning explained above the following procedure was adopted.

The animals were sacrificed by decapitation without previous anaesthesia. The cervical and upper thoracic spinal cord with the bony coverings was rapidly removed and the cord and its nerve roots exposed by laminectomy The structures were fixed in Carnoy s solution (absolute ethanol, chloroform and glacial acetic acid in proportions 6.3.1) for two hours. The fixed spinal cord was cut by means of a razor blade under a dissecting microscope perpendicular to the long axis of the cord at the level of the most cranial attachment of the posterior root of the 7th cervical segment.

The caudal part of the cord containing the 7th cervical segment was dehydrated for two hours in absolute ethanol, cleared for 30 minutes in benzene, and embedded in soft paraffin (melting point 52—54 C) From the cranial end of the preparation thus corresponding to the level of attachment of the 7th posterior root on the cord sections 40, 60 or 80 μ in thickness were cut with an ordinary sliding microtome. The sections were mounted on cover glasses (12×30×0.17 mm) and flattened at 37 C without using water The cover glasses were fastened with two strips

of tape on to conventional glass slides on which identification data were applied. Prior to dissection with the micromanipulator the sections were deparaffinized with chloroform for 5 minutes and transferred to successive baths of absolute ethanol and 0 01 N acetic acid, 5 minutes in each To render the nerve cell bodies more easily distinguishable the hydrated sections were lightly stained with methylene blue in 0 01 N acetic acid (Edstrom 1959).

The isolation of spinal anterior horn neurones from the hydrated sections was carried out in an oil chamber with the aid of two dissecting glass needles directed by a de Fonbrune micromanipulator (Etablissements Beaudouin, Paris, France) as described by Edström (1964). The microscope used in combination with the micromanipulator was a Zeiss Standard microscope equipped with phase contrast optics.

4 Determination of neuronal dry mass

For mass determination the isolated nerve cell bodies (Fig. 2a & b) were individually transferred to a supporting membrane attached on an aluminium ring. The cells were allowed to dry overnight in the oil chamber and the preparation was passed through four chloroform baths, 5 minutes in each, to remove the paraffin oil completely The supporting 12 μ thick polyester membrane used (Mylar^{R} Du Pont De Nemours) has been found to be very suitable for X-ray absorption measurements because of its physical and chemical resistance and uniform absorption characteristics (Haljamae 1969)

Fig. 2 a. Isolated cell bodies of spinal anterior horn neurones from the anterolateral nuclei of the 7th cervical segment of a newborn rat. b Corresponding cell bodies of 180-day-old rat. Phase contrast 180.

As noted above, Rosengren s direct \ ray absorption technique (Rosengren 1959) was used for the mass determinations. The essential equipment consists of an \-ray tube of the sealed-off type (a 0 μ aluminum filter also serves as the window) fed from servo-regulated, stabilized anode and filament current supplies, a specimen holder and specimen stage with an aperture, and a proportional counter tube with a decatron counter and a display unit (Fig. 3)

The aluminium ring with the membrane was attached to the specimen holder with pressure sensitive tape and the specimen holder was placed on the specimen stage. A nerve cell was centered on the aperture with the aid of a light microscope provided with both incident and transmitted light. The \-ray transmission was then measured with the cell centered over the aperture followed by background reading of the foil close to the cell. The mass value was calculated from the observed difference in transmission.

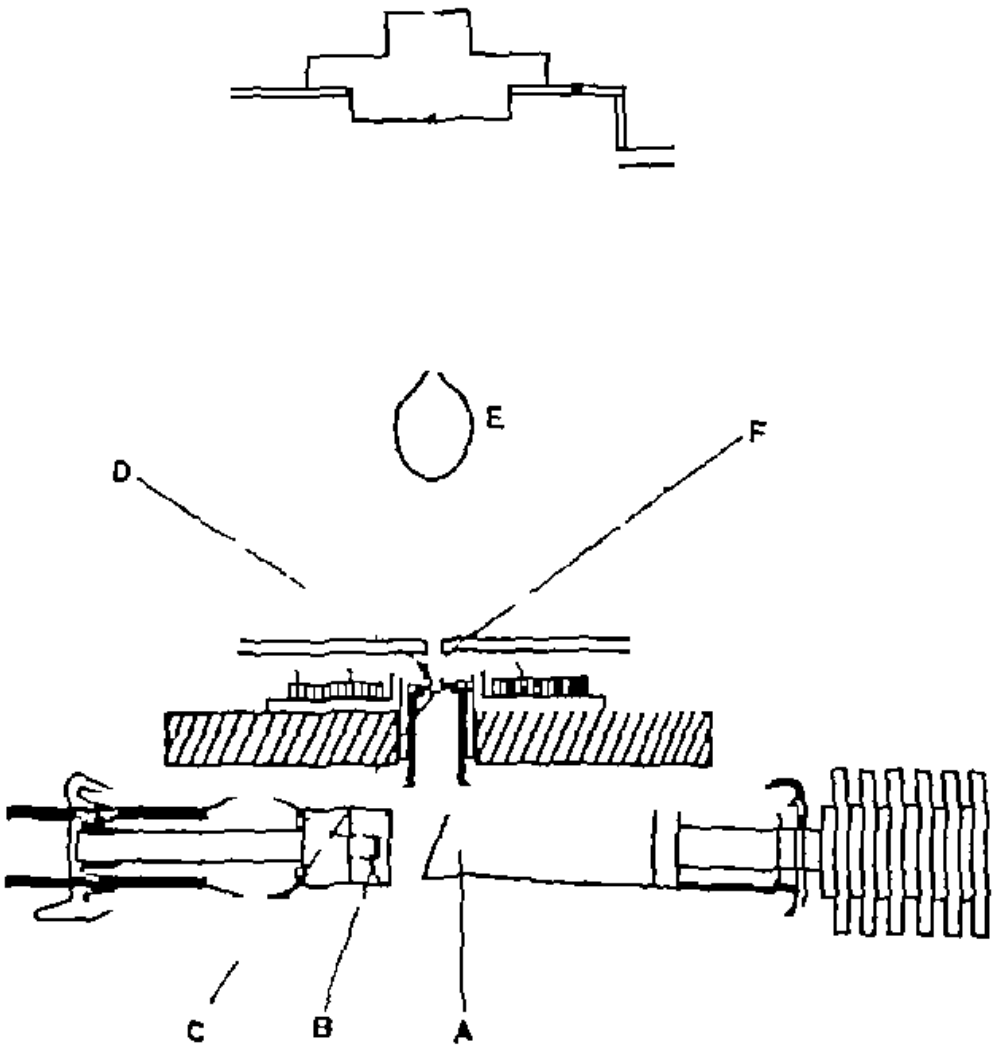

Fig 3. \-ray tube specimen mount and proportional detector \ — anode B — filament. C — 0 μ Al. window D — pecimen tape with aperture E — high voltage lectrode. F — specimen. (Reproduced by kind permission from B Rosengren: Acta Radiologica, Suppl 178 1959).

The standard curves used in the calculations were based on a nitrocellulose reference system covering a transmission range from 95 to 75 per cent. With the apertures used this corresponded to cellular mass values from 0.41 to 11.45 × 10^3 pg. The rather large size range of the neurones from animals of different ages necessitated the use of three different apertures, 30, 50 and 80 μ in diameter. The apertures were made of thin gold foil, as described by Rosengren (1959).

The accuracy of the transmission measurements is influenced by the instability of the apparatus (see Rosengren 1959) and by variations in the positioning of the cell over the aperture and in the placing of the specimen stage over the window of the X-ray tube. To analyse the random variation of the transmission measurements 36 successive measurements were made on the same cell, repositioned over the aperture after each measurement. The mean transmission value proved to be 90.3 per cent and the standard deviation 1.2 per cent. This corresponds to a mean mass value of 1.62 × 10^3 pg and a standard deviation of 0.51 × 10^3 pg or about 11 per cent. This figure is somewhat larger than that reported by Rosengren (1959) who states that the inaccuracy of the method is about 5 to 6 per cent.

b. Determination of neuronal RNA content and composition

For the determination of the RNA content of the isolated cell bodies of anterior horn neurones the method devised by Edström (1961) was used. The isolated nerve cell bodies were transferred in pairs through the oil chamber to a clean cover glass and left to dry. The cell pairs were then incubated for 1 hour at 37° C in droplets of buffered ribonuclease solution (Worthington Biochemical Corporation, Freehold, New Jersey; free of proteolytic activity). The individual extracts were transferred in a micropipette to a dry quartz slide where they were evaporated to dryness. The extraction and evaporation procedure was repeated three times. The spots, each containing all three extracts of a cell pair, were then dissolved in a buffer solution to form lens-shaped droplets. The droplets were photographed in ultraviolet light at 257 mμ together with a reference system at a magnification of × 130. The pictures of the ultraviolet absorbing droplets (Fig. 4a & b) were finally investigated by photometry at a further magnification of × 5. Two tracks were run through the centre and superimposed (Fig. 4c). A mean curve was drawn on transparent paper and the amounts of RNA per droplet determined with the aid of a device for integration of the absorption.

The accuracy of the method was checked with measured amounts of RNA. With amounts of 211 pg RNA the standard deviation was 13 and the coefficient of variation 6.2. These values agree well with those reported by Edström (1961). The completeness of extraction was checked at times by staining with methylene blue in 0.01 N acetic acid.

A tentative microelectrophoretic analysis was made of the base composition of the neuronal RNA after hydrolysis with hot 1N HCL, according to Edström (1961).

Fig. 4. a. Microdrops, each containing the pooled RNA extract of liver and rib bone marrow neurones from newborn rat photographed in ultraviolet light at 257 mμ together with the reference system (×130). b. Corresponding RNA extract from 180-day-old rat. c. Microphotodensitometric tracings of the photographs of the ultraviolet light absorbing RNA extract from newborn rat (left) and 180-day-old rat (right).

D Statistical methods

The standard deviation and the standard error of the mean (S.E.M.) of the neuronal dry mass and RNA content of each individual animal as well as of the different age groups were calculated according to the usual formula. The statistics obtained in this manner are given in connection with the various results.

In dealing with neuronal mass or RNA content as a function of age, it appeared desirable to make inference on the corresponding regression function in its entirety not only on individual values of the independent variable (age). Accordingly it was considered preferable to measure the precision of the estimation of the entire function rather than to analyze only the confidence limits for various individual values of the regression function. Thus, by using the principles of simultaneous statistical inference, to be more specific, the Bonferroni inequality (Miller 1966), and without any assumptions as to the shape of the regression function, confidence bands were constructed. Assuming some slight regularity of the curve describing the regression function such a band contains the entire regression function with a prescribed probability. An attempt was also made to describe the relation between neuronal mass or RNA content and the age or body weight of the animals in simple mathematical terms. For this purpose various equations have been tried on the material.

The nature of the correlation between neuronal dry mass and RNA content was investigated by means of single regression analysis. The product-moment correlation coefficient was also estimated.

The significance of the difference between the means of various experimental and control groups was analyzed by means of Student's t test.

III. DRY MASS AND RNA CONTENT OF RAT SPINAL ANTERIOR HORN NEURONES DURING NORMAL POSTNATAL DEVELOPMENT

A Review of the literature

While the literature contains a great deal of quantitative data on the morphologic development of the nerve cell (cf Brizzee and Jacobs 1959 Mellström and Skoglund 1969 Conradi and Skoglund 1969) quantitative information concerning the chemical maturation of the neurone is relatively sparse. This is also true as far as the RNA and protein metabolism of the nerve cell is concerned though the topographic distribution of the nucleic acids in developing nerve cells has been examined more frequently (cf Spector 1965, Friede 1966 Lodin *et al* 1968).

Ultraviolet spectrography was the first reliable method to be used for the quantitative analysis of nucleic acids in single cells (Caspersson 1940). This method was applied by Hydén (1943) to the study of nucleic acids and proteins in the spinal neuroblasts and young anterior horn cells of rat and other mammalian embryos. The protein content was reckoned approximately with the aid of the absorption due to the cyclic amino acids at 2800 Å. In order to estimate the total content of nucleic acids or protein *per cell*, the volume of the Carnoy-fixed cells was computed from measurements of cell diameter Roughly estimated by these means, the cytoplasmic proteins in the cell body were found to increase more than 2000 fold during the development of the neurone from an apolar neuroblast to an adult anterior horn cell. When the neurite was included it increased much more. Judging from the ultraviolet absorption spectra the proteins increased at a higher rate than the nucleic acids during embryonic development. Hydén concluded that instead of cessation of growth together with a reduction in the size of the nucleolar apparatus, as in most other embryonal cells, the young nerve cell passes through a second period of growth during which the nucleolar material as well as the cytoplasmic nucleotides and proteins rapidly increase.

Sourander (1953) investigated the dry mass and nucleic acid content of spinal anterior horn cells from the ventrolateral nuclei of the brachial swelling of chick embryos. The mass *per* unit of volume was measured using X-ray microradiography and changes in concentration of nucleic acids were estimated with the aid of ultraviolet microscopy and photography Cell body volume was approximately calculated by the method used by Hydén (1943). The amount of dry

substance or the bulk of the protein *per* unit of volume increased from the 7th day of incubation to the 9th day. After 9 days of incubation the values for the amount of dry substance in the cytoplasm remained at about the same level. Calculations of the mass *per* cellular cytoplasm showed a 12 fold increase in mass between the 9th and 21st day of incubation. The young nerve cells absorbed ultraviolet light intensely at 2570 Å, near the absorption maximum of the nucleic acids. No differences in the intensity of absorption were observed at different stages.

Hughes (1955) studied the relative density in ultraviolet light of developing nerve cells of embryonal chick spinal cord and spinal ganglia with a simple microdensitometer. He observed a peak in the cytoplasmic density of nucleic acids at 2—5 days of incubation. On the 6th day the level of nucleic acid was low, but thereafter there was a steady rise in the cytoplasmic concentration up to the 12th day. He emphasized the similarity between his own results and the biochemical findings of Novikoff and Potter (1948) on whole chick embryos and concluded that the density of RNA was an index of neuronal differentiation.

The only quantitative information available on postnatal changes in the nucleic acids of spinal anterior horn cells is the short comment by Hydén (1960) that the RNA content of these cells in the human spinal cord increases from 3 to 40 years of age, followed by a constant period up to 55—60 years. At higher ages there is a *decrease*.

The postnatal development of rabbit retinal ganglion cells was analysed by Brattgård (1952). Applying X-ray microradiography on Carnoy-fixed material from rabbits 11 days, 10 weeks and 8 months old, he found an increase in the total dry weight *per* unit of volume from 11 days to 8 months of age. The pentose nucleoprotein fraction (estimated after treatment with ribonuclease) already reached a high level at 10 weeks of age, after which there was no significant change. On the contrary, the protein fraction at 8 months was markedly higher than that at 10 weeks of age.

Ringborg (1960) investigated the content and composition of RNA in the pyramidal cells of rat hippocampus in foetal, newborn, adult and old rats. Using Edstrom's microchemical methods (Edström 1961) he observed an increase in the neuronal RNA content from 21 pg in the newborn to 110 pg in the adult rats. In the very old rats the neuronal RNA content was down to 53 pg. He also observed that *the guanine-cytosine/adenine-uracil-ratio increased with advancing age*.

Numerous quantitative studies have dealt with the biochemistry of nucleic acids and proteins of the developing nervous system at the organ level (for recent comprehensive reviews see Oja 1966, Dobbing 1968, Miller 1969, Talwar 1969, Rappoport *et al.* 1969, Roberts *et al.* 1970). Most of these studies have been concerned with the whole brain or its subdivisions, the extremely scanty information concerning the spinal cord has been reviewed by Levi (1969). Winick and collaborators (Winick and Noble 1965, Winick 1968, Fish and Winick 1969) have tried

to elucidate trends in the cellular growth of the brain on the basis of such gross biochemical analyses of the whole organ or its parts. Using a principle devised by Enesco and LeBlond (1962), they have calculated the mean cellular RNA and protein content of brain cells by determining the total amounts of DNA, RNA and protein *per* brain. As in other organs, Winick and collaborators found that three phases could be separated in the cellular growth of the brain During the first period, hyperplasia, DNA RNA and protein increased in proportion. This was followed by the period of hyperplasia and hypertrophy when DNA synthesis still continued but RNA and protein increased out of proportion to DNA increment. During the last period, that of hypertrophy alone, DNA synthesis stopped while RNA and protein continued to accumulate indicating increase in cell size.

Although the biochemical procedures mentioned above do give valuable information on the overall trends of cellular growth in many organs, they do not account for the extraordinary structural complexity of nervous tissue. The results of the macrochemical determinations merely reflect the sum of numerous simultaneous cellular processes following extremely varying time schedules in the different cell populations and anatomical regions of the nervous system. The neurones, the basic structural and functional units of the nervous system constitute only a fraction of the total number of cells, or total volume, of the nervous tissue (Pope 1955). Thus, conclusions reached on the basis of averaging biochemical determinations cannot be considered valid for nerve cells.

To sum up, it may be stated that previous quantitative cytochemical studies have mainly been concerned with the early embryonal period of neuronal development and that in most of these studies spinal anterior horn neurones have served as model. On the other hand, relatively little attention has been devoted to the postnatal growth and differentiation of the mammalian nerve cell. The available information is limited to very few ages and practically nothing is known about neuronal development during the immediate postnatal period.

B Results of the present investigations

1 Neuronal dry mass

Neuronal dry mass as function of age. Table IV gives the mean values, S.E.M., and frequency distributions in groups of 0.50×10^3 pg of the dry mass of the cell bodies of Carnoy fixed rat spinal anterior horn neurones from the anterolateral nucleus of the seventh cervical segment at different ages.

In Fig 5 the frequency distributions of the neuronal dry mass in some age groups are graphically shown in histograms. From the table and the histograms it is seen that both the median and the range of the frequency distributions of the neuronal dry mass change with advancing age. At birth the distribution of the neuronal mass is seen to fall within a relatively narrow range, i.e. the mass values

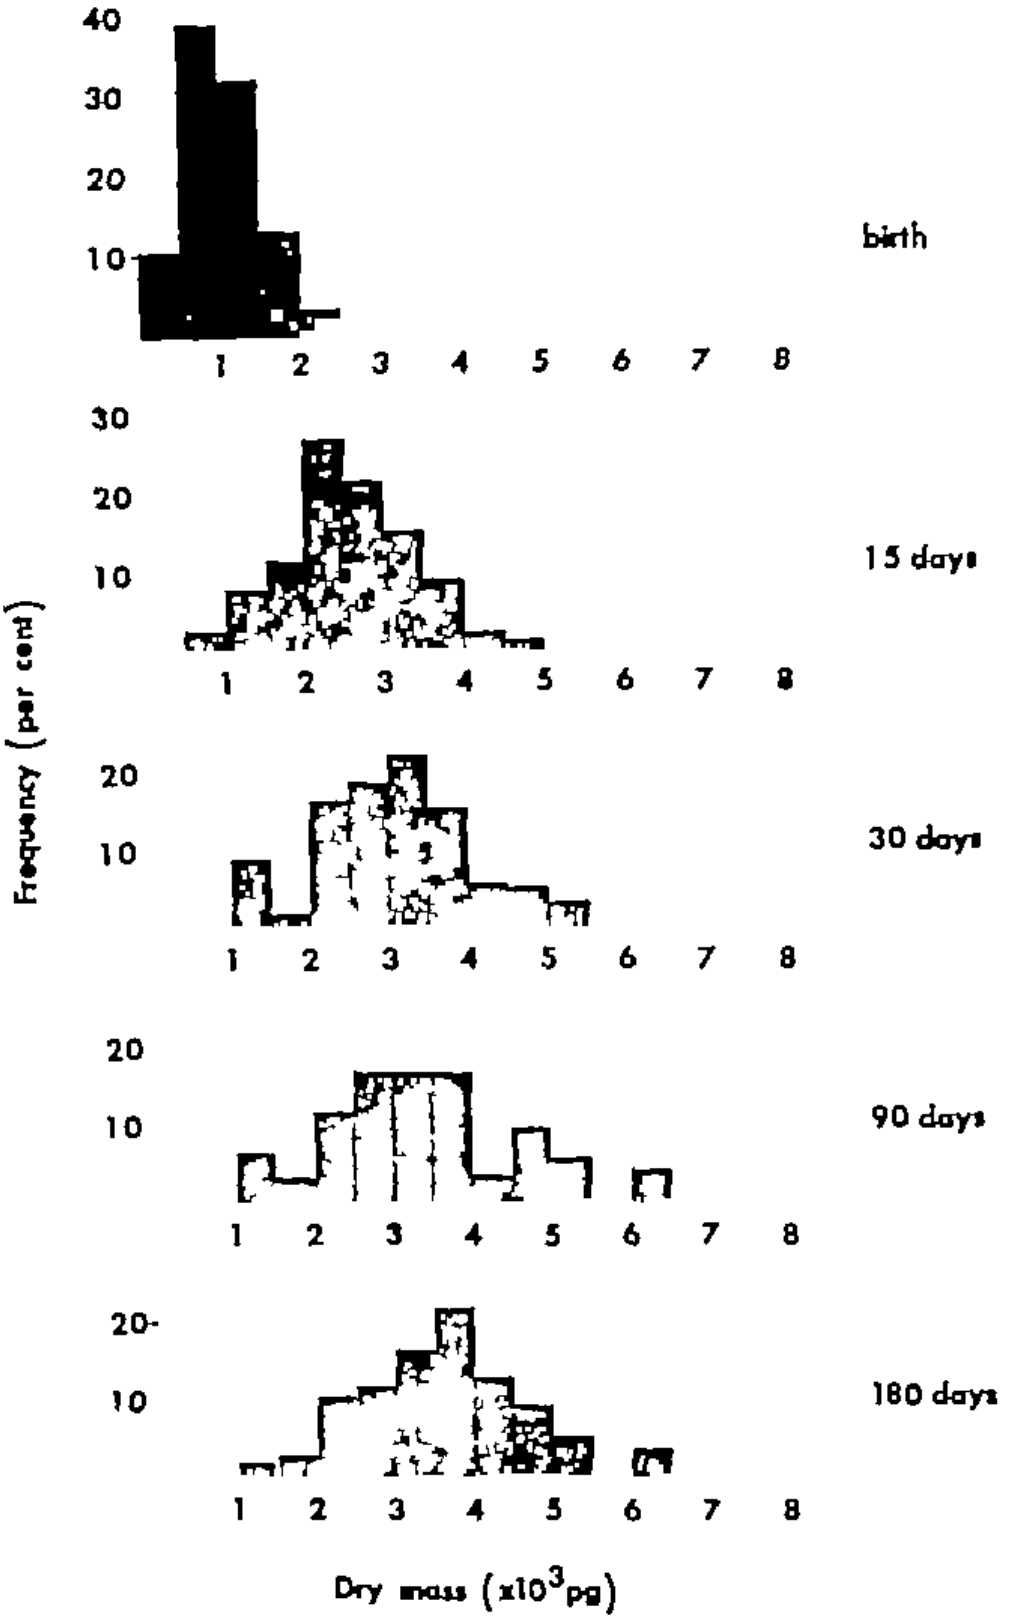

Fig. 3. Frequency distribution of the dry mass of the cell bodies of spinal anterior horn neurones from the 7th cervical segment of normal rats at various ages.

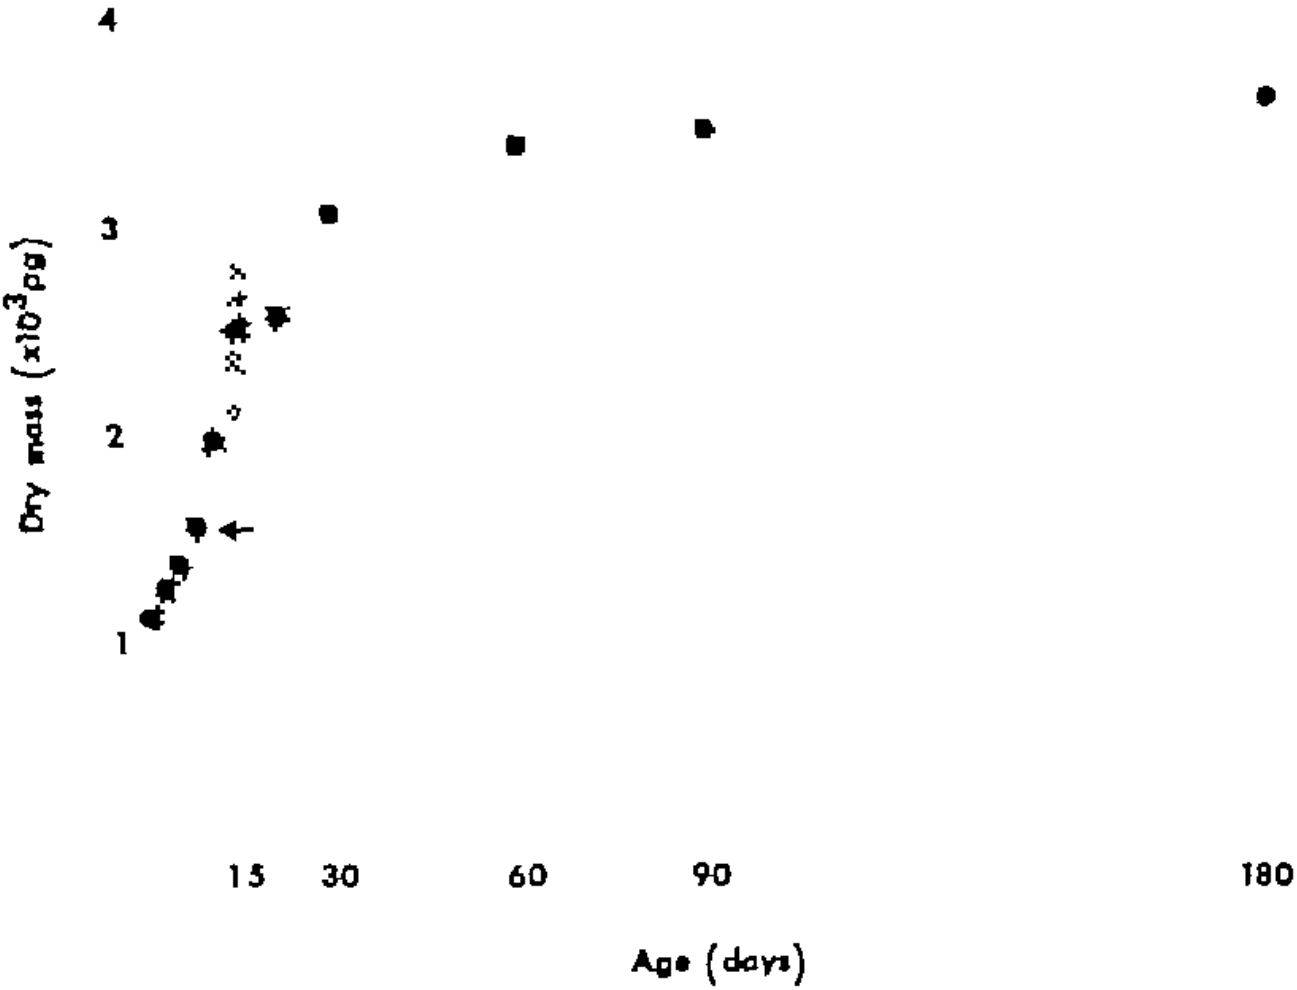

Fig. 6. Mean dry mass f th cell bodies f spinal anterior horn neurones from the 7th cervical segment f normal rats plotted against ge Each pol t represents the mean alue for 6 animals. The angular pol ts of the ppe and lower edges f the shadowed area give the observed ppe and low confidence limits, respectively on a confidence level exceeding 99 per cent, for the mean neuronal dry mass of the corresponding age. This implies that the simultaneous confidence level for all confidence interval is over 90 pe cent. N t the rapid increase f the mean neuronal dry mass aft the age f 3 days (plle).

are rather homogeneous. During the first days of postnatal life the changes are slight but from the age of 10 days onwards there is a marked shift of the entire distribution to the right and an increase in the distribution range At 30 days of age the distribution of the neuronal dry mass is already very much like that at 180 days.

From table IV it is seen that the mean dry mass of the anterior horn neurones increases from 1 10 $\pm$ 0.0) $\times$ 10^3 pg at birth to 3.60 $\pm$ 0 11 $\times$ 10^3 pg at the age of 180 days. The postnatal increase in mean neuronal mass is thus more than threefold (3.3 times)

The change in mean neuronal dry mass with advancing age is graphically shown in Fig. 6. The simultaneous confidence level for the confidence intervals in Fig. 6 was calculated without any assumptions as to the shape of the curve representing the neuronal mass as a function of age. Assuming some slight regu-

lurity of the curve, the shadowed area can be regarded as a confidence band for the curve on a confidence level exceeding 90 per cent. On the basis of these calculations it appears sound to assume that the curve representing the neuronal dry mass as a function of age is convex-concave (S-shaped) with a very steep rise between the ages of 8 and 16 days. Nearly adult values are already attained at 30 days of age after which there is only a very slow increase in neuronal dry mass up to the age of 180 days.

An attempt was also made to describe the neuronal dry mass as a function of age in simple mathematical terms. The simplest function, which describes the observed values satisfactorily was found to be a rational function

$$y = \frac{3290\ x^2 + 157000\ x + 1403000}{x^2 + 29\ x + 1280}$$

In this equation y is the neuronal dry mass in pg and x the age of the animal in days.

Neuronal dry mass in relation to body size. Table I and Fig 7 show the body weights of the rats used in the present study at the time of sacrifice The steepest

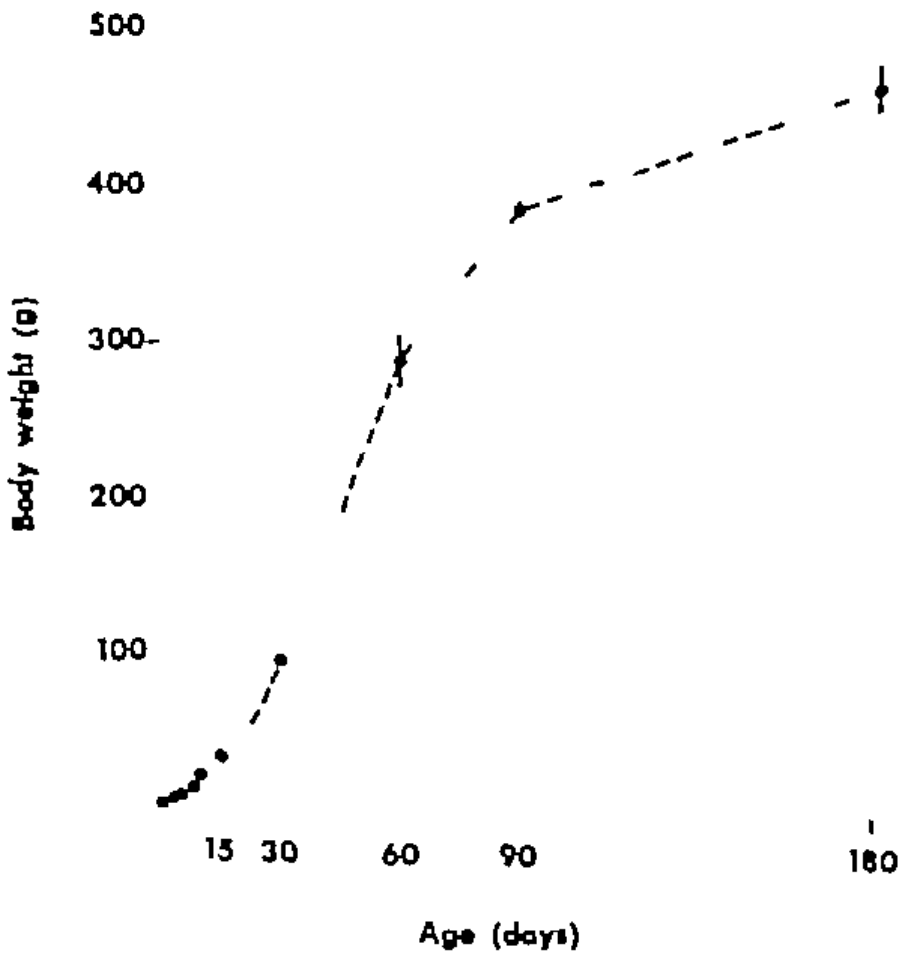

Fig 7 Mean body w ights ± S E M t th time f sacrifice f the normal rat plotted against ge

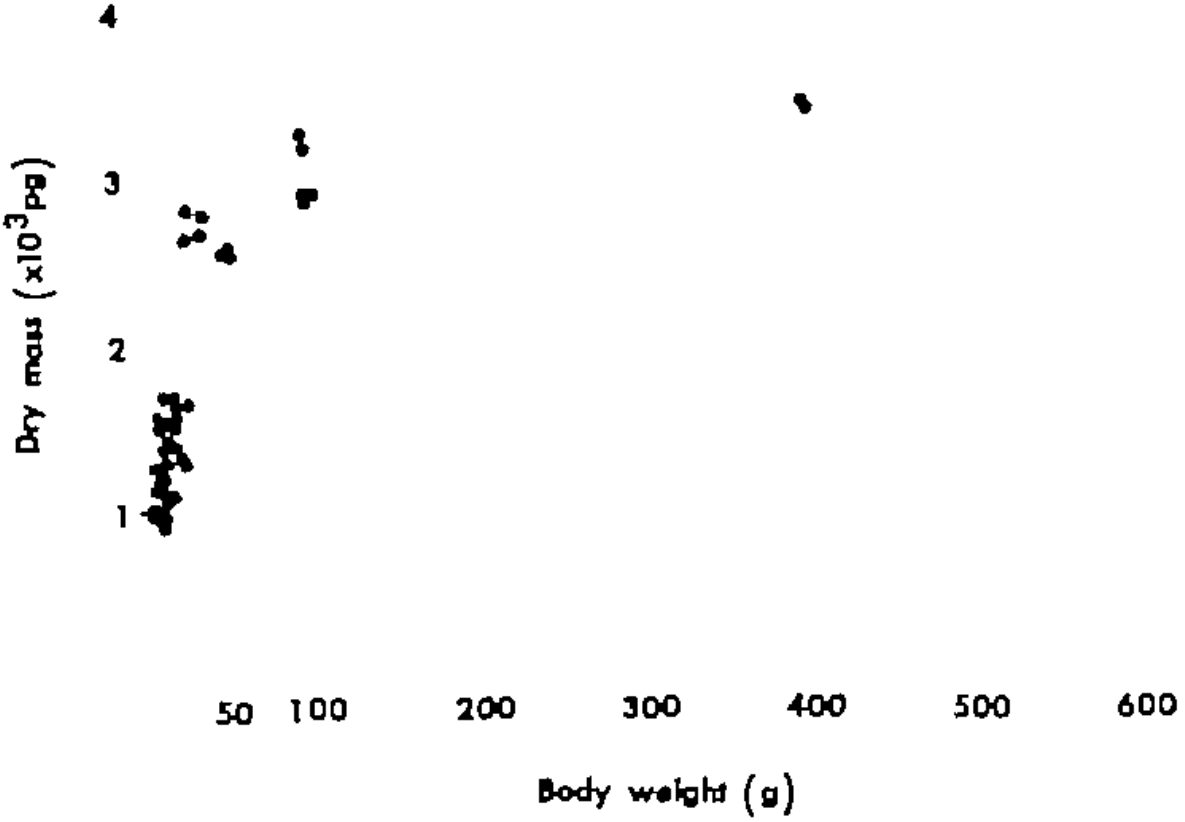

Fig. 8. Mean dry mass of the cell bodies of spinal anterior horn neurones from the 7th cervical segment of normal rats plotted against body weight.

rise of the body weight curve is seen between one and two months of age. It is thus evident, by comparison with Fig. 6 that the increase in mean neuronal dry mass principally occurs before the main increase in body weight.

In Fig. 8 the mean neuronal dry mass is plotted against the body weight. The scatter diagram shows a steep, nearly linear rise in neuronal dry mass from birth weight up to a body weight of about 50 g However increase of body weight beyond 100 g is accompanied with only a very slight increase in neuronal dry mass. It is thus obvious that no direct proportional relation exists between these variables. For the purpose of description a simple mathematical expression for the relation between neuronal dry mass and body weight was sought. The simplest function which describes the observed values well was found to be a rational function

$$y = \frac{3550\ x - 11100}{x + 10}$$

In this equation y is the neuronal dry mass value in pg and x is the body weight of the animal in g

To illustrate the relation between the neuronal dry mass and body weight with increasing age the mean neuronal dry mass/body weight ratio for each age

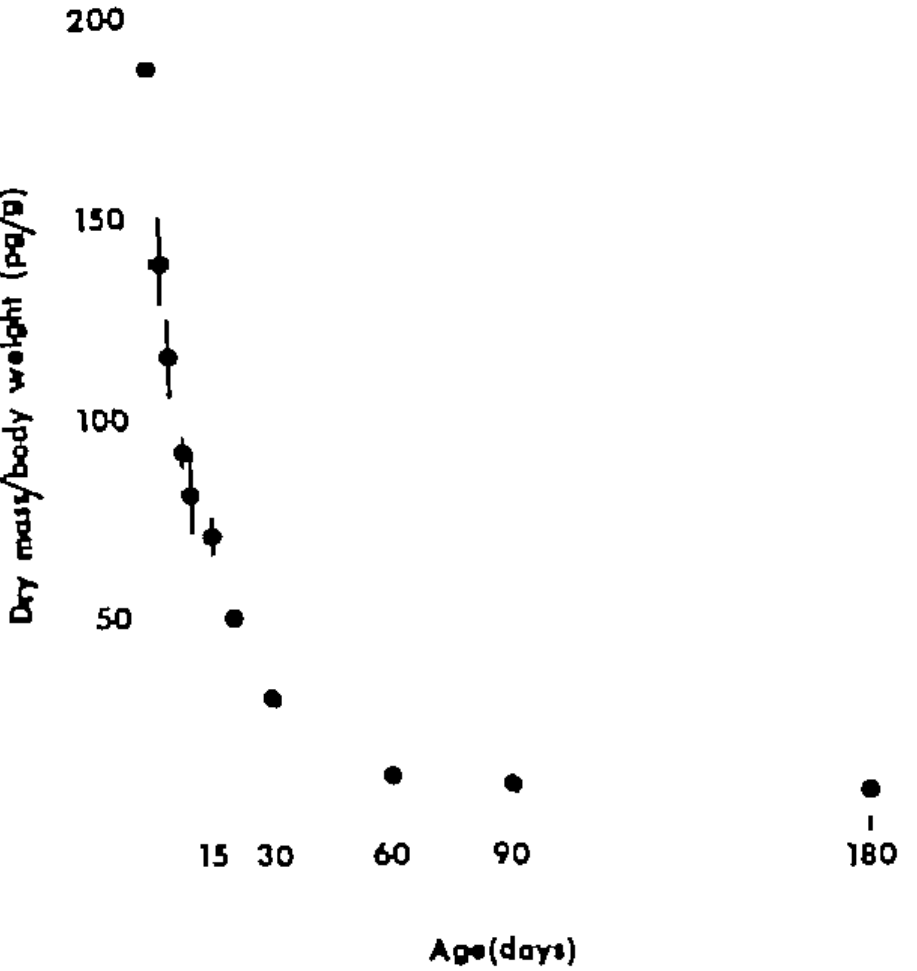

Fig. 9 Mean neuronal dry mass/body weight ratio ± S.E.M. in normal rats plotted against age. Each point represents the mean value for 6 animals.

group is calculated and plotted against age (Fig. 9). It will be seen that there is a continuous decrease in the neuronal dry mass/body weight ratio with advancing age. This decrease is very rapid during the first three postnatal weeks but then gradually slows down and the ratio reaches a nearly constant level at the age of three months.

As the growth characteristics of the anterior horn neurones and body weight thus obviously differed very markedly from each other, an attempt was made to plot the mean neuronal dry mass values against other parameters of somatic growth. A scatter diagram suggesting a roughly linear correlation (Fig. 10) was then obtained using the length of the humerus and ulna added together to denote extremity length. These values were obtained from Donaldson's tables (1924) giving the length of rat humerus and ulna as a function of body weight.

Neuronal RNA content and composition

Neuronal RNA content as function of age. Table V gives the mean values, S.E.M., and frequency distributions in groups of 25 pg of the RNA content of the cell

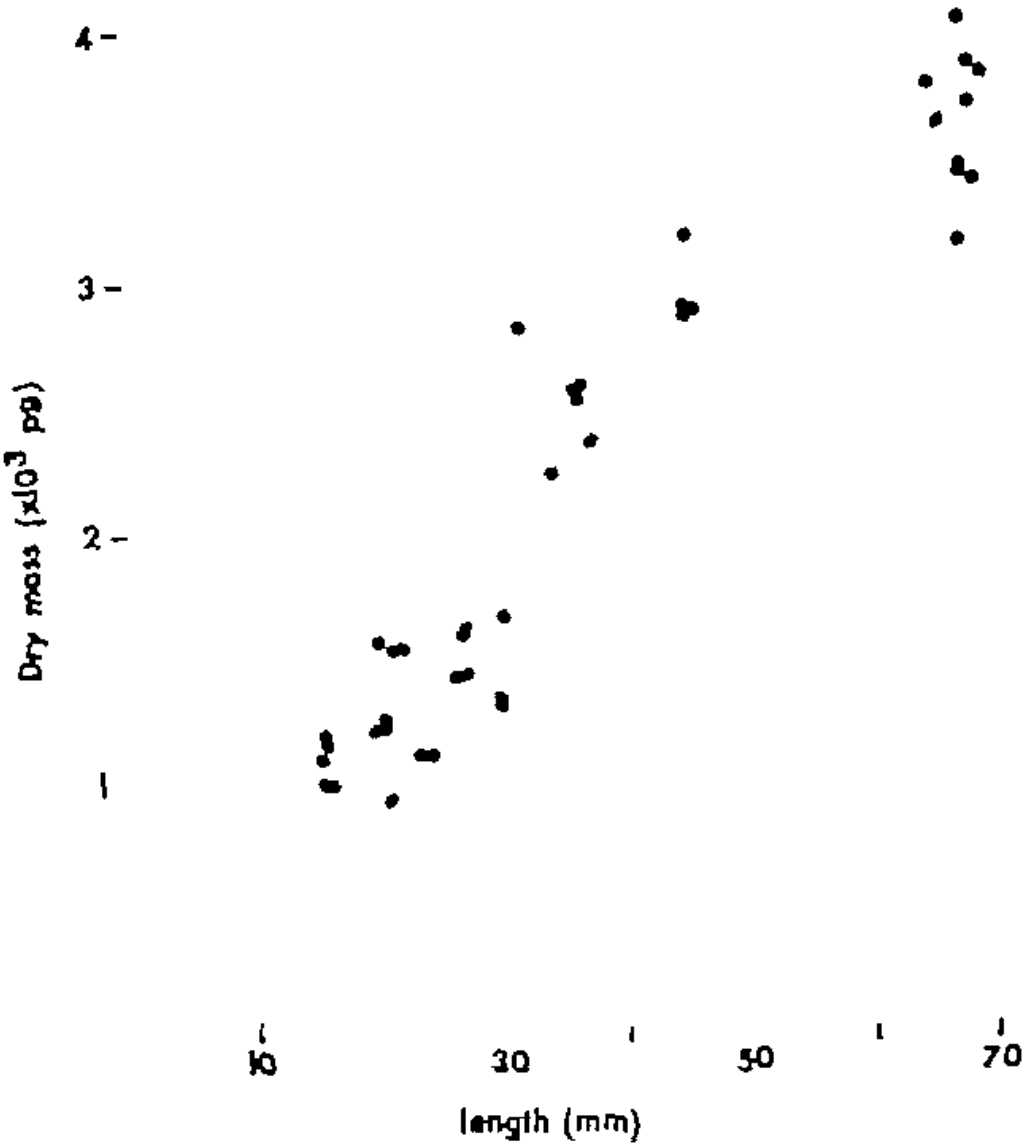

Fig. 10 Mean dry mass of the cell bodies of spinal anterior horn neurones from the 7th cervical segment of normal rat plotted against extremity length (length of humerus and ulna added together)

bodies of rat spinal anterior horn neurones from the anterolateral nucleus of the seventh cervical segment at different ages.

In Fig. 11 the distribution of the neuronal RNA content in some age groups is graphically shown in histograms. From the table and the histograms it will be seen that the median and the range of the frequency distribution of the neuronal RNA content change with advancing age. At birth the distribution of the neuronal RNA content is seen to be within a rather small range. From the age of 8 days onwards a rapid shift of the entire distribution to the right and a marked increase in the distribution range are observed. At the age of 30 days the distribution range is already very much like that at 180 days.

Table V shows that the mean neuronal RNA content increases from 120 ± 1 pg at birth to 500 ± 23 pg at 90 days of age to remain at approximately the

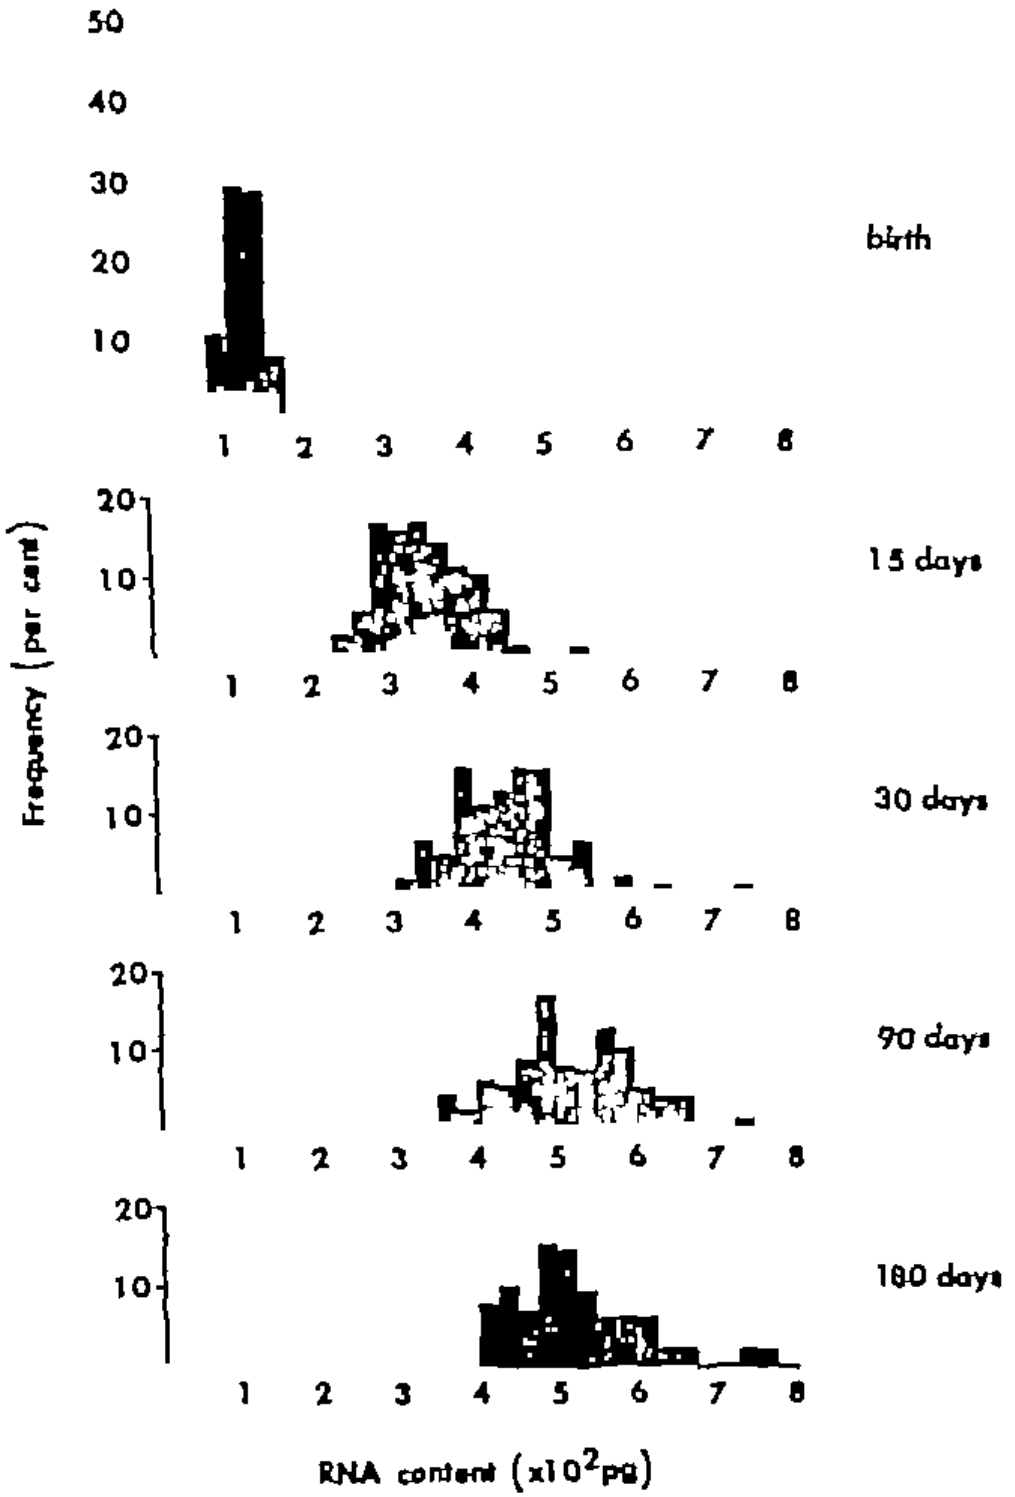

Fig. 11 Frequency distribution of the RNA content of the cell bodies of spinal anterior horn neurones from the 4th cervical segment of normal rat at various ages.

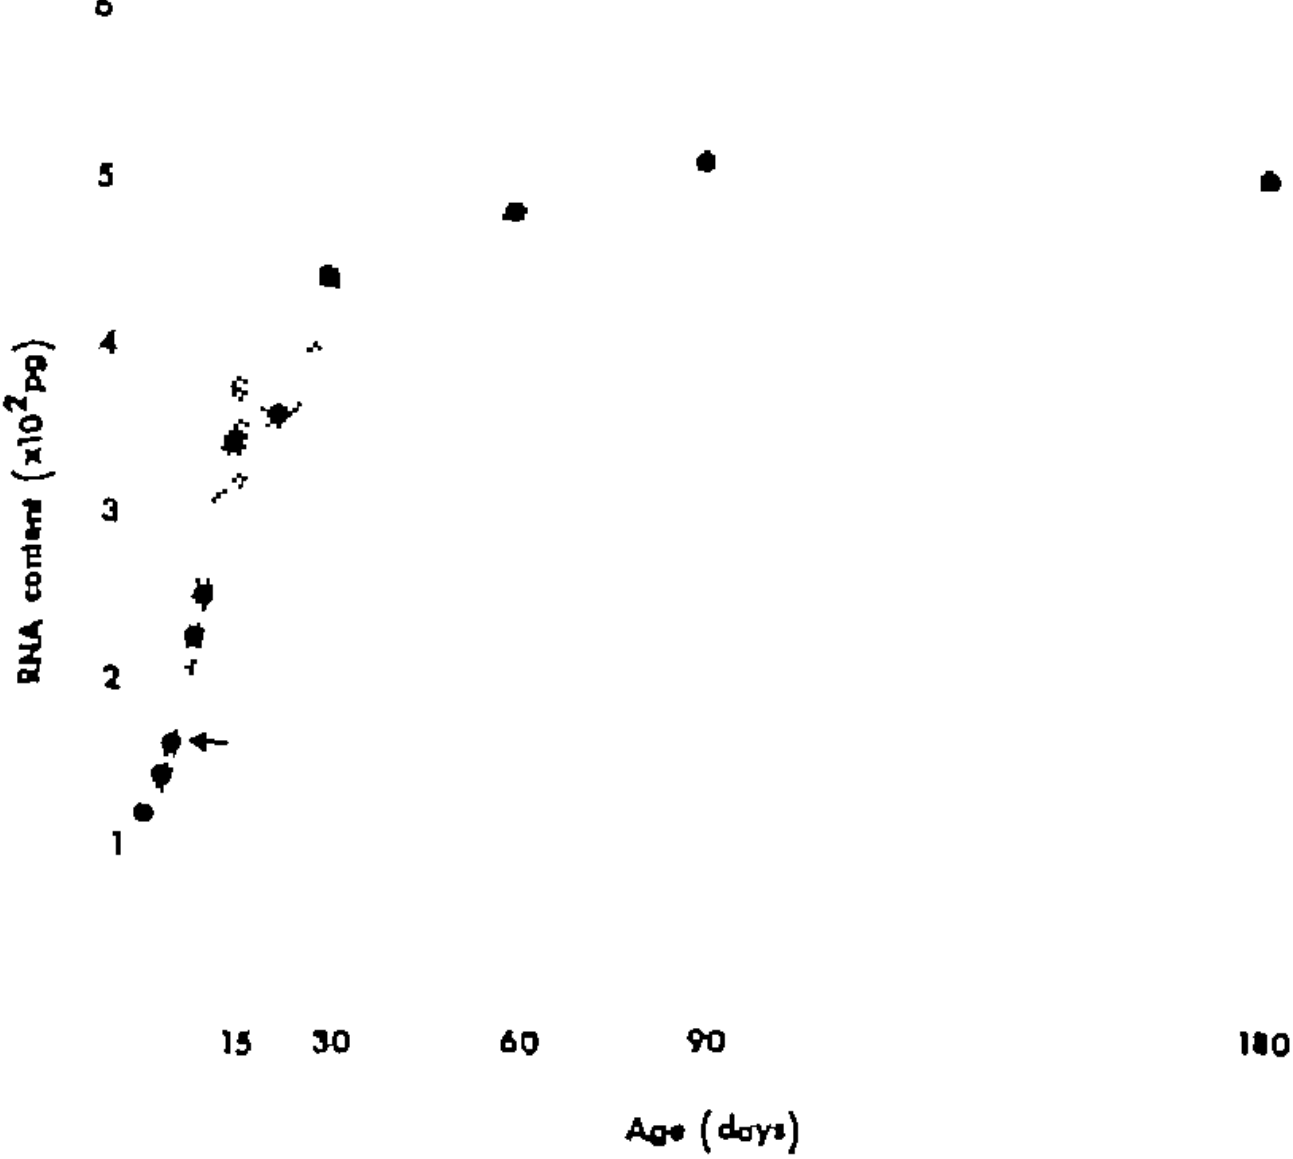

Fig. 12. Mean RNA content of the cell bodies of spinal anterior horn neurones from the 7th cervical segment of normal rats plotted against age. Each point represents the mean value for 6 animals. Statistical calculations as in Fig. 6. Note the rapid increase in the mean neuronal RNA content after the age of 5 days (pile).

same level at 180 days of age. The mean neuronal RNA content has thus increased postnatally more than four-fold (4.2 times).

The change in the mean neuronal RNA content with advancing age is graphically shown in Fig. 12. The simultaneous confidence level for the confidence intervals in Fig. 12 was calculated without any assumptions as to the shape of the curve representing the neuronal RNA content as a function of age. Assuming again some slight regularity of the curve, the shadowed area can be regarded as a confidence band for the curve on a confidence level exceeding 90 per cent. On the basis of these calculations it appears sound to assume that also the curve representing the neuronal RNA content as a function of age is convex-concave (S-shaped) with a very steep rise between the ages of 5 and 15 days. Nearly adult values are

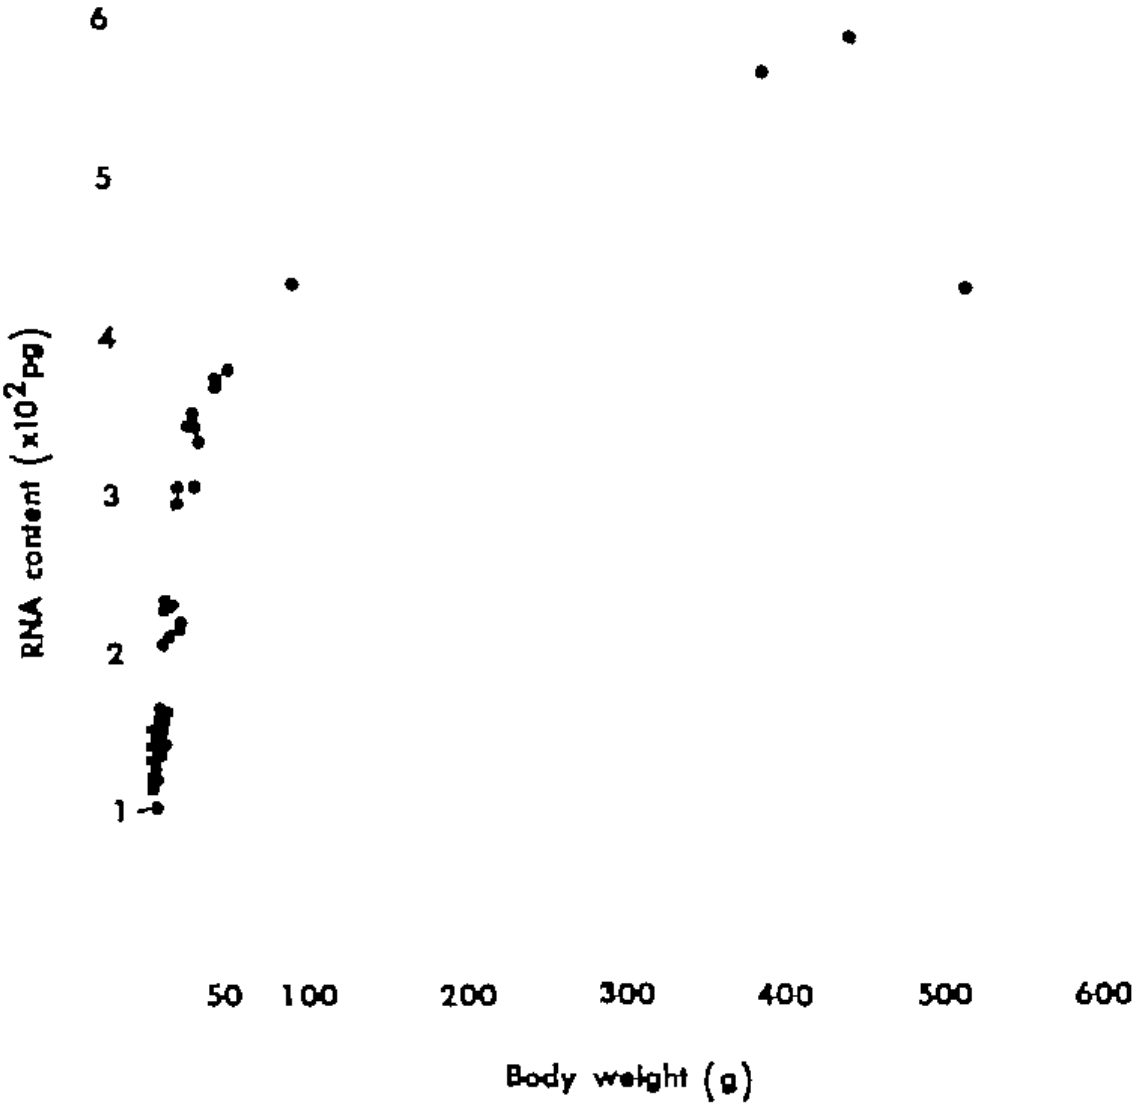

Fig. 13 Mean RNA content of the cell bodies of spinal anterior horn neurones from the 7th cervical segment of normal rats plotted against body weight.

already attained at the age of 30 days after which the increase is very slow. A plateau is reached at 90 days of age. The rational function

$$y = \frac{185\ x^3 + 15000\ x + 122800}{x^3 + 19\ x + 1000}$$

was found to describe the observed values well. In this equation y is the neuronal RNA content in pg and x the age of the animal in days.

Neuronal RNA content in relation to body size. It is evident by comparing Figs. 7 and 12 that the increase in neuronal RNA content principally occurs before the main growth spurt of the whole body.

In Fig. 13 the neuronal RNA content is plotted against total body weight. The scatter diagram shows a steep, nearly linear rise in the neuronal RNA content up to a body weight of approximately 50 g. Above this body weight there is only

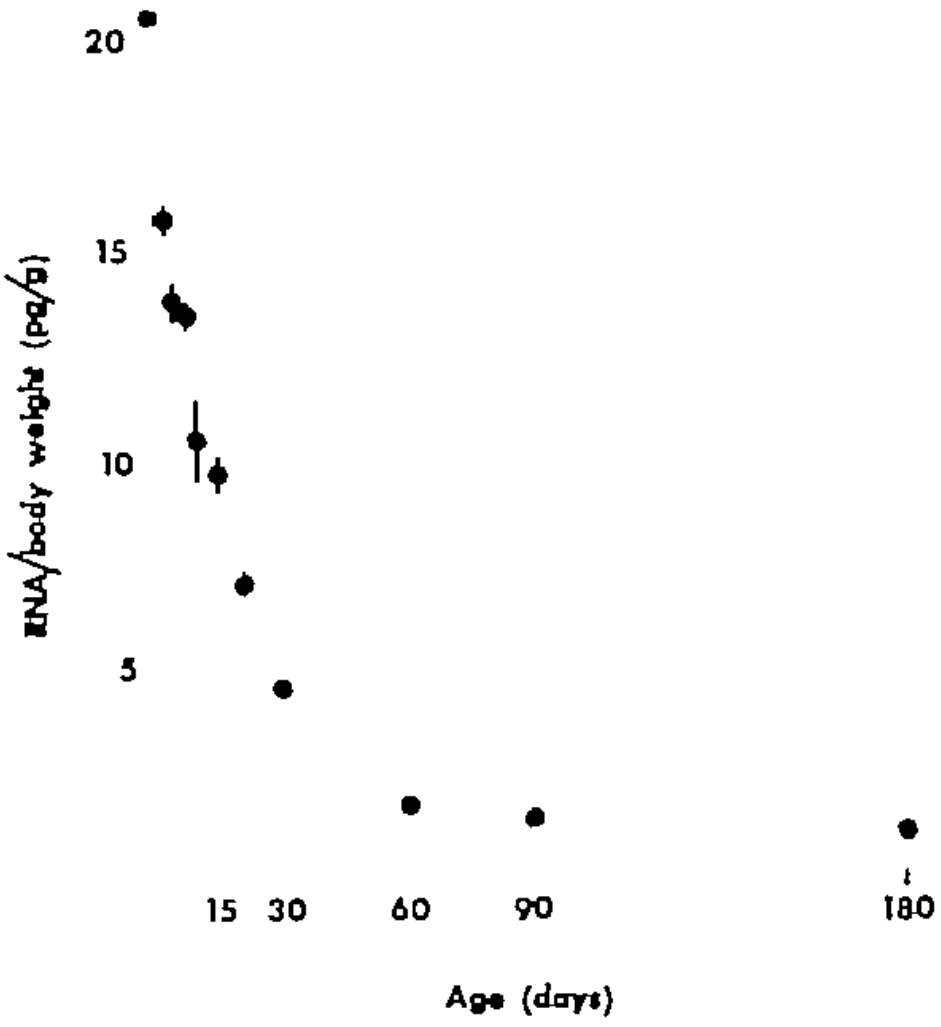

Fig. 14 Mean neuronal RNA content/body weight ratio ± S.E.M. in normal rats plotted against age. Each point represents the mean value for 6 animals.

a very slight increase in neuronal RNA content. An attempt has been made to describe the neuronal RNA content in relation to body weight with a single equation. The simplest function which describes the values actually observed satisfactorily was found to be a rational function

$$y = \frac{520\,x - 2100}{x + 14}$$

In this equation y is the neuronal RNA content in pg and x is the body weight of the animal in g. There was a rapid decrease in the neuronal RNA content/body weight ratio after birth (Fig 14)

A scatter diagram (Fig. 15) suggesting a roughly linear correlation was again obtained when the mean values for the neuronal RNA content were plotted against sextremity lengths (see p. 26).

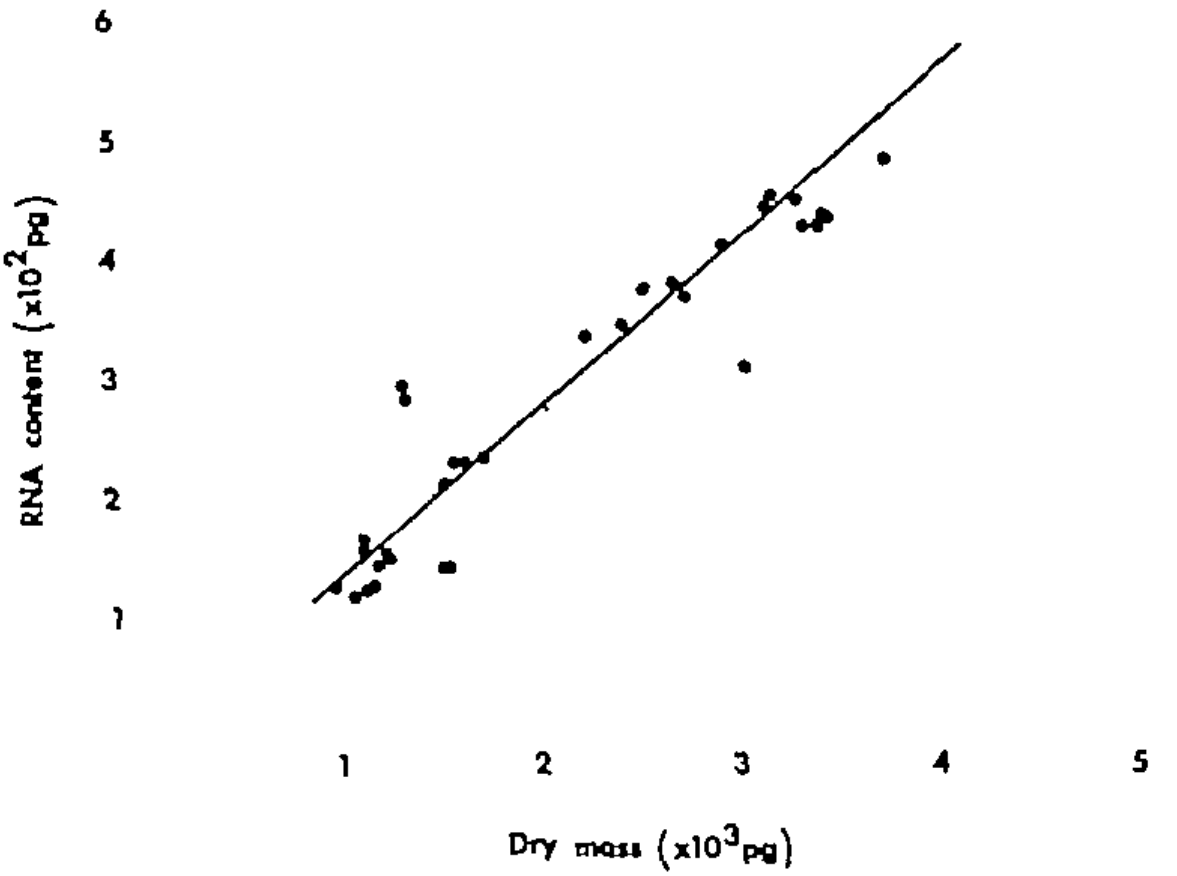

Fig. 17 Mean neuronal RNA content of normal rats of various ages plotted against corresponding mean neuronal dry mass. The regression line has been calculated by using the method of least squares.

reaches a high level at about 8 days of age. This level is then maintained until adult age

C. Discussion

The entire population of large spinal anterior horn neurones studied appears to follow a rather uniform developmental pattern. There is a shift of the whole frequency distribution of both neuronal dry mass and RNA content indicating an increase in the dry mass and RNA content of all cells of the population studied. On the other hand, the distribution range of both of these parameters is widened with advancing age reflecting differences in the rate of accumulation of cell constituents between individual anterior horn neurones. This agrees with the volumetric observations of Mellstrom and Skoglund (1980) of a differential growth rate of cat anterior horn neurones during postnatal development. At all ages they also noted a persistent peak, corresponding to the volume groups with the highest frequencies during the immediate postnatal period. Such a peak was not observed in the present study obviously because of the different principles of sampling.

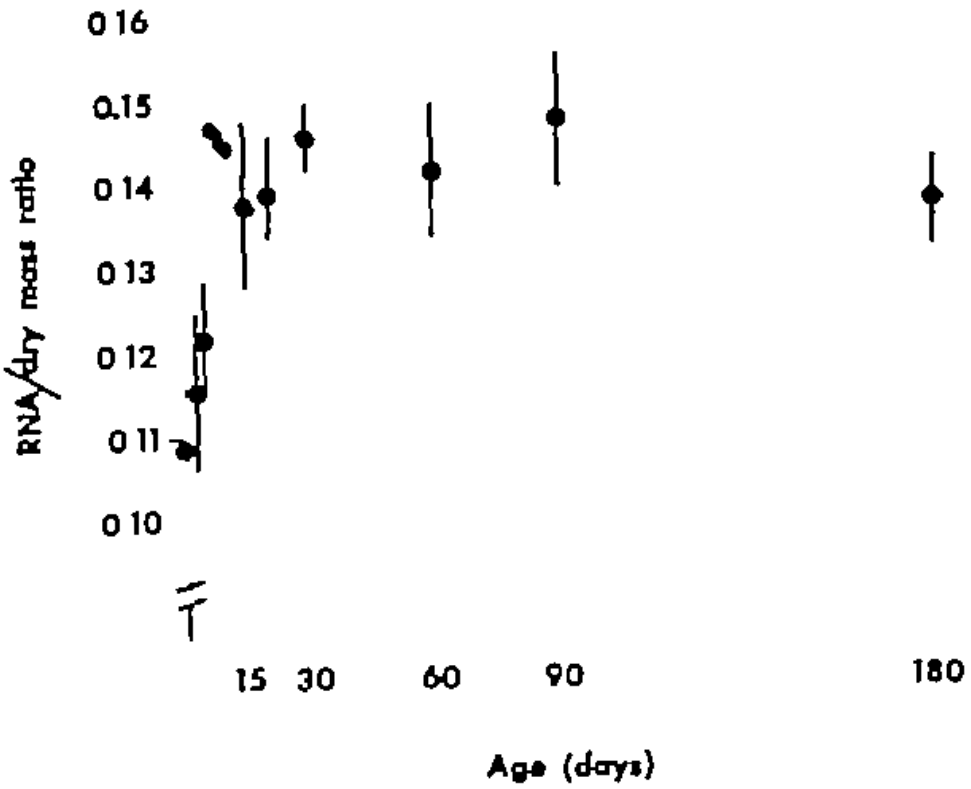

Fig. 18. Mean neuronal RNA content/dry mass ratio ± S.E.M. in normal rats plotted against age. Each point represents the mean value for 6 animals.

The variation in the neuronal dry mass values appears to be considerably higher than in RNA values. This is obviously partly due to the larger methodological error of the mass determinations. A further explanation is that the RNA determinations were performed in pairs, which reduces the biological variation by a factor of $\frac{1}{\sqrt{2}}$. A true difference in the biological variation of neuronal dry mass and RNA content cannot be excluded, however.

Treatment of the experimental results according to the principles of simultaneous statistical inference (Miller 1966) provides a sound basis for the assumption that the curve representing the mean neuronal dry mass as a function of age is convex-concave (S-shaped). The same is true for the mean neuronal RNA content as a function of age. This means that there is relatively little change in the mean dry mass and RNA content of anterior horn neurones during the first three to five days of postnatal life. Between days 5 and 8 an abrupt increase in mean neuronal RNA content is observed, followed slightly later between days 8 and 10, by a rapid augmentation of neuronal dry mass. A similar acceleration of the growth rate of cat anterior horn neurones at about 14 days of age was noted by Mellström and Skoglund (1969) in their volumetric study. They suggested that this

change in growth rate might be associated with simultaneous qualitative alterations in the metabolism of anterior horn neurones (see below)

The rapid increase in neuronal dry mass and RNA content continues up to 15 days of age and then slows down slightly Nearly adult values are reached at 30 days of age after which only relatively small increases in dry mass and RNA content occur in the anterior horn neurones. An increase in diameter (Donaldson and Nagasaka 1918 and volume (Ford and Cohan 1968) of the cell body of rat spinal anterior horn neurones during the later phases of postnatal development has been reported to follow a similar course. If the differences in the time scale are taken into consideration, the results of Mellström and Skoglund (1960) concerning the postnatal increase in the volume of cat spinal anterior horn cells also fit into this general pattern Sakla (1959) found that the volume of mouse anterior horn cells decreased after the age of 20 days, but his method is open to criticism (Mellström and Skoglund 1969).

It would be tempting to compare the postnatal changes reported to occur in neuronal volume with those in dry mass or RNA content in order to obtain information about possible changes in the concentration of protein or RNA. Unfortunately such comparisons prove to be rather fallacious. Mellström and Skoglund (1969) found a 3.8-fold increase in the mean volume of cervical anterior horn neurones of cats from birth to maturity This figure is close to the 3.3-fold augmentation of neuronal dry mass in rats found in the present study However even if relative volume changes of the same order were measured in rats, this would not justify the conclusion that the protein concentration of anterior horn neurones remains constant during development. As pointed out by Mellström and Skoglund (1969) figures for relative changes in cellular volume during development obtained by measurements on fixed tissue, are probably too high. The X-ray microradiographic observations of Brattgård (1952) and Sourander (1953) suggest, in fact that the neuronal protein concentration actually increases during development

The observations made during the present study on the dry mass and RNA content of mature rat anterior horn neurones appear to be consistent with data provided by previous investigations on other species if due allowance is made for the differences in sampling and the level of the spinal cord. The mean neuronal dry mass after lipid extraction of large spinal anterior horn neurones from the antero-lateral nucleus of the 7th cervical segment of the 180-day-old rats was 3.60×10^3 pg Assuming that lipids constitute about 20 per cent of the total dry mass of the neuronal cell body (Hydén 1960) the total dry mass of these cells would be of the order of 4.5×10^3 pg. This figure is somewhat lower than that reported by Embree *et al* (1967) for rabbit cervical anterior horn neurones (6.7×10^3 pg) They used the same method as was used in the present study for mass determination. Lowry (1957), in an example, quotes the figure 5.8×10^3 pg for the mass of spinal anterior horn cells dissected free hand from freeze-dried material and

weighed with quartz fiber balance. The largest values obtained in the present study correspond to a total mass of 7—8 × 10^3 pg which agrees well with the figures given by Hydén (1960) for anterior horn cells investigated by x ray microradiography

It is hardly possible to compare the dry mass values obtained in the present study with those recently published by Ford and Cohan (1968) They weighed formalin-fixed lumbar anterior horn neurones, dissected free hand from rats aged 15 days to 180 days, with a Sauter micro balance. The mass values obtained by them are about ten times larger than those reported by other workers and also quite inconsistent with the neuronal volumes obtained by themselves. In an earlier investigation (Ford *et al.* 1965) they explain this as possibly being due to their dissection method, by which varying, considerable lengths of cell processes are taken along with the cell bodies.

The values obtained in the present study for the mean neuronal RNA content of spinal anterior horn cells were 500 pg for the 90-day-old rats and 497 pg for the 180-day-old rats. These figures agree well with those given by Edström (1956) for rabbit motor anterior horn cells from the anterolateral nucleus at the thickest part of the cervical enlargement. The values given by Embree *et al.* (1967) for corresponding cells are somewhat higher

As noted above, an acceleration in the increase in the RNA content and dry mass of the anterior horn neurones was noted between 5 and 10 days of age. During this period there is a very distinct peak in the rate of net accumulation of RNA and dry mass, suggesting an increased rate of synthesis of RNA and protein, although the degradation rate might also change during development, as observed at the whole brain level (Oja 1967). The regulation mechanisms controlling the RNA synthesis (transcription) and protein synthesis (translation) in developing mammalian cells are poorly understood, especially as regards such factors as developmental changes in the activity of DNA-dependent RNA polymerase or precursor pools (Mandel and Jacob 1970) Therefore only some tentative suggestions can be made to explain this sudden increase in the rate of accumulation of RNA and protein in the anterior horn neurones.

At the neuroblast stage the beginning of the rapid elaboration of the Nissl substance and of RNA in the cytoplasm seems to depend on the maturation of the nucleolus (e.g. Hydén 1943, Flexner 1955, Sensenbrenner and Mandel 1967 Lodin *et al* 1968). A well developed nucleolus, however is already present in the spinal anterior horn neurones of the rat before birth (Hydén 1943) indicating that other explanations must be sought for the sudden postnatal increase in the rate of RNA accumulation.

Mellstrom and Skoglund (1960) suggested that the postnatal change in the growth rate of cat anterior horn neurones might be associated with alterations in the energy metabolism of these cells. A great increase in the number of mitochondria was demonstrated in cat motoneurones during the first 20 days after

birth. A coincident change in the NAD-diaphorase activity was also observed (Skoglund 1967). These and other simultaneous alterations (Mellström and Skoglund 1969) indicate an increase in aerobic metabolic processes. The accompanying increase in the efficiency of energy production might lead to an intensified synthesis of both RNA and protein. In the rat, as well, the oxygen consumption of the nervous tissue, activity of enzymes linked to the oxidative metabolism, and number of mitochondria increase rather abruptly around the 10th day postnatally (cf. Flexner 1955 Richter 1967 Seller 1969) It is assumed that most of the increase in energy turnover in this period of development is correlated with an increase of the adenosinetriphosphatase system. Thus it may be significant that adenosinetriphosphatase activities start to increase around the 6th day after birth (cf. Seller 1969), coincident with the abrupt acceleration of the rate of RNA accumulation in the anterior horn neurones.

The bulk of the cellular RNA is contained in the cytoplasmic ribosomes (Datta 1966) which constitute an essential part of the protein-synthesizing apparatus of the cell (cf De Man and Noorduyn 1969) Not only an increase in the number of ribosomes (e.g Eschner and Glees 1963, Wechsler 1966) which may thus be interpreted as the morphological counterpart of the increase in the neuronal RNA content, but also a change in the ratio free/membrane-bound ribosomes in maturing nerve cells may influence the rate of protein synthesis during cytodifferentiation (Wechsler and Kleihues 1968, Murthy 1970) Recent evidence suggests that hormones may also influence the rate of neuronal protein synthesis during development, operating primarily through the regulation of polyribosome formation and translation (Tata 1968, Geel and Timiras 1970).

The RNA/dry mass ratio appears to rise during the first 8 days of postnatal life in the cell bodies of the anterior horn neurones, to remain thereafter at an extremely high level. This is in clear contrast to most other somatic cells where the amount of RNA diminishes rapidly in relation to the cellular protein content during the later phases of development (Winick and Noble 1965) The exceptional characteristics of the postnatal RNA and protein metabolism of the neurone may be illustrated by comparing the present cytochemical data with biochemical findings at the organ level. In the whole rat brain the RNA/DNA ratio reflecting the mean cellular RNA content in the brain, was found to rise only up to about 14 days of age, and then to level off On the other hand, there was a consistent, pronounced rise in the protein/DNA ratio up to adult age (e.g Winick and Noble 1965 Oja 1966, Balazs et al. 1968) This results in a rapid decrease in the RNA/protein ratio of brain cells after birth This striking difference between the development of the RNA/protein ratio in the anterior horn cells and the average brain cell probably reflects profound differences in the RNA and protein metabolism of the neurones and glial cells, which are known to differ in their metabolism also in many other respects (Hamberger 1963, Hydén 1968).

The increasing RNA/protein ratio in the cell bodies of the anterior horn neurones

is followed by an increase in the rate of protein accumulation, as evidenced by the sudden increase in the dry mass of the cell body But in spite of the nearly constant dry mass of the cell body after the age of 30 days the RNA/protein ratio remains at an extremely high level until adult age, reflected morphologically by the tremendous number of ribosomes contained in the Nissl substance of adult neurones (Palay and Palade 1955, Peters *et al* 1970) This suggests continued active protein synthesis in the neuronal cell bodies, direct evidence for which has been obtained from studies of incorporation of labeled amino acids (Fisher *et al.* 1956 Altman 1963, Ford and Rhines 1967 Ford *et al* 1967). A possible explanation, for the persistence of this extensive protein-synthesizing apparatus is the dependence of the neuronal processes on the cell body The cell body remains the major site of macromolecular synthesis in the neurone and apparently has to cover the protein needs for the growth and maintenance of the increasingly long cellular processes (cf Weiss 1969 Drox and Koenig 1969 1970) although evidence for some local protein synthesis in the Mauthner axon of fish and in the nerve endings has been presented (cf A Edström 1969 Barondes 1969 Austin *et al* 1970) The persistence of the extremely high RNA/protein ratio in the neuronal cell body may thus reflect the unique cytological organization of the neurone.

It appears reasonable to suppose that the size of the central protein-synthesizing apparatus, reflected by the RNA content of the cell body is at least partly determined by the extent of the neuronal processes. In the large anterior horn neurones innervating the musculature of the extremities (like in those of the 7th cervical segment) the axon is by far the dominating cellular process because of its huge length. If it is assumed that the length of the axon changes in proportion to the length of the extremity then the observation that the RNA content of the cell body increases at roughly the same rate as the length of the extremity suggests, in fact, that a close relationship exists during development between the RNA content of the cell body and axon length.

Previous volumetric studies on the relation between neuronal and somatic growth gave conflicting results. Donaldson and Nagasaka (1918) and Levi (1925) concluded that the volume of spinal ganglion cells increased in proportion to the body area (square of the cube root of body weight) Other investigators found that the rate of growth of the spinal ganglion cells was proportional to the body weight (Olivo *et al.* 1932, Rondinini 1936) and that the growth of the spinal ganglion cells in man continued during the entire life (Pilati 1938). Donaldson and Nagasaka (1918) also noted that the growth in volume of the spinal anterior horn neurones did not follow the same pattern as that of spinal ganglion cells.

If the increase in dry mass is used as an indicator of neuronal growth it is evident that no linear correlation exists between the dry mass of the cell body of the anterior horn neurones and the body weight or body area. The same is true for the neuronal RNA content There is a consistent, rapid drop in the neuronal

dry mass/ body weight ratio as well as in the neuronal RNA content/body weight ratio during postnatal development, indicating that the growth rates of the muscle and the nerve cell bodies are quite different. The real differences in the growth rates are actually still more pronounced as the percentage of muscle of the body weight increases markedly during development (Miller 1960). On the other hand, the dry mass of the nerve cell body appears to increase roughly at the same rate as the length of the extremity. This might indicate that the size of the cell body of an anterior horn neurone is more related to the length of its axon than to the size of its peripheral field of innervation.

Although there was a remarkable increase in the content of RNA of the anterior horn neurones during postnatal development, no significant changes were observed in its base composition. Ringborg (1966) offered as a possible explanation for the increase in the guanine-cytosine/adenine-uracil-ratio observed by him in the pyramidal cells of rat hippocampus that this change might be due to the relative increase in the ribosomal RNA (which has a higher content of guanine and cytosine; Hydén and Egyházi 1962) as opposed to nuclear RNA. This explanation seems quite tenable for the cells of the Ammon's horn which are very immature at birth with extremely scanty cytoplasm in relation to the relatively large nucleus. This is not the case with the anterior horn cells which already have a relatively well developed cytoplasm at birth and in which, consequently the ratio of ribosomal to nuclear RNA need not markedly change.

IV NEURONAL DRY MASS AND RNA CONTENT IN RATS SUBJECTED TO POSTNATAL UNDERNUTRITION

A. Review of the literature

In the early years of this century Donaldson and his collaborators carried out extensive studies, thoroughly reviewed by Jackson (1925), on the effect of under nutrition on the nervous system of adult and growing rats. They found that brain weight was little affected by undernutrition instituted after weaning (Hatai 1908, Donaldson 1911 Jackson 1915). On the other hand, undernutrition from birth to weaning resulted in brain weights below normal for corresponding age but above normal for corresponding body weight (Stewart 1918 a, b Sugita 1918). These early observations on the susceptibility of the developing nervous system to undernutrition were confirmed and extended during recent years by a number of workers using mainly neurochemical methods (cf Dobbing 1968, Counan 1968, Miller 1969 Winick 1969).

Dobbing studied the process of myelination in undernourished pigs and rats, as reflected by changes in cholesterol concentration. He found that undernutrition instituted during the period of active myelination resulted in a permanently lowered brain cholesterol concentration. On the basis of these studies he put forward the general hypothesis that the period of fastest developmental change might be one of heightened vulnerability (Dobbing 1966, 1968). The studies of Winick and collaborators (Winick and Noble 1966, Winick and Rosso 1969) concerning the cellular growth of the brain lend further support to this hypothesis. They demon strated that the total DNA content of the brain in rats and children subjected to undernutrition during the early postnatal period was markedly lower than that of normal controls. This indicates that undernutrition curtails cell division in the brain during the period of active cellular proliferation.

The neurochemical observations cited above, however do not give any infor mation concerning the effect of undernutrition on the nerve cells. The macro-neurones of the rat brain are formed prenatally (Altman and Das 1966) and it is thus not probable that postnatal undernutrition would reduce their number through inhibition of the proliferation of neuroblasts. On the other hand, there is some histological evidence indicating that early undernutrition might affect the growth and maturation of nerve cells. Sugita (1918) reported that the size of cortical neurones was diminished in rats undernourished from birth. Eayrs and

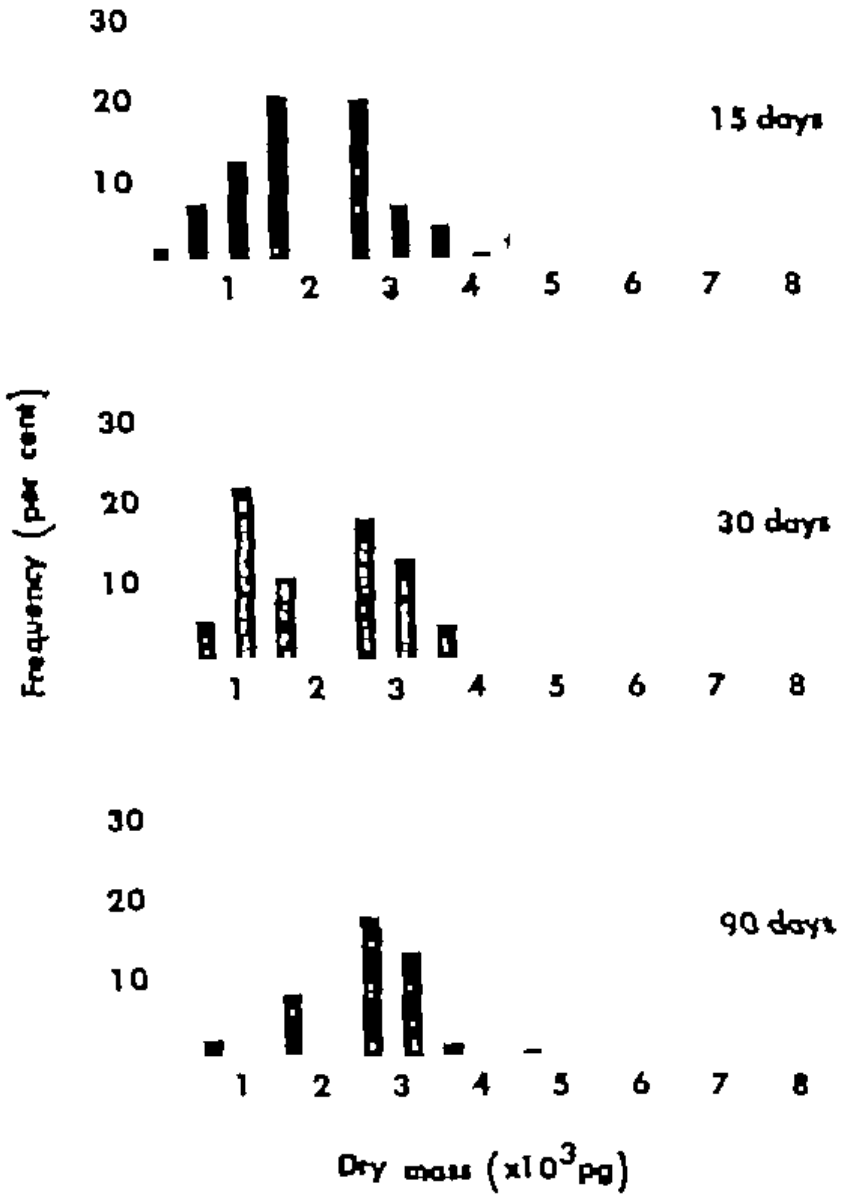

Fig. 19 Frequency distribution of the dry mass of the cell bodies of spinal anterior horn neurones of rat undernourished from the age of 1 day and sacrificed at 15, 30 or 90 days of age (dark stippled) compared with the corresponding frequency distribution for normal rats of the same age (light stippled).

Horn (1955) noted a decrease in the amount of cortical neuropil in such rats. Platt and collaborators observed consistent abnormalities in the spinal anterior horn cells of protein-calorie deficient pigs and dogs. The nerve cells exhibited an apparent loss of Nissl substance (Stewart *et al* 1968).

B. Results of the present investigations

1 Neuronal dry mass

Table VI gives the mean values, S.E.M., and frequency distributions in groups of 0.50×10^3 pg of the neuronal dry mass after lipid extraction of the spinal

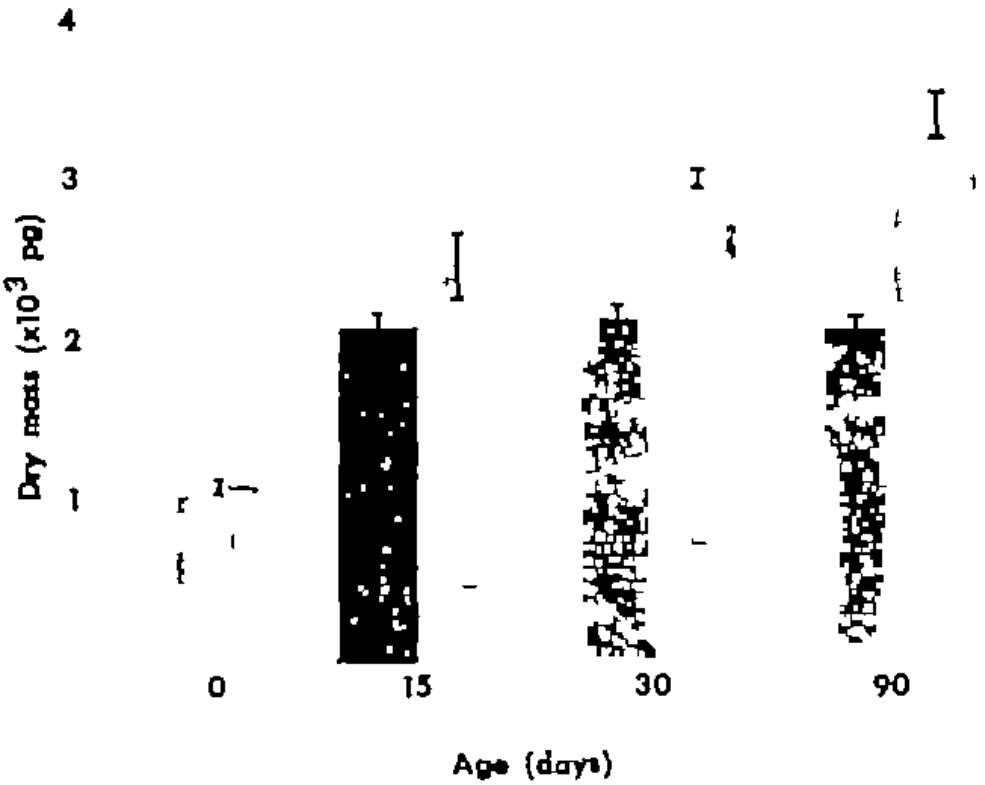

Fig. 20. Mean dry mass of the cell bodies of spinal anterior horn neurones in the various age groups of undernourished rats (dark staples) compared with the corresponding values for normal rats of the same age (light staples).

anterior horn neurones from the 7th cervical segment of rats undernourished from the age of 1 day and sacrificed at the ages of 15 30 or 90 days.

As the body weight, neuronal dry mass and neuronal RNA content of the control animals (table V) did not differ significantly from those of normal animals of the same age the values for the undernourished animals are in the following compared directly with corresponding figures for normal rats. In Fig. 19 the frequency distribution of the neuronal dry mass in undernourished rats is compared with that of normal rats of corresponding age. It is evident that the distributions differ from each other In the normal rats there is a marked shift of the median to the right and an increase in the distribution range with advancing age, i e. the number of cells with high mass increases. In the undernourished rats, on the contrary the distribution does not essentially change after the age of 15 days.

In a comparison of the mean neuronal dry mass values of the undernourished rats (Table VI) and those of normal rats of corresponding age (Table IV) it will be seen that in all age groups the values for the undernourished rats are markedly lower (Fig 20). There is already a statistically significant difference ($p<0.05$) between the experimental and the normal group at the age of 15 days. This difference becomes more accentuated at 30 and 90 days of age ($p < 0.001$) as the mean neuronal dry mass of the undernourished rats remains at a practically constant

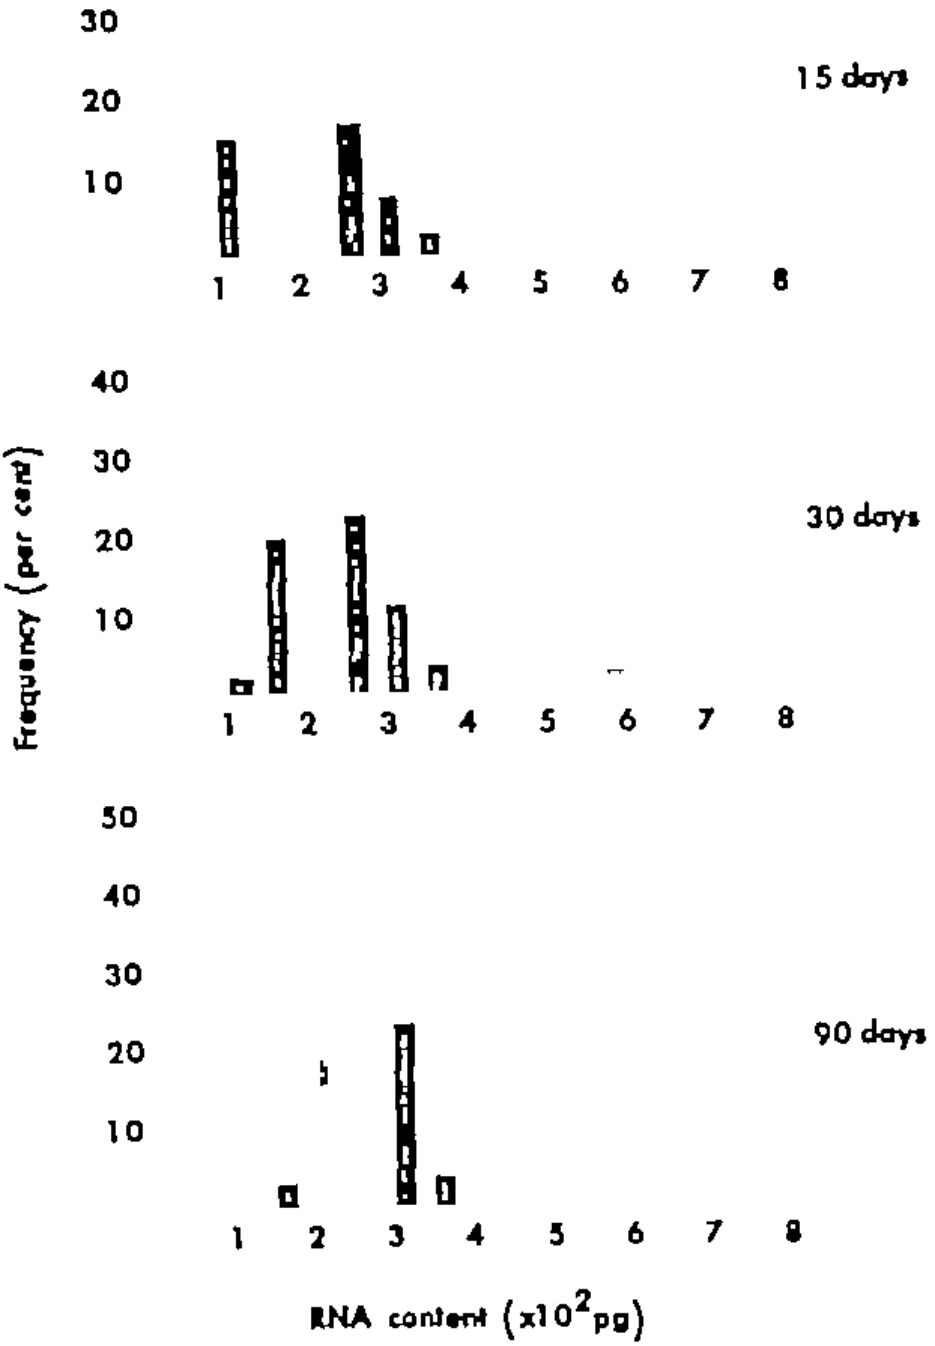

Fig. 21 Frequency distribution of the RNA content f the cell bodies f spinal anterior horn neurones of rats undernourished from the age of 1 day and sacrificed t 15, 30 or 90 days f age (dark staples) compared with the corresponding frequency distribution for normal rats of the same age (light staples).

level (between 2.10 and 2.10 $\times$ 10^3 pg) whereas a marked increase is noted in the neuronal dry mass values of the normal animals (from 2.51 to 3.15 $\times$ 10^3 pg).

It may be noted that the mean neuronal dry mass value (2.10 $\times$ 10^3 pg) of the 15-day-old undernourished rats (mean body weight 9.8 g) is markedly and significantly ($p < 0.001$) higher than the mean neuronal mass values of 3-day-old

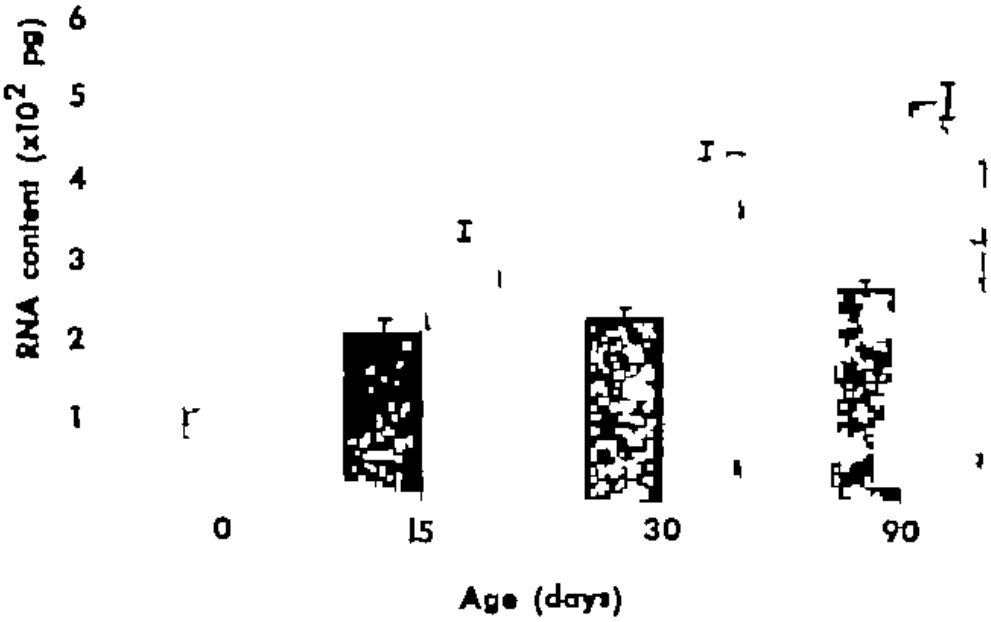

Fig. 22. Mean RNA content of th cell bodies of pinal anterior horn neurones in the different age groups of undernourished rats (dark taples)compared with the corresponding values for normal rats f the same age (light taples).

(1.27×10^3 pg) or 5-day-old (1.37×10^3 pg) normal rats of approximately similar body weight (mean body weight 9 1 g and 11.8 g, respectively). It is thus evident that the neuronal dry mass/body weight ratio increases after birth in the under nourished animals in contrast to the rapid decrease of the ratio in normal rats.

2. *Neuronal RNA content*

The mean values, S.E.M., and frequency distributions in groups of 25 pg of the neuronal RNA content of the undernourished rats are shown in Table VII.

The frequency distribution of the neuronal RNA content in the various experimental groups, as compared with that of normal animals of corresponding age, is shown in Fig 21 The distributions of the experimental and normal groups differ very markedly from each other at all ages studied. In the experimental animals there is practically no shift of the distribution to the right or increase in the distribution range with advancing age, such as is observed in the correspond ing normal rats. Whereas more and more cells with high RNA content occur in the normal groups with advancing age, such differentiation of spinal anterior horn neurones is not observed in the undernourished animals.

The mean values for the neuronal RNA content of the undernourished animals are markedly lower ($p < 0.001$) than normal values (Fig. 22) in all age groups. The differences increase with advancing age as the neuronal RNA content of normal animals becomes larger whereas the values for the undernourished animals remain at a low level. At 90 days of age the mean neuronal RNA content of the undernourished group (275 pg) is 16 per cent lower than the corresponding normal value (509 pg).

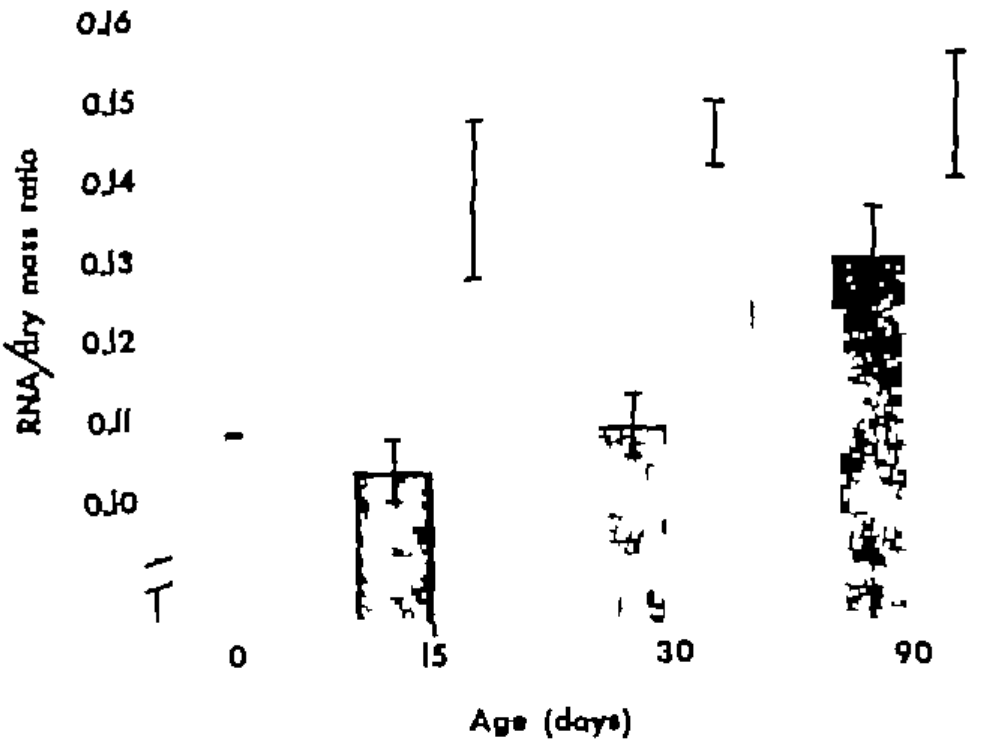

Fig. 23. Mean neuronal RNA/dry mass ratios ± S.E.M. in the different age groups. I under nourished rats (dark staples) compared with those for normal rats of the same age (light staples).

The mean neuronal RNA content of 15-day-old undernourished rats is markedly higher ($p < 0.01$) than that of 3 or 5-day-old normal animals of similar body weight. The neuronal RNA content/body weight ratio of the undernourished animals thus seems to increase postnatally unlike that in normal rats.

The mean neuronal RNA content/dry mass ratios are consistently lower in the undernourished animals than in the control animals of corresponding age (Fig. 23). These differences are statistically significant in the case of the 15 and 30-day-old animals ($p < 0.02$ and $p < 0.001$ respectively).

C. Discussion

At all ages studied both the mean neuronal dry mass and mean neuronal RNA content of the undernourished animals were significantly lower than the corresponding values for normal rats of the same age. This effect was already evident in the 15-day-old animals. It is interesting to note that further periods of undernutrition up to 90 days of age did not essentially change the neuronal dry mass and RNA values established during the first 15 days after birth i.e. during the period of most intense accumulation of RNA and dry mass in the anterior horn neurones in normal rats. These observations emphasize once more the importance of the immediate postnatal period for the chemical maturation of the neurone and demonstrate the sensitivity of the maturational processes to nutritional deprivation.

It may be noted that the distributions of both the neuronal dry mass and RNA content of the undernourished animals remain within a very narrow range, indicating that the differential growth of the neurones is impaired The neuronal RNA content appears to be more affected than the neuronal dry mass, as reflected by the low neuronal RNA/dry mass ratios, recalling the histological observations of a loss of Nissl granules in the anterior horn neurones of undernourished pigs and dogs (Stewart *et al* 1968) This might have unfavorable consequences for the neuronal protein synthesis.

The precise mechanism of the effect of undernutrition on neuronal maturation can only be a matter of speculation. Miller (1969) has stressed the important and central role of diet in the regulation and maintenance of development. It is obvious that diet provides the necessary precursor pools for macromolecular synthesis and that a reduction in pool size may affect the synthetic rate. But the explanation for the reduced neuronal RNA content and dry mass of the undernourished rats may be more complicated, and disturbances in enzyme patterns, in the energy metabolism or in hormonal regulation may be involved.

The mean neuronal dry mass and RNA content of the 15-day-old undernourished rats was much higher than in normal animals of similar body weight. This dissociation of neuronal and somatic growth in young animals illustrates the relative independence of neuronal development from increase in body mass. This observation also suggests the existence of efficient protection mechanisms which allow the nerve cells to grow at the expense of most other cells of the body

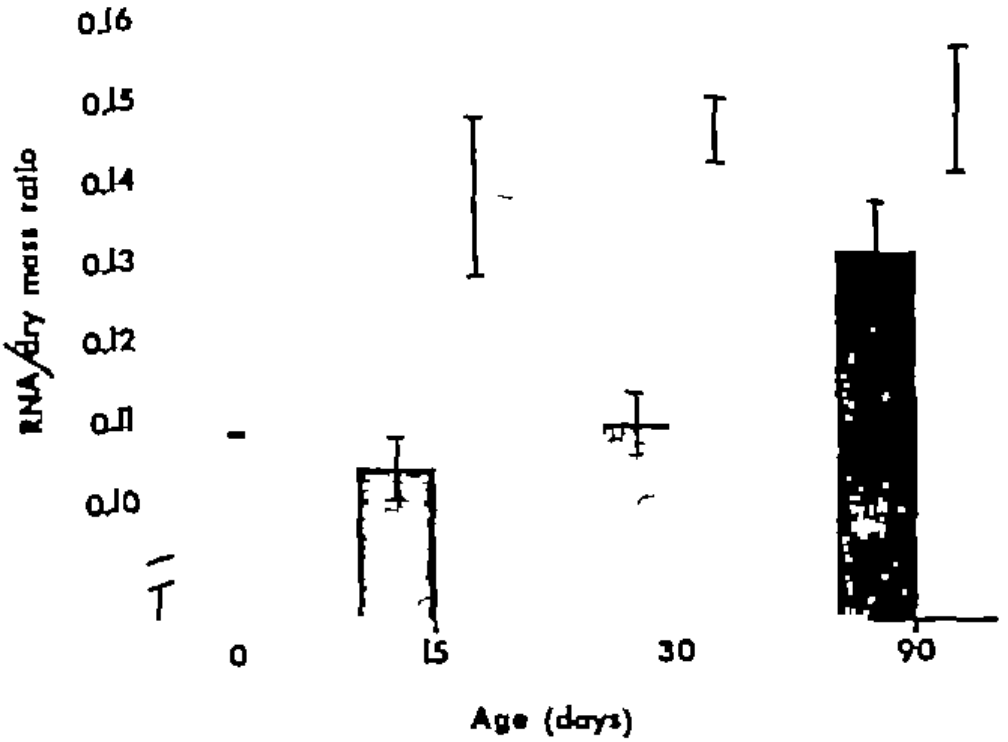

Fig. 23. Mean neuronal RNA/dry mass ratios ± S.E.M. in the different age groups of undernourished rats (dark staples) compared with those for normal rats of the same age (light staples).

The mean neuronal RNA content of 15-day-old undernourished rats is markedly higher ($p < 0.01$) than that of 3 or 5-day-old normal animals of similar body weight. The neuronal RNA content/body weight ratio of the undernourished animals thus seems to increase postnatally unlike that in normal rats.

The mean neuronal RNA content/dry mass ratios are consistently lower in the undernourished animals than in the control animals of corresponding age (Fig. 23). These differences are statistically significant in the case of the 15 and 30-day-old animals ($p < 0.02$ and $p < 0.001$ respectively).

C. Discussion

At all ages studied both the mean neuronal dry mass and mean neuronal RNA content of the undernourished animals were significantly lower than the corresponding values for normal rats of the same age. This effect was already evident in the 15-day-old animals. It is interesting to note that further periods of undernutrition up to 30 days of age did not essentially change the neuronal dry mass and RNA values established during the first 15 days after birth, i.e. during the period of most intense accumulation of RNA and dry mass in the anterior horn neurones in normal rats. These observations emphasize once more the importance of the immediate postnatal period for the chemical maturation of the neurone and demonstrate the sensitivity of the maturational processes to nutritional deprivation.

VI. SUMMARY AND CONCLUSIONS

Changes in the dry mass after lipid extraction (reflecting the protein content) and RNA content of isolated cell bodies of large spinal anterior horn neurones from the anterolateral nuclei of the 7th cervical segment were studied during normal postnatal development of the rat, in animals subjected to controlled undernutrition from birth for various periods, and in animals subsequently rehabilitated.

The cell bodies of the anterior horn neurones were isolated by micromanipulation from Carnoy-fixed tissue sections. The neuronal dry mass was determined with the aid of Rosengren's direct X ray absorption method. Edström's microchemical methods were used for determinations of the neuronal RNA content and base composition. A state of severe undernutrition was produced by daily isolation of the young rats from the mother. After weaning they were given restricted amounts of a defined balanced diet.

The main observations may be summarized under the following points:

1. The neuronal dry mass was found to increase 3.3 times, and the neuronal RNA content 4.2 times from birth to the age of 180 days.

2. A marked acceleration of the rate of increase of the neuronal RNA content was observed between 5 and 8 days of age and a corresponding distinct peak in the rate of increase of the neuronal dry mass between 8 and 10 days of age.

3. The rapid increase in both neuronal dry mass and RNA content slowed down after the age of 15 days and nearly adult values were reached at 30 days of age. No significant changes were noted after the age of 90 days.

4. The RNA/dry mass ratio of the neuronal cell bodies appeared to increase from birth up to 8 days of age to remain thereafter at approximately the same very high level until adult age.

5. A consistent rapid decrease was found postnatally in the neuronal dry mass/body weight ratio and the neuronal RNA content/body weight ratio. On the other hand, the neuronal parameters studied appeared to increase roughly in proportion with the length of the extremity assumed to reflect axon length.

6. At all ages studied both the neuronal dry mass and RNA content of the undernourished animals were significantly lower than the corresponding values for normal rats of the same age. Further periods of undernutrition did not essentially change the neuronal dry mass and RNA values established during the first 15 days after birth.

7 The neuronal RNA content was more affected than the dry mass resulting in a lowered neuronal RNA/dry mass ratio in the undernourished animals.

8. The neuronal dry mass values of the rehabilitated animals were only slightly lower than those of normal rats of the same age. The neuronal RNA values of the rehabilitated rats, on the other hand, remained at a remarkably low level.

These results show that the intense accumulation of RNA and protein, previously demonstrated in the neuroblasts of embryonal rat spinal cord, not only *continues after birth but that by far the major part of this accumulation actually* occurs postnatally During this »third period of growth» of the neurone the RNA/protein ratio appears to increase in the cell body in contrast to other somatic cells.

These maturational changes take place during an early and limited period, mainly between 5 and 15 days of age. Caloric restriction imposed during this period results in marked disturbances in the growth and chemical maturation of the neurone which are only partly reversed by rehabilitation.

ACKNOWLEDGEMENTS

This study was carried out at the Neuropathological Laboratory Department of Pathology I, and at the Institute of Neurobiology Univeraity of Göteborg

I would like to express my sincere gratitude to Associate Professor Patrick Sourander M.D., who stimulated me to perform the present investigations, for his guidance, encouraging support and constructive criticism throughout the work, and for the opportunity to use the resources of his laboratory

I am very much obliged to Professor Holger Hydén, M.D., for his interest in my work, for valuable advice, and for generously providing me with necessary laboratory facilities.

To Professor Jan Mellgren, M.D., I want to express my thanks for kindly placing the departmental facilities at my disposal.

I am greatly indebted to Assistant Professor Bengt Rosengren, M.D., for expert advice, and for kindly allowing me to use his equipment for mass determinations.

My sincere thanks are due to Professor Jan-Erik Edström, M.D Karolinska Institutet, Stockholm, and Assistant Professor Jan Jarlstedt, M.D., for expert advice and for introducing me into the technical details of the RNA analyses.

I am most grateful to Associate Professor Lars Svennerholm, M.D., and Associate Professor Sanford A. Miller Department of Nutrition and Food Science, Massachusetts Institute of Technology for advice and stimulating discussions, and Assistant Professor Bo Hallgren, M.D Astra Nutrition Research Laboratories, for providing me with the experimental diet.

I would like to express my great appreciation to my teachers, Professor Harald Teir and Professor Erkki Kivalo, University of Helsinki, for their continued interest in my work, and for their support in various ways.

My heartfelt thanks are due to my Colleagues at the Departments of Pathology and Histology for their cooperation and support during my stay in Goteborg.

I am glad to extend my sincere thanks to Miss Hermengild Schucht for her superb, devoted technical assistance during the entire study I am grateful to Miss Kristina Müntzing, Miss Margareta Persson and Miss Ann-Christine Bergquist for their technical assistance in some parts of the present investigation.

Miss Henrietta Ågren, dietist, helped me in dietary questions. Mr Anders Odén, M.A., Department of Mathematics, University of Göteborg, gave me expert advice and performed the more complicated statistical analyses. Mrs. Lotte

Troupp M.A., checked my English manuscript. I wish to thank them for their kind cooperation.

I am grateful to my wife, Dr Tuula Haltia, for her patient help and encouragement.

This work was done during the tenure of a research fellowship of the Finnish Medical Research Council. The costs have been partly defrayed by a grant from the Swedish Medical Research Council No. B70—12X—82—06B to Associate Professor Patrick Sourander. A travel grant from the University of Göteborg, donated from the Knut and Alice Wallenberg Foundation, is gratefully acknowledged.

Abstract

Andersson K. E., G Gennser and E. Nilsson *Influence of contraction rate coronary perfusion pressure and diastolic pressure on the mechanical performance of isolated human foetal hearts.* Acta physiol. scand. 1970. *80* Suppl. 353 5—19.

Left intraventricular pressure and electrogram were recorded in isolated hearts, perfused *ad modum* Langendorff, from human foetuses at midgestation. The Frank-Starling mechanism could be demonstrated in these preparations. An increase in coronary perfusion pressure increased both the active systolic pressure and the end diastolic pressure. Active systolic pressure declined at contraction rates above the spontaneous one both during perfusion with a Ringer's solution and with an erythrocyte suspension. A lowering of the contraction rate, induced by excision of the sinus node region and/or addition of acetylcholine to the perfusion solution, increased the active systolic pressure. The rate of rise of intraventricular pressure decreased both at contraction rates above and below the spontaneous one, whereas the duration of the contractile cycle measured at 50 % level decreased with increasing contraction rates at all frequencies studied. The frequency dependence of the active systolic pressure in isolated human foetal hearts differs from that of the isometric tension of excised papillary muscles of these hearts (Gennser and Nilsson 1968). This discrepancy is most likely explained by the asynchronous activation of the whole heart. It is concluded that foetal bradycardia *per se* does probably not reduce the mechanical output of the individual foetal heart beat.

Introduction

The isometric twitch tension of isolated ventricle myocardial preparations such as papillary muscles of various mammalian species is dependent upon contraction rate (for references, see Koch Weser and Blinks 1963). In most species the contractile force of excised ventricle preparations is diminished when the contraction rate is reduced below the frequency range normally existing *in vivo*. This has been demonstrated also for papillary muscles from human foetal hearts (Gennser and Nilsson 1968). It was shown that at 30° C the isometric tension of the papillary muscles decreased markedly with decreasing contraction rates below approximately 70 beats per min. The influence of contraction rate upon the mechanical output of the individual foetal heart beat might be considered of great clinical interest, as marked alterations in heart rate are often related to "foetal distress" during delivery

(Quilligan, Katigbak and Hofschild 1965 Caldeyro-Barcia *et al.* 1966, Hon 1968) The present study was undertaken in order to elucidate to what extent the mechanical output of the individual beat of the isolated human foetal heart was influenced by changes in contraction rate. The mechanical parameter measured was the isovolumetrically developed left intraventricular pressure. It was considered of interest to find out how far results obtained in animal experiments might be applicable also to the preparation used in the present study and therefore the influence of coronary perfusion pressure and end diastolic pressure was also analysed.

Methods

Material

This and the following two reports (Andersson, Gennser and Nilsson 1970 a, b) are based upon investigations on 30 human foetal heart preparations performed during the period December 1968—November 1969 The foetal hearts were obtained at legal interruptions of pregnancy performed by hysterotomy Hearts from foetuses with no signs of malformation or intrauterine disorder were used. The estimated gestational age ranged from 14 to 24 weeks and the foetal crown-heel length from 14 to 30 cm. The weight of the heart preparations ranged 0.5—3 g. Due to the technical difficulties in mounting the preparations (depending on the small size and the friability of the hearts) and to the time-consuming experimental procedures used, only a limited number of observations could be obtained from each heart.

Preparation and mounting of the hearts

After the uterine evacuation the hearts were removed from the foetuses as soon as possible Within a few minutes perfusion was started *ad modum* Langendorff at room temperature with an oxygenated Ringer's solution of the composition described below Care was taken to tie the perfusion cannula to the superior part of the ascending aorta to avoid interference with the closure of the aortic valve. During preparation the heart was immersed in Ringer solution and the perfusion pressure was kept at about mm Hg. The preparation was then mounted in a thermostatically controlled bath (volume 25 ml) containing Ringer's solution flowing from the coronary circulation. The temperature of the bath and the perfusing solution was kept at 37±0.5 C During each experiment the hydrostatic perfusion pressure was kept constant. Depending on the size of the hearts, the perfusion pressure was set within the range of 29 to 35 mm Hg This range was chosen on the basis of arterial pressure measurements on human foetuses at midgestation (Enhörning and Westin 1954)

In some experiments, the left part of the insertion of the superior vena cava into the right atrium (the sinus node region) was excised in order to reduce the contraction rate of the heart

Recording techniques

Pressure was recorded within the isovolumetrically contracting left ventricle by means of a Statham pressure transducer. Three different arrangements were used. In two of these a polyethylene catheter (external diameter 1·0 or 1·5 mm, internal diameter 0·5 or 1·0 mm) whose one end was connected to the pressure transducer was inserted into the left ventricle *via* the mitral ostium. The catheter ended either (1) directly in the ventricular cavity or (2) in a thin, nonelastic balloon firmly tied to the catheter. When an intraventricular balloon was used, the catheter connected to the balloon was fixed at the mitral ring by means of a silk suture. The volume of the balloon was chosen larger than the estimated volume of the ventricular cavity. With this type of registration the diastolic volume and hence the diastolic pressure could be altered by changing the volume of the balloon. In a few preparations the catheter connected to the pressure transducer was placed (3) within the aortic perfusion cannula, running into the left ventricle *via* the aortic ostium. In all the cases the pressure recording system was filled with Ringer's solution. In none of the experiments using the open catheter types of registration did the total systolic pressure (see Terminology) exceed perfusion pressure. Left ventricular contractions were therefore considered as isovolumetric also in these preparations.

Before starting an experiment the end diastolic pressure was adjusted to approximately 7 mm Hg, range 3—12 mm Hg. However when an open catheter through the mitral ostium was used for pressure registration, the diastolic pressure could not be altered by changing the volume of the left ventricle probably owing to opening of the mitral valve during diastole. End diastolic pressure in these preparations did not exceed 5 mm Hg at spontaneous contraction rates (95—120 beats per min).

The maximal rate of rise of intraventricular pressure, $(dp/dt)_{max}$, was determined graphically from the curves. The electrogram of the heart was obtained by means of glass electrodes with external tip diameter of 0·5 mm containing Ag/AgCl-wires in 3-M NH_4Cl-agar. One electrode was placed above the superior part of the right atrium, the other near the apex.

Coronary inflow was measured with a photoelectric drop counter. Intraventricular pressure, electrogram and coronary inflow were recorded on a Grass polygraph. The frequency response of the electrical recording system was 75 Hz, the frequency response of the pressure recording device exceeded 40 Hz irrespective of the size of the catheter used.

Electrical stimulation

The heart preparations were stimulated electrically at all frequencies above the spontaneous contraction rate by passing a current through a bipolar platinum electrode placed in the region of the sinus node. The strength of the stimulus was approximately 50 per cent above threshold and the duration was 2 msec.

Perfusing solution

A Ringer's solution of the following composition was used (mM) NaCl 117 $NaHCO_3$ 20 $MgSO_4$ 1.5 NaH_2PO_4 1.5 KCl 5 $CaCl_2$ 2 and glucose 3.3. A low molecular weight dextran, Rheomacrodex® was added to the Ringer's solution to a final concentration of 2.5 %. The perfusing solution was equilibrated with a gas mixture containing 80 vol. % O_2, 15 vol. % N_2 and 5 vol. % CO_2. pH of the perfusion solution was 7.35 (range 7.29–7.41). pCO_2 of the solutions was calculated as $\frac{A \cdot (P-B)}{100}$ where A is % (vol./vol.) CO_2 in gas mixture, P atmospheric pressure (760 mm Hg) and B vapour pressure of water at 37°C (47 mm Hg). Double distilled water was used. Chemicals used were of analytical grade. Acetylcholine was used in the form of acetylcholine chloride (British Drug House Ltd).

Erythrocyte suspensions

were prepared by adding Ringer's solution to freshly obtained human adult erythrocytes, which had been washed twice in Ringer's solution. The haematocrit was adjusted to 20 % and the pH of the suspension was set to 7.35. Samples from the erythrocyte suspension were taken at various times during the experiment for analysis of potassium in the supernatant after separation of the erythrocytes. The potassium concentration in this supernatant did not exceed the concentration in the ordinary Ringer's solution by more than 10 %.

The temperature of the Ringer's solution and the erythrocyte suspension was kept constant at 37 ± 0.5° C.

Terminology

The term *end diastolic pressure* is used in its usual sense. *Active systolic pressure* denotes the maximal pressure developed above the end diastolic pressure during the contraction cycle studied. *Total systolic pressure* is the sum of the end diastolic and the active systolic pressure.

In the electrogram the distance between the peak of the atrial wave (or when electrical stimulation was used the beginning of the stimulation artefact) and the beginning of the ventricular complex was taken as a measure of atrio-ventricular conduction time. The duration of the ventricular complex was measured at the 50 % level above the isoelectric level.

Results

Influence of contraction rate on active systolic pressure

After an equilibration period of approximately 30 min, the spontaneous contraction rates of the preparations were 108 ± 11 beats per min (mean ± SD, n = 8). At contraction rates above the spontaneous rate active systolic pressure decreased to a varying extent with increasing contraction rates. The active systolic pressure devel-

TABLE I Activ systolic pressure at contraction rates 100 125 and 150 beats per min.

oped during steady state conditions at contraction rates of 100 125 and 150 beats per min is shown in Table I. The negative inotropic effect of an increase in contraction rate was associated with a reduction in the maximal rate of rise of intraventricular pressure $(dp/dt)_{max}$. Both the rise time and the duration of the systolic contraction, measured at the 50 % level, decreased with increasing contraction rate. The results from one typical experiment are shown in Fig 1

A lowering of the contraction rate below the spontaneous level, induced by excision of the sinus node region and/or by addition of acetylcholine to the perfusion medium, had a positive inotropic effect. In preparations with pressure registration by means of an aortic catheter or an intraventricular balloon a slow and constant increase in intraventricular pressure occurred during diastole. This was not seen in preparations in which the pressure was recorded with a mitral catheter In these latter preparations active systolic pressure could therefore be studied at low contrac tion rates without interference by changes in end diastolic pressure. The results of two such experiments are shown in Fig 2. In order to reduce the contraction rates of the hearts, they were perfused with acetylcholine chloride ($1—2\times10^{-7}$ g/ml) preparation A during the whole experiment, preparation B only when measuring the active systolic pressure at the lowest contraction rate studied. (In concentration 10^{-7} g/ml acetylcholine chloride itself caused a minor negative inotropic effect in the human foetal heart preparations.) In preparation A the sinus node was also excised. In this way steady state conditions could be achieved during contraction rates as low as 44 and 23 beats per min. Active systolic pressure increased with decreasing contraction rates within the range studied (Fig. ?) This positive inotropic effect of a reduction in contraction rate was attributable only to a prolongation of the contrac tion cycle, as $(dp/dt)_{max}$ decreased with decreasing contraction rates below approximately 90 beats per min.

Influence of oxygen supply and co nary perfusion pressure on intraventricular pressure

In order to ascertain whether the reduction of the active systolic pressure at high stimulation frequencies could be ascribed to inadequate oxygen supply to the

myocardium, two preparations were perfused with an erythrocyte suspension (hematocrit 0 %) of the same pH and aerated with the same gas mixture as the preceding Ringer's solution (see Methods). Fig. 3 shows that replacement of the Ringer's solution by the erythrocyte suspension did not alter the relation between contraction rate and active systolic pressure although the oxygen content of the erythrocyte suspension was 5.5 times that of the Ringer's solution.

The amount of physically dissolved oxygen i 100 ml Ringer sol tion in equilibration w th gas mixture containing 80 % oxygen is

Pressure recorded by means of an intraventricular balloon. Vertical bar 0 mm Hg, horizontal bar 200 msec.

Changes in contraction rate of the heart preparations were not accompanied by any consistent alterations in coronary blood flow. It was, however considered of interest to study the effect of coronary perfusion pressure and coronary flow upon the mechanical performance of the isolated foetal hearts. In four heart preparations with a balloon in the isovolumetrically working left ventricle, the coronary perfusion pressure was varied from 14 to 37 mm Hg. The results are summarized in Fig. 4 A and show that an increase in perfusion pressure within the range studied raised both the active systolic pressure and the end diastolic pressure. As changes in coronary blood flow always accompanied alterations in perfusion pressure, it was not possible to distinguish between the individual effects of these two variables. A linear relation was found between coronary blood flow and perfusion pressure as shown in Fig. 4 B. Thus no autoregulatory mechanisms in the myocardial vascular bed occurred in response to changes in perfusion pressure.

End diastolic pressure as a determinant of active systolic pressure

The influence of the end diastolic pressure upon active systolic pressure was studied in two preparations; the results obtained were similar in both. Data from one experiment are shown in Fig. 5. It can be seen that active systolic pressure increased with increasing end diastolic pressure up to approximately 10 mm Hg, but remained constant at higher diastolic pressures.

Influence of stimulation frequency on foetal electrogram

This is illustrated by the sequence shown in Fig. 6 obtained from one preparation without a balloon in the left ventricle. The atrio-ventricular conduction time

increased with increasing stimulation frequency In three preparations, the mean increase was 4 msec for an increase in contraction rate of 10 beats per min within the frequency range of 105—18° beats per min. An increase in stimulation frequency also caused a broadening of the ventricular complex and at stimulation frequencies above 180 per min distortions of the ventricular complex appeared. These effects of stimulation frequency upon the ventricular complex of the electrogram were most pronounced in preparations with a balloon type of pressure recording (Fig 7)

Discussion

The main purpose of the present study was to assess the influence of contraction rate upon the mechanical output of the individual heart beat of isolated human foetal hearts. In view of the clinical significance of foetal bradycardia, effects induced by a reduction in contraction rate were considered particularly important. Three different recording arrangements were used, all giving similar results except for the fact that intra ntricular pressure alterations occurred during diastole in two of these types but not in preparations in which an open mitral catheter was used for recording the pressure

When comparing the results obtained with these heart preparations perfused via the coronary arteries with findings in isolated tissue preparations such as papillary muscles, the following factors should be considered The spread of excitation in perfused hearts resembles that seen i tiro in contrast with the situation in excised preparations where this factor has largely been excluded by the use of small preparations and/or multielectrode stimulation Therefore ontr ction of the myocardial cells in the whole heart is not compl t ly synchronous i e some muscle fibres are

still (or already) relaxed, while other fibres contract. A different type of inhomogeneity of myocardial contraction is due to the thickness of the walls of the cardiac chambers. Tissue pressure gradients exist within the ventricle walls. At a given pressure in the ventricle cavity tissue pressure is greater close to the endocardium than in the epicardial cell layers (Kirk and Honig 1964 Streeter *et al.* 1970). It might also be added that perfusion of an isolated heart *via* the coronary arteries is quite different from the perfusion of an excised tissue preparation the former reflecting physiological conditions more closely than the latter.

The general conditions of the heart preparations used in the present study are perhaps best judged by comparing the developed intraventricular pressure with the applied coronary perfusion pressure. In heart preparations with the pressure recorded by means of an intraventricular balloon, the total systolic pressure generally exceeded the coronary perfusion pressure when the diastolic pressure was increased above approximately 5 mm Hg these preparations would therefore have been able to perform external work. In preparations with a catheter type of pressure registration, however diastolic pressure was kept only at a few mm Hg. Hence total systolic pressure was lower than the coronary perfusion pressure, which allowed isovolumetric determination of intraventricular pressure also in these preparations.

Contraction rate

Abundant evidence support the view that a reduction in contraction rate below the frequency range existing *in vivo* causes a decrease in isometric twitch tension of excised ventricle preparations from various mammalian species (Koch Weser and Blinks 1963). On the other hand the effects of changes in contraction rate upon the whole heart are less clear. In the isolated dog ventricle a decrease in contraction rate reduces peak intraventricular pressure (Monroe and French 1961) and stroke volume (Rosenblueth *et al.* 1959) to a moderate extent, whereas experiments on dog hearts *in situ* have shown stroke work measured at constant end diastolic volume to remain unchanged over a wide range of contraction rates (Mitchell Wallace and Skinner 1963). By means of strain gauges applied to heart ventricle segments of patients during heart surgery peak contractile force was found to be uninfluenced by a change in contraction rate from 145 to 75 beats per min (Sonnenblick, Morrow and Williams 1966). In adult patients with a complete heart block, it has been shown that a lowering of the contraction rate from 117 to 47 beats per min approximately doubled stroke work index (Rowe *et al.* 1969). However a change in end diastolic volume might have contributed to this effect as intraventricular pressure was not measured in this investigation.

The present study shows that an increase in contraction rate above the spontaneous level (95—120 beats per min) reduced the active systolic pressure, whereas a decrease in rate induced a moderate increase in active systolic pressure. When the diastolic pressure and hence the diastolic volume of the heart was kept constant, such a positive inotropic effect of a reduction in contraction rate could be demon-

strated down to a contraction rate around 90 beats per min. The rate of rise of intraventricular pressure, $(dp/dt)_{max}$ has been taken as an index of the inotropic state or "contractility" of the myocardium (Wallace Skinner and Mitchell 1963 Mason 1969 Morgenstern *et al* 1970) It is of interest to note that in the present study $(dp/dt)_{max}$ decreased at contraction rates below as well as above the spontaneous rate of approximately 100 beats per min. Judging from the active systolic pressure developed, such a reduction in contractility at low contraction rates was fully compensated by an increased duration of the contraction cycle. The frequency dependence of the active systolic pressure of the isolated foetal heart appears to be in contrast with an earlier observation on isolated papillary muscles from human foetuses (Gennser and Nilsson 1968) It was shown that a reduction in contraction rate from 96 to 24 beats per min reduced the isometric tension of the preparations to about half of its original value. These results were obtained at 30 C, whereas the present study was performed at 37°C. The temperature difference probably causes an underestimation of the apparent discrepancy between the results obtained in the two studies, because at temperatures below 37 C the isometric twitch tension is enhanced at low contraction rates owing to a prolongation of the action potential (Kaufmann and Fleckenstein 1965) The present study offers no certain explanation for the difference in frequency-dependence between the active systolic pressure in the whole heart and the isometric tension of the excised papillary muscles. This might however be ascribed to a difference between the two preparations in modes of stimulation. Complete excitation of the foetal ventricles takes an appreciable time, approximately 40 msec at a physiological contraction rate (Durrer *et al.* 1961) whereas excitation of an isolated papillary muscle is complete within a few msec. (The latter figure would be 9 msec, assuming a conduction velocity of 0.5 m/sec (Gennser and Nilsson 1970) and a conduction length of 1 mm using a multielectrode assembly) This lightly asynchronous activation of the whole heart will tend to reduce the developed intra-ventricular pressure by increasing the extension of elastic elements in series and in parallel with the contractile system of conventional models for myocardial contraction (for discussion of these models see Brady 1968 Jewell and Blinks 1968) This effect of the asynchronous excitation of the heart will increase at high contraction rates due to shortening of the duration of the contractile process in myocardial cells (Gennser and Nilsson 1968) The decreased conduction velocity of the action potential at high stimulation frequencies might further increase the physiological asynchrony (Gennser and Nilsson 1970)

In the present study the contraction rates of the isolated human foetal hearts could be reduced to values below those usually encountered during foetal bradycardia. The positive inotropic effect of a decrease in contraction rate observed in isolated hearts, suggests that foetal bradycardia *in vivo* does not in itself diminish the capacity of the individual foetal heart beat to perform external work.

End diastolic pressure

As pointed out by Downing, Talner and Gardner (1965) the Frank-Starling mechanism might be considered of special importance in the adjustment of the foetal circulation from intra to extrauterine life with the accompanying marked reduction in pulmonary vascular resistance and increase in aortic pressure and systemic blood flow (Cross, Dawes and Mott 1959 Dawes 1961 Dawes 1966) The present results indicate that also in the midterm foetus, the left ventricle can change its mechanical output considerably in response to alterations in end diastolic pressure. It is of interest to note that in the experiment shown in Fig 5 active systolic pressure reached a plateau at approximately the same end diastolic pressure as that at which maximal stroke volume is approached in the adult mammalian left ventricle (Sarnoff and Mitchell 1961) This seems to be in agreement with the fact that end diastolic pressures are of the same magnitude in the foetus and the adult (Assali, Bekey and Morrison 1968) although systolic pressure is much greater in the adult than in the foetal left ventricle (Dawes 1961)

Coronary perfusion pressure and coronary flow

In isolated human foetal hearts studied under the present experimental conditions, coronary flow did not set an upper limit for the mechanical output of the ventricles by restricting metabolic supply to the myocardium. This conclusion is based upon the fact that several positive inotropic responses (induced by an increase in calcium concentration an increase in pH an increase in pCO_2 of the perfusion solution or addition of adrenaline (Andersson, Gennser Nilsson 1970 a)) could be evoked without alterations in coronary perfusion flow Furthermore, when the oxygen content of the perfusing medium was increased by the addition of erythrocytes, the mechanical performance of the entricles did not change.

In the present study an increase in coronary perfusion pressure was found to enhance the active systolic pressure within the range studied. This is in accordance with previous results (Arnold *et al.* 1968) obtained in isolated guinea pig hearts. The authors reached the conclusion that changes in myocardial contractility following alterations in perfusion pressure are due to effects of perfusion pressure *per se* (an increase in perfusion pressure causing stretching of arteries and hence of muscle fibres) and not to variations in coronary blood flow In the present experiments with a balloon type of pressure recording, an increase in perfusion pressure enhanced also the end diastolic pressure. Such changes in diastolic pressure probably reflect alterations in myocardial intravascular pressure and/or an accumulation of fluid in the ventricular cavity outside the pressure recording balloon due to a flow through the Thebesian vessels. The diastolic pressure changes were most evident at low contraction rates owing to the relatively slow and constant increase in intraventricular pressure during diastole. It is not possible to state to what extent the changes observed in end diastolic pressure might have contributed to the inotropic

effects of alterations in coronary perfusion pressure. The relation between coronary flow and perfusion pressure was linear. Thus no autoregulatory mechanisms in the myocardial vascular bed occurred in response to changes in perfusion pressure.

Skilful technical assistance was given by Miss Margareta Olsson, Mrs Mania Winitsky and Miss Karin Jönsson. Thanks are due to Professor K. A. P. Edman for valuable discussions during preparation of the manuscript and to AB Pharmacia, Uppsala for supplies of Rheomacrodex®. Influence of Acid Base Changes on Isolated Human Foetal Hearts

By

K. E. Andersson G Gennser and E. Nilsson

Abstract

Andersson K. E., G Gennser and E. Nilsson *Influence of acid base changes on isolated human foetal hearts* Acta physiol. scand. 1970. *80* Suppl. 353 20—33.

Left intraventricular pressure and electrogram were recorded in isolated human foetal heart preparations during perfusion with solutions of different [$NaHCO_3$] and pCO_2. In spontaneously beating hearts a decrease in pH within the range 7.75—6.62, induced by an increase in pCO_2 and/or decrease in [$NaHCO_3$] reduced spontaneous contraction rate, active systolic pressure and $(dp/dt)_{max}$. Within the pH range studied contraction rate was reduced more than active systolic pressure. In electrically stimulated preparations lowering of external pH, caused by a decrease of [$NaHCO_3$] or by increase of pCO_2 reduced active systolic pressure. This reduction was more pronounced at high than at low contraction rates. Electrogram changes indicated that reduction in pH of the perfusion solution reduced the intraventricular conduction velocity. A parallel increase in both [$NaHCO_3$] and pCO_2 at a constant external pH of 7.04 or 7.33 increased active systolic pressure and $(dp/dt)_{max}$. Judging from electrogram recordings, such parallel increase in [$NaHCO_3$] and pCO_2 was accompanied by an increased intraventricular conduction velocity. The mechanisms of inotropic changes induced by alterations of acid-base parameters are discussed.

Introduction

This report is concerned with the effect of pH and pCO_2 changes on the electrogram and the intraventricular pressure of isolated human foetal hearts. In a preceding investigation (Andersson Gennser and Nilsson 1970) it was shown that the mechanical output of the individual heart beat of isolated foetal heart preparations was markedly affected by changes in contraction rate. The role of the contraction rate in modifying effects induced by acid-base changes will therefore be considered in this study.

Material and methods

15 foetal hearts were used (estimated gestational age of the foetuses ranged from 16 to 20 weeks and their crown-heel length 16—24 cm). Some of the hearts were identical with those reported in a previous paper (Andersson Gennser and Nilsson 1970). That report also described the mounting and recording techniques used in the present study.

Solutions

A Ringer's solution of the following composition was used as standard solution (mM) NaCl 117 $NaHCO_3$ 20 $MgSO_4$ 1.5 NaH_2PO_4 1.5 KCl 4 $CaCl_2$ 2 and glucose 3.3. In other perfusion solutions used the sum of [NaCl] and [$NaHCO_3$] was kept constant at 137 mM other constituents being as indicated for the standard solution. Solutions of different [$NaHCO_3$] were equilibrated with gas mixtures containing 5.0 (4.9—5.1) or 13.5 (13.4—13.6) vol. % CO_2, 80 vol. % O_2 and N_2 to 100 vol. %. The composition and pH of the various solutions are given below

[$NaHCO_3$] mM	10	20	54	10	27	54
CO_2, vol. %	5	5	5	13.5	13.5	13.5
pCO_2, mm Hg	35	35	35	96	96	96
pH	7.04	7.33	7.75	6.62	7.04	7.33
range	6.98— 7.10	7.28— 7.38	7.70— 7.80	6.55— 6.69	6.98— 7.10	7.28— 7.38

Rheomacrodex® was added to all solutions to a final concentration of 2.5 %.

As bicarbonate- and Ca^{2+} ions form diffusable calcium complexes (Moore 1970) changes in [HCO_3^-] might be expected to alter the ionized calcium concentration, [Ca^{2+}], of a solution. Therefore the [Ca^{2+}] was measured by means of an Orion "flow through" ion-exchange calcium electrode (No. 90—20) in the solutions with 20 and 54 mM $NaHCO_3$ (both containing 2 mM $CaCl_2$). Measurements were made in these solutions at a pCO_2 of 35 and 96 mm Hg. The [Ca^{2+}] in 20 and in 54 mM $NaHCO_3$ solutions was found to be equal to [Ca^{2+}] in 150 mM NaCl solutions containing 0.90 and 0.71 mM Ca^{2+} respectively. Changes in pCO_2 and pH were not found to influence [Ca^{2+}]. Thus at any pH replacement of 10 mM NaCl by 10 mM $NaHCO_3$ in the Ringer's solution decreases the [Ca^{2+}] by 6.2 %.

The temperature of the perfusion solutions was kept constant at 37° C±0.5.

Results

Influence of acid-base changes on contraction rate and active systolic pressure in spontaneously beating hearts

The effects of acid-base changes were studied by perfusing heart preparations with buffer solutions of pH 7.04, 7.33 and 7.75 equilibrated at pCO_2 35 mm Hg, and with solutions of pH 6.6., 7.04 and 7.33 equilibrated at pCO_2 96 mm Hg. The preparations were perfused with the standard solution of pH 7.33 (20 mM $NaHCO_3$) and pCO_2 35 mm Hg between perfusions with the other solutions. Data from the two most complete experiments are given in Fig. 1 A and B, a third experiment yielding similar results. The values in Fig. 1 are steady state determinations after at least ten min perfusion in the respective solutions. All points in Fig. 1 and 2 are given as percentages of the mean value of corresponding measurements in the preceding and

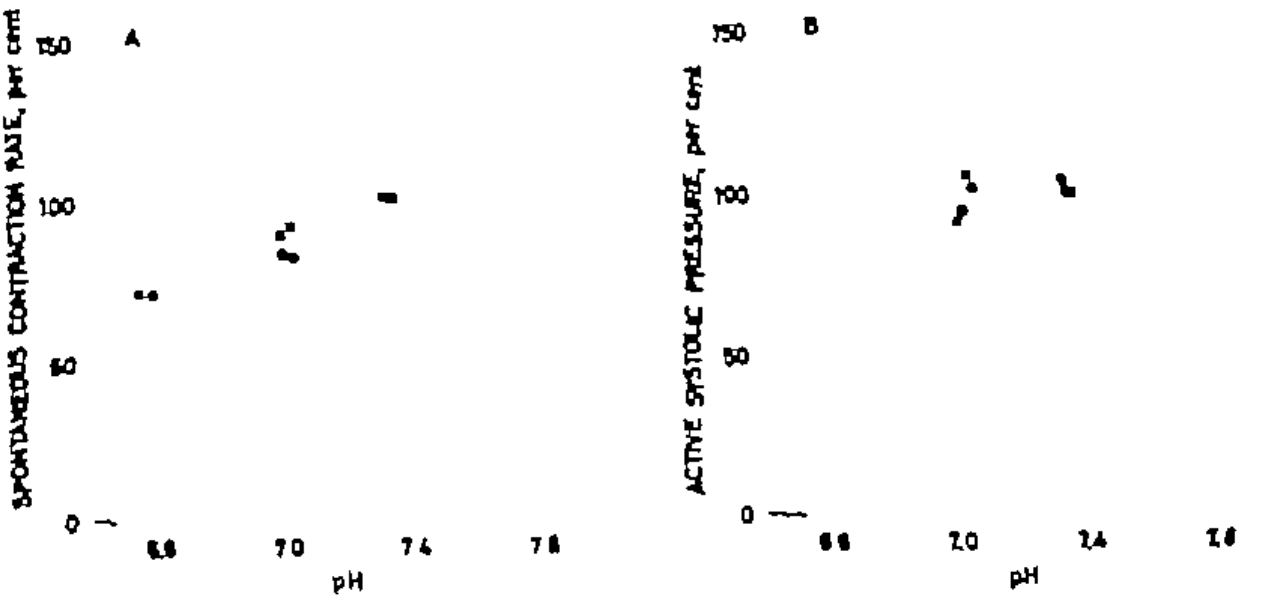

Fig. 1 A. Change in spontaneous contraction rate as a function of external pH. Squares and circles denote different preparations. Filled symbols indicate pCO_2 96 mm Hg, unfilled symbols pCO_2 35 mm Hg. Spontaneous contraction rate at $[NaHCO_3]$ 20 mM and pCO_2 35 mm Hg is taken as 100 %. Pressure recorded by means of an intraventricular balloon.

B. Change in active systolic pressure as a function of external pH. Same preparations and symbols as in Fig. 1 A. Note that at pH 7.0 and 7.3 active systolic pressure is slightly higher at pCO_2 96 mm Hg than at pCO_2 35 mm Hg.

following standard solution. This reduced the influence of deterioration of the heart preparations with time. (The experiments shown in Fig. 1 lasted approximately two hours. During this time the active systolic pressure fell in one experiment from 37.5 to 30.3 mm Hg, in the other from 33.7 to 27.2 mm Hg, while the spontaneous contraction rate changed from 101 to 104 and from 96 to 90 beats per min, respectively.) In the two experiments shown in Fig. 1 A and B a decrease in pH from 7.33 to 6.62 caused a 10 % decrease in active systolic pressure whereas the spontaneous contraction rate was reduced by 70 %. An increase in pH from 7.33 to 7.75 enhanced the active systolic pressure and the contraction rate by 5 and 15 % respectively. The effect of pH-changes upon $(dp/dt)_{max}$ and the duration of the active systolic contraction measured at the 50 % level is given in Fig. 2 A and B. As can be seen, a decrease in pH prolonged the systolic contraction, and $(dp/dt)_{max}$ was reduced to a greater extent than the active systolic pressure by this acid-base change. At a given pH the spontaneous contraction rate does not seem to be dependent upon the concentration of $NaHCO_3$ and pCO_2 (Fig. 1 A). On the other hand Fig. 1 B suggests that a parallel increase in both $[NaHCO_3]$ and pCO_2 at a constant external pH enhances active systolic pressure. The effect of pCO_2 and $[NaHCO_3]$ is also illustrated in Table I which shows that a decrease in pH from 7.33 to 7.01 at a constant pCO_2 of 35 mm Hg reduced the active systolic pressure and $(dp/dt)_{max}$ more mar-

kedly than when the same pH change was induced by an increase in $[NaHCO_3]$ and pCO_2 (from 35 to 96 mm Hg).

Influence of pH and pCO_2 on active systolic pressure in electrically stimulated heart preparations

It was considered desirable to eliminate the effect of changes in contraction rate in the analysis of inotropic effects of alterations in external pH and pCO_2. Intraventricular pressure was therefore recorded in heart preparations stimulated at selected

TABLE I. Changes in spontaneous contraction rate, active systolic pressure (ASP) and $(dp/dt)_{max}$ induced by acidosis. Decrease of pH of perfusion fluid from 7.33 to 7.04 produced by reduction of $[NaHCO_3]$ (II) or by simultaneous increase in $[NaHCO_3]$ and pCO_2 (I).

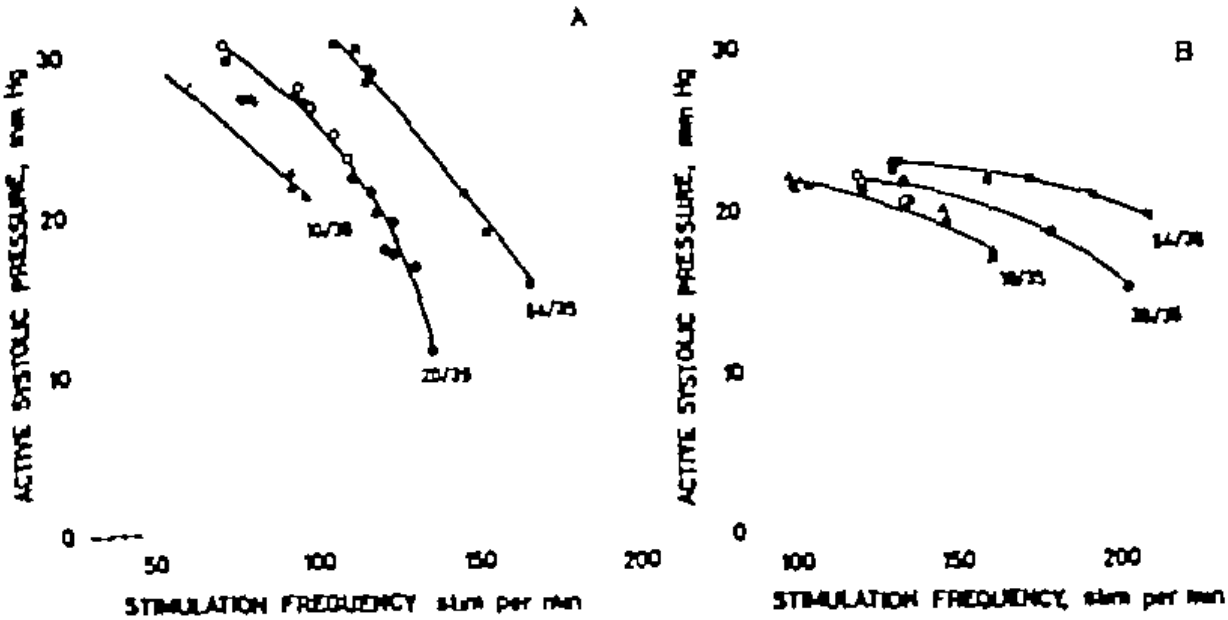

Fig. 3. Active systolic pressure at pH 7.75, 7.33 and 7.04 (right to left) as a function of stimulation frequency in two heart preparations, (A) and (B). Numbers before the oblique lines indicate [NaHCO$_3$] in mM; numbers after the oblique lines indicate pCO_2 in mm Hg in the perfusing solution.

A. Measurements were performed in the following order: ○ ▲ ○ ■ ●. Pressure recorded by means of an intraventricular balloon. In order to reduce spontaneous contraction rate the sinus node of the preparation was excised. The lines in this and following figures are drawn by the eye.

B. Measurements were performed in the following order: ○ ▲ ○ ■. Pressure recorded by means of an open catheter in the left ventricle.

frequencies during perfusion with solutions of different [$NaHCO_3$] and pCO_2. Solutions with pH 7.04, 7.33 and 7.75 equilibrated at a pCO_2 of 35 mm Hg were used. The maximum frequency at which the heart preparations could be paced without the appearance of an atrio-ventricular block decreased with decreasing pH in the perfusion solution. The influence of external pH upon active systolic pressure is illustrated in Fig. 3 A and B. The difference in active systolic pressure at the beginning and the end of the experiment measured in the standard solution at any contraction rate within the range studied was less than ten per cent. The values given were recorded under steady state conditions after five to ten minutes perfusion of the preparations with the respective solutions. As can be seen a *decrease in pH* from 7.33 to 7.04 caused a shift of the contraction frequency pressure curve to the left. At a contraction rate of 120 beats per min the decrease in active systolic pressure induced by such a pH change from 7.33 to 7.04 was 16 % (range 5—28 % in three preparations). In most experiments, the inotropic change induced by a reduction in pH was greater at contraction rates above 120 beats per min. The response of the active systolic pressure to an *increase in pH* from 7.33 to 7.75 at a constant pCO_2 of 35 mm Hg is also shown in Fig. 3. At a contraction rate of 120 beats per min this pH change caused a positive inotropic change of 20 % (range 8—36 % in three

preparations) Neither the interval between the beginning and the peak of the contraction nor the duration of the contractile cycle measured at the 50 % level at any given contraction rate varied with external pH, and the inotropic alterations were attributable only to changes in the rate of development of intraventricular pressure (Fig 4 A and B) At any given external pH the duration of the systolic contraction decreased with increasing contraction rate (cf Andersson, Gennser and Nilsson 1970)

In five experiments both [$NaHCO_3$] and pCO_2 in the perfusion solution were increased 2.7 fold, keeping the external pH constant at 7.33 or 7 04 respectively (see Methods) These experiments showed that after steady state conditions had been established (after 3—10 min) the active systolic pressure was augmented by such a parallel increase in both [$NaHCO_3$] and pCO_2 within the frequency range studied At a contraction rate of 120 beats per min the increase in active systolic pressure induced by this inotropic intervention was 6.4 % (range 2.6—11.6 % in four heart preparations) In three of the four preparations this positive inotropic effect was greater at high than at low contraction rates Two of these experiments are shown in Fig 5 A and B. The rate of intraventricular pressure development increased at high contraction frequencies, (Fig. 6) whereas the duration of the systolic contraction was unaffected by this inotropic intervention.

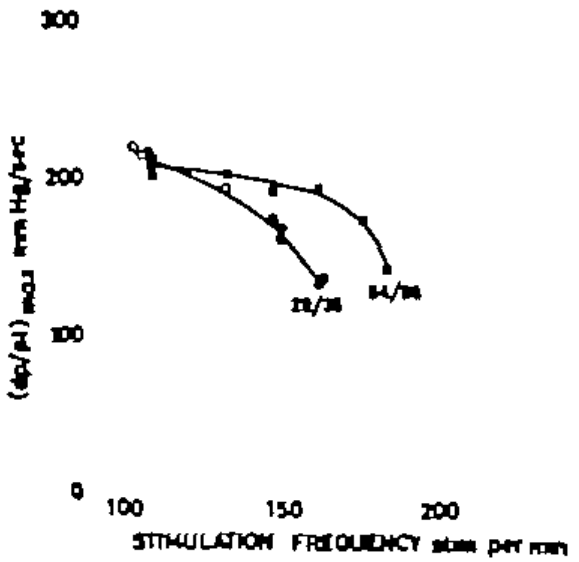

Fig 6. $(dp/dt)_{max}$ t different [$NaHCO_3$] and pCO_2 as f nction of stimulation frequency Numbers indicate [N HCO_3] and pCO_2 as in Fig. 5 pH is 7.33 in both solution 20/35 and solution 54/36. Inotropic effect of adrenalin e a d calcium at n rmal and low pH

Adrenaline in concentrations 1×10^{-8} to 5×10^{-7} g/ml had a positive chronotropic and inotropic effect on isolated human foetal heart preparations. The effect of adrenaline (1×10^{-7} g ml) upon intraventricular pressure in one electrically stimulated heart preparat n perfused with a solution of pH 7.33 (20 mM $NaHCO_3$, pCO_2 35 mm Hg) is shown n Fig 7 A. The positive inotropic ffect of an increase in

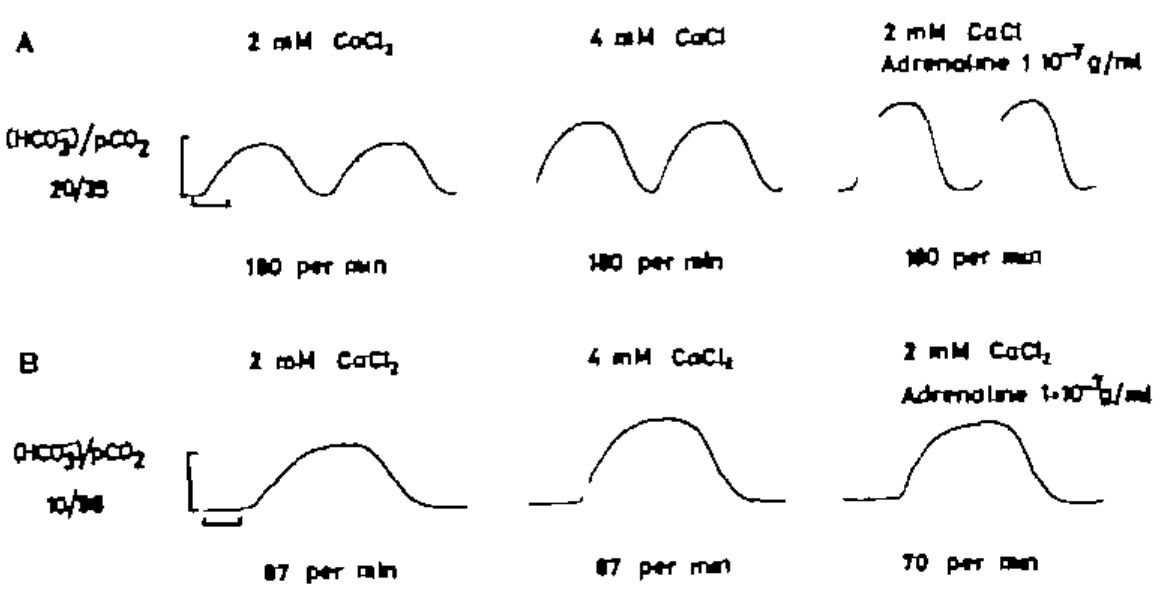

Fig. 7 Intraventricular pressure curves showing effects of adrenaline and changes in [$CaCl_2$] at pH 7.33 (A) and pH 6.62 (B). Sinus node of the preparation was excised. Pressure recorded by means of a catheter in the left ventricle. Numbers indicate [$NaHCO_3$] and pCO_2 as in Fig. 3. Stimulation frequencies indicated. Calibration: Vertical bars 20 mm Hg, horizontal bars 100 msec.

external calcium concentration is also illustrated. In contrast with an increased calcium concentration adrenaline reduced the time to maximal intraventricular pressure and the duration of the contractile cycle. Fig. 7 B shows the inotropic effects of adrenaline and calcium at pH 6.62 (10 mM $NaHCO_3$, pCO_2 96 mm Hg). No quantitative analysis was performed concerning the influence of pH changes upon these inotropic effects. It should be noted, however, that also at this low pH both calcium and adrenaline exerted a positive inotropic effect.

Electrogram changes induced by acid-base alterations

At any given pH in the range 7.04—7.75 atrio-ventricular conduction time and the duration of the ventricular complex increased with increasing stimulation frequency (cf. preceding paper (Andersson, Gemzer and Nilsson 1970). This may be ascribed to a decrease in conduction velocity of the myocardial action potential at high contraction rates (Gemzer and Nilsson 1970). At a given contraction frequency a decrease in pH increased the atrio-ventricular conduction time and the duration of the ventricular complex, an increase in pH inducing the reverse changes. A parallel increase in [$NaHCO_3$] and pCO_2 shortened the atrio-ventricular conduction time and decreased the duration of the ventricular complex. These electrogram alterations indicate that a lowering of pH reduces conduction velocity in the foetal myocardium, whereas an increase of both [$NaHCO_3$] and pCO_2 at constant external

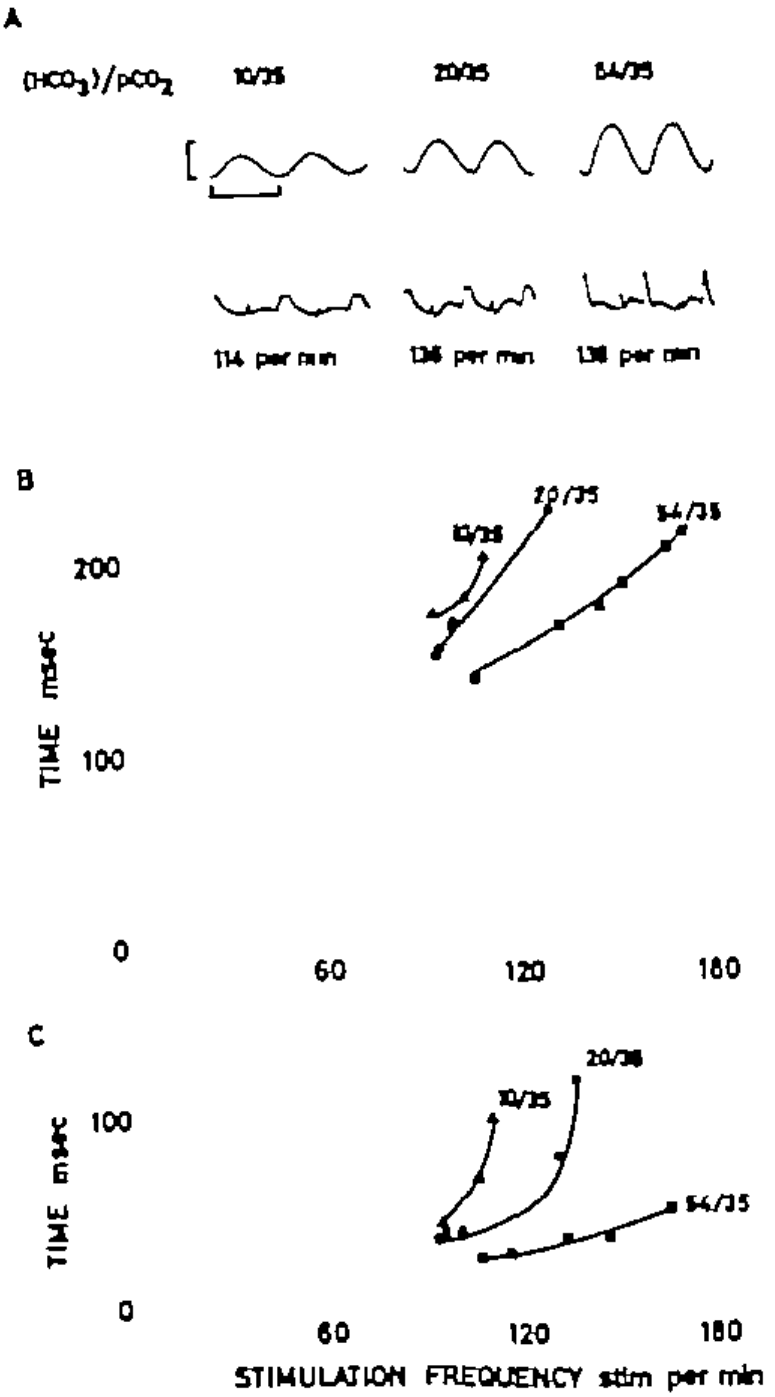

Fig. 8. Influence of pH-changes induced by variation of [$NaHCO_3$] on electrogram of one foetal heart preparation. Numbers indicate [$NaHCO_3$] and pCO_2 as in Fig. 3.

A. Recordings of intraventricular pressure (upper curves) and electrogram (lower curves) during perfusion with solutions of pH 7.75, 7.53 and 7.04 (right to left). Solution 10/35, pH 7.04; atrioventricular conduction block occurred at stimulation frequencies above 114 per min. Calibration: Vertical bar 20 mm Hg, horizontal bar 0.5 sec. Pressure recorded by means of an intraventricular balloon. Sinus node of the preparation was excised.

pH raises the conduction velocity Tracings and diagrams obtained in one typical experiment are shown in Fig 8 and 9 Similar results were obtained in two other experiments.

Discussion

The present report deals with the effect of changes in acid-base variables upon spontaneous contraction rate, electrogram and intraventricular pressure in isolated, isovolumetrically contracting human foetal heart preparations. The pH and pCO_2 range studied exceeds that found in foetal blood at delivery of both normal foetuses and depressed foetuses (Jacobson 1970) In the latter investigation a pH of *7 11±0 01 (mean±SD) and a pCO_2 of 66±6 mm Hg was found in* umbilical artery blood of depressed foetuses (with Apgar score < 7)

Chronotropic and inotropic effects induced by changes in external pH

In the present study a decrease in pH within the range studied (6.62—7 75) was found to reduce the spontaneous contraction rate and the maximum frequency at which the preparations could be stimulated without the appearance of A—V-conduction block This is in agreement with earlier investigations on isolated hearts or heart lung preparations (McElroy Gerdes and Brown 1958 Nejad and Ogden 1967) A lowering of pH also reduced the conduction velocity within the ventricles, as judged from widening of the ventricular electrogram complex. The latter finding agrees with direct measurements of influence of pH-changes on conduction velocity in isolated rabbit atrial preparations (Vaughan Williams and Whyte 1967) A *decrease in external pH at constant pCO_2 diminished the contractility of the isolated* human foetal hearts in accordance with earlier observations on excised myocardial preparations (Vaughan Williams 1955 Vaughan Williams and Whyte 1967 Pannier and Leuven 1968) isolated hearts and heart lung preparations (McElroy Gerdes and Brown 1958 Opie 1965 Nejad and Ogden 1967 Ng, Lewy and Zieske 1967 Kolliardt Wirth and Dudeck 1967) The present study was not aimed at elucidating the mechanism( ) behind the negative inotropic effect of acidosis. However it should be pointed out that a *reduction in conduction velocity reduced* by e g. acidosis can in itself have a negative inotropic effect on the whole heart and to a less extent on excised myocardial preparations by causing an asynchronous contraction (cf Andersson, Gennser and Nilsson 1970) It is reasonable to assume that inotropic changes observed in the present study following alterations of external pH may be explained in part by diff rences in intra entricular conduction velocity

Factors influ enci g the negat v inot opic ff ct f acido is

In the intact organism a negative inotropic effect of reduction in pH can, at least temporarily be compensated by an activation of the sympathetic nervous system

induced by acidosis (Downing, Talner and Gardner 1965 Downing Talner and Gardner 1966 a, b Wildenthal *et al* 1968) It has been shown that during beta receptor blockade with propranolol a decrease in pH from 7.34 to 7.08 significantly reduced cardiac contractility in cats, whereas cardiac function was unaffected by a similar pH-change in cats with intact adrenergic function (Rocamora and Downing 1969) Divergent results have been obtained, however concerning the time course of the activation of the sympatho-adrenal system induced by acidosis (Talner Gardner and Downing 1966 Wildenthal *et al.* 1968) The present report indicates that at midgestation adrenaline can cause a positive inotropic response of the human foetal heart also at low extracellular pH. The negative inotropic effect induced by a decrease in pH may therefore to some extent be offset by adrenergic influences also in the human foetus.

In the present study an increase in external calcium concentration was found to exert a positive inotropic effect. It has been shown (Moore 1970) that a reduction in pH from 7 4 to 6.8 causes approximately a 15 % increase in $[Ca^{2+}]$ of serum and heparinized whole blood. Such an increase in $[Ca^{2+}]$ might be of importance *in vivo* in reducing the negative inotropic effect of acidosis.

As described in a preceding paper (Andersson, Gennser and Nilsson 1970) a lowering of the contraction rate of the isolated human foetal heart below the spontaneous rate enhanced the amplitude of the isovolumetric contraction. *In vivo* such a positive inotropic effect of bradycardia might be of significance for maintenance of the efficiency of the individual heart beat during acidosis.

Inotropic effects induced by changes in pCO_2

The influence of pCO_2 upon myocardial contractility is still a matter of controversy Hypercapnia has been found to increase cardiac stroke volume in man (Richardson, Wasserman and Patterson 1961 Robseth 1966 Cullen, Eger and Gregory 1969) adult dog (Carson *et al.* 1965) and foetal lamb (Koivikko 1969) The interpretation of the observed effects of pCO_2 upon myocardial contractility is, however complicated by simultaneous variations in pH and by activation of the sympathetic nervous system. Early investigations showing negative inotropic effects of carbon dioxide on isolated hearts or heart lung preparations did not distinguish pH-effects from those due to pCO_2-alterations (Jerusalem and Starling 1910 Ketcham, King and Hooker 1912, Boniface and Brown 1953 Nahas and Cavert 1957) In experiments with isolated whole heart preparations for elucidating the selective influence of pH and pCO_2, it has been concluded that pCO_2 changes do not alter the mechanical performance of the heart (McElroy Gerdes and Brown 1958, Nejad and Ogden 1967 Ng, Lewy and Zieske 1967) In rabbit atrial preparations a parallel increase in $[NaHCO_3]$ and pCO_2 at constant pH in the external medium was found not to alter the contractile force of the preparations (Vaughan Williams and Whyte 1967) whereas in cat papillary muscles a transient (Pannier and Leusen 1968) or a slight permanent reduction of the contractile strength (Cingolani *et al.* 1970) was noted

after such an alteration of the perfusing medium. The divergency between these conclusions is not surprising, as the investigations differ not only in animal species and type of preparation used but also in experimental conditions which can influence the results such as temperature, mode of stimulation and stimulation frequency. Furthermore, the fact that an increase in $[HCO_3^-]$ decreases the ionized calcium concentration seems to have received no attention in previous studies.

The present study shows that in human foetal hearts an increase in $[NaHCO_3]$ and pCO_2 at constant external pH has a moderately positive inotropic effect despite a decrease in $[Ca^{2+}]$ concomitant with this change. (A shift in $[NaHCO_3]$ from 20 to 54 mM reduced $[Ca^{2+}]$ by 21 % see Methods). This positive inotropic effect may be of clinical relevance in the discussion of the pathophysiology of acid-base changes in the foetus. It should be pointed out, however that the present results were obtained during a relatively short period of exposure to high pCO_2 (< 20 minutes). Electrogram recordings indicate a shortened intraventricular conduction time following a parallel increase in pCO_2 and $[NaHCO_3]$. This suggests that a more synchronous activation of the myocardium may be responsible for the observed increase in contractility. In this connection it is of interest that a raised conduction velocity has been demonstrated in atria after a parallel increase in $[NaHCO_3]$ and pCO_2 (Vaughan Williams and Whyte 1967).

Skilful technical assistance was given by Miss Margareta Olsson, Mrs Manja Winitsky and Miss Karin Jönsson. Thanks are due to Professor K. A. P. Edman for valuable discussions during preparation of the manuscript and to AB Pharmacia, Uppsala for supplies of Rheomacrodex®. Influence of Mepivacaine on Isolated Human Foetal Hearts at Normal and Low pH

By

K. E. Andersson G Gennser and E. Nilsson

Abstract

Andersson K. E., G Gennser and E. Nilsson *Influence of mepivacaine on isolated human foetal hearts at normal and low pH* Acta physiol. scand. 1970 *80* Suppl. 353 31—47

In human foetal hearts from midgestation, perfused *in vitro* in Langendorff the influence of mepivacaine (concentrations 2.5—20 μg/ml) on spontaneous contraction rate, active systolic pressure, and electrogram was studied at pH 7.35 and 7.00. In each individual heart the effects of the local anaesthetic were dependent on its concentration in the perfusion fluid. Active systolic pressure and $(dp/dt)_{max}$ was reduced by 23 and 30 per cent, respectively at a concentration of 2.5 μg/ml. Only a moderate reduction (12 per cent) of the spontaneous contraction rate was seen even at the highest concentration used (20 μg/ml). In the electrogram, changes indicating a prolongation of the atrio-ventricular and intra-ventricular conduction time were seen at mepivacaine concentrations in the perfusion fluid exceeding 2.5 μg/ml. A lowering of pH from 7.35 to 7.00 induced changes in the parameters studied similar to those evoked by mepivacaine. It was found that the effects of a lowering of pH were added to those produced by the local anaesthetic. Possible mechanisms behind the mepivacaine induced changes are discussed.

Introduction

After the administration of local anaesthetics for obstetrical analgesia as paracervical block (PCB) changes in the heart rate of the foetus have been observed. Both bradycardia and tachycardia have been noted, bradycardia being the more common finding (for references, see Teramo and Widholm 1967). The significance of changes in the foetal heart rate during labour is difficult to evaluate (Assali, Bekey and Morrison 1968 Sureau 1969) and the nature of foetal bradycardia during PCB is not clear. It has been suggested that rapid absorption of the local anaesthetic into the foetal circulation would give concentrations in foetal blood high enough to have a direct depressive action on the myocardium (Page Kamm and Chappel 1961 Teramo and Widholm 1967 Gordon 1968 Asling *et al* 1970). High concentrations of local anaesthetics are known to diminish excitability conduction velocity and contractility of mammalian myocardium. These effects are seen in intact mammals including man they can also be demonstrated in isolated heart preparations (Harrison Sprouse and Morrow 1963, Austen and Moran 1965 Lieberman *et al* 1968, Nayler *et al* 1969 Nahas, Lachapelle and Tremblay 1969)

The aim of the present study was to analyse the influence of mepivacaine on the electrical and mechanical performance of isolated, human foetal hearts. The parameters investigated were spontaneous contraction rate, intraventricular pressure, and electrogram. A fall in pH of foetal scalp-blood samples has been observed in association with bradycardia during PCB (Teramo and Widholm 1967, Hickl and Kirchner 1968, Asling *et al.* 1970). Combined effects of local anaesthetics and acidosis on foetal myocardium could be of clinical importance. It was therefore considered of interest to study the effects of mepivacaine both at normal and at low pH.

Methods

Material

Foetal hearts were obtained at *legal interruptions of pregnancy performed by* hysterotomy. Fourteen hearts with no signs of malformation were used. The estimated gestational age of the foetuses ranged from 14 to 24 weeks and their crown-heel length from 14 to 30 cm. The wet weight of the hearts was 0.5—3 g and their spontaneous contraction rates ranged from 83 to 135 beats per min at the beginning of the experiments.

Preparation and mounting

As soon as possible after the evacuation of the uterus, the hearts were dissected, perfused *via* the coronary arteries *ad modum* Langendorff and mounted in a thermostated bath under the same experimental conditions as described previously (Andersson, Gennser and Nilsson 1970 a).

Stimulation and recording technique

Electrical stimulation and recording of left intraventricular pressure and electrogram were performed as described in an earlier report (Andersson, Gennser and Nilsson 1970 a). In five hearts, the pressure was registered by means of a thin, non-elastic balloon, and in five preparations, an open catheter was inserted into the ventricle through the *mitral ostium*. *In two other hearts, pressures within the right* and left ventricles were recorded simultaneously. For the pressure recording within the right ventricle, a catheter was introduced through the valve of the pulmonary artery. This catheter was fixed to the pulmonary artery by a ligature just above the valvular plane. In these two hearts, left ventricular pressure was recorded by means of an open catheter through the mitral ostium.

Simultaneous registrations of intraventricular pressure and electrogram were performed in eight preparations. Either the electrogram or the intraventricular pressure alone was studied in two and four hearts, respectively.

Contraction rate, active systolic pressure, maximum rate of pressure development ($(dp/dt)_{max}$) and electrogram measurements were performed as described (Andersson, Gennser and Nilsson 1970 a).

Solutions

A Ringer's solution of the following composition was used as a standard solution (mM) NaCl 117 $NaHCO_3$ 20 $MgSO_4$ 1.5 NaH_2PO_4 1.5 KCl 5 $CaCl_2$ 2, glucose 3.3 *Rheomacrodex® to a final concentration of 2.5 %* was added. The standard solution was equilibrated with a gas mixture containing 80 vol.% O_2, 15 vol.% N_2 and 5 vol. % CO_2, and in this way pH was kept at 7.35 (range 7.30—7.40) In order to obtain a pH of 7.00 (range 6.95—7.05) during equilibration with the described gas mixture, a Ringer's solution containing $NaHCO_3$ 10 mM and NaCl 1.97 mM was used, the other components being as indicated for the standard solution. To these Ringer's solutions mepivacaine (mepivacaine hydrochloride, Carbocain®) was added to final concentrations of 2.5 5 10 and 20 μg/ml. In two cases, a Ringer's solution (pH 7.35) containing lidocaine (lidocaine chloride, Xylocain®) 20 μg/ml was used.

The temperature of the perfusion solutions was kept constant at 37±0.5 C.

Chemical analysis

Chemical determination of mepivacaine was performed by gas-liquid chromatography

Results

Only heart preparations were used in which before the experiment began, a steady state condition could be obtained, as judged from the electrical and mechanical recordings. All preparations were perfused with the different solutions in periods of 1—15 min. During these perfusion periods, a new steady state was obtained in all spontaneously beating hearts (except in two preparations in high mepivacaine concentrations, see below) The active systolic pressure and the spontaneous contraction rate of the preparations in the standard solution were slightly reduced during the experiments (2—4 hours) The mean change of the active systolic pressure was 3.5% (n 12, range −19 — +14 %) and that of the contraction rate 2.5% (n 13 range −13 — +8 %) To reduce this source of error the values obtained during steady state in the test solution were expressed in per cent of the mean of the corresponding values obtained in the preceding and following standard Ringer's solution

Influence of mepivacaine on spontaneously beating hearts

The effects of mepivacaine on spontaneous contraction rate, active systolic pressure and/or electrogram were investigated in 1 hearts. The results of these experiments are summarized in Table 1 The changes in the spontaneous contraction rate in the A—V conduction time and in the duration of the ventricular complex in the electrogram were directly related to the concentration of mepivacaine in the perfusion

fluid. In every heart in which more than one concentration of mepivacaine was tested, the changes in all parameters studied increased with increasing concentration of the local anaesthetic (as in preparation No. 1 Fig. 1 A—F) although not evident in the mean values of Table I. As each heart was not perfused with all concentrations of mepivacaine used, the lack of correlation in Table I between the mepivacaine concentration and the mean changes in active systolic pressure and $(dp/dt)_{max}$ can be explained by differences in sensitivity of the hearts towards the local anaesthetic.

In this connection it should be recalled, that a reduction in contraction rate has a positive inotropic effect in this type of heart preparation (Andersson, Gennser and Nilsson 1970 a). The slowing of the contraction rate, which was more pronounced at high mepivacaine concentrations than at low, therefore tends to counteract the negative inotropic action of the local anaesthetic.

Panel (F) shows typical tracings of the mechanical and electrical registrations at two different concentrations of mepivacaine 5 and 20 μg/ml respectively. Calibration horizontal bar 200 msec vertical bar 20 mm Hg. Symbols mepivacaine 5 μg/ml Δ mepivacaine 10 μg/ml ( ) mepivacaine 20 μg/ml ( )

Fig. 1 E and F on opposite page

The effects of mepivacaine were evident as soon as the mepivacaine solutions reached the hearts and were maximum after 3—5 min. They disappeared with the same time course after changing to perfusion with the standard Ringer's solution.

a) Spontaneous contraction rate

The contraction rate of the spontaneously beating hearts was reduced only to a moderate extent even at high mepivacaine concentrations (a 12 per cent reduction was seen at a mepivacaine concentration of 20 μg/ml). In two hearts (results not included in Table I) an arrhythmia due to atrio-ventricular conduction block occurred at concentrations of 10 and 20 μg/ml, respectively. This arrhythmia ended in slow regular idio-ventricular rhythm.

b) Intraventricular pressure

Even at the lowest concentration used 2.5 μg/ml, a reduction of the intraventricular pressure could be recorded (Table I). Maximum rate of pressure development, $(dp/dt)_{max}$ was often more reduced than active systolic pressure. No significant change in the duration of the contraction was found. In the two hearts where the intraventricular pressure in both right and left ventricle was recorded simultane

ously the reduction of the developed pressure was more pronounced in the right ventricle.

c) Electrogram

Changes in electrogram were inconspicuous at a mepivacaine concentration of 2.5 μg/ml, but were pronounced at higher concentrations. The atrio-ventricular conduction time and the duration of the ventricular complexes increased with increasing mepivacaine concentration (Table I and Fig. 1 C, D and F) In the two hearts where an arrhythmia was registered, a reversible atrio-ventricular conduction block occurred. In both hearts, the pressure was recorded by means of a balloon in the left ventricle. It should be noted that electrogram changes were constantly more pronounced in this type of preparation than in those where an open catheter was used for pressure registration (Andersson, Genmer and Nilsson 1970 a)

Lidocaine

Changes in spontaneous contraction rate, intraventricular pressure, and electrogram similar to those produced by mepivacaine, were seen in the two hearts where the perfusion fluid contained lidocaine 20 μg/ml. No analysis of possible quantitative differences between the effects of lidocaine and mepivacaine was performed.

Influence of mepivacaine on electrically stimulated hearts

In order to avoid inotropic influences due to changes in spontaneous contraction rate five heart preparations were electrically stimulated. Two hearts were paced at a constant frequency throughout the experiment and three preparations at various selected frequencies during each of the different perfusion periods.

a) Intraventricular pressure

Fig 2 A and B illustrate data from one experiment in which a constant stimulation frequency was used. The changes in $(dp/dt)_{max}$ and active systolic pressure were dependent on the concentration of mepivacaine and were more pronounced at high stimulation frequencies than at low (compare Fig 1 A, B and E with Fig. 2 A and B, which show results obtained with the same preparation at an initial spontaneous contraction rate of 118 beats per min and during electrical stimulation 128 stimulations per min, respectively)

b) Electrogram

Similar mepivacaine effects on the electrogram as were seen in spontaneously beating hearts could be demonstrated in electrically stimulated preparations. The atrio-ventricular conduction time and the duration of the ventricular complexes were prolonged in proportion to the mepivacaine concentration used. In all five preparations a reversible atrio-ventricular conduction block could be produced at high concentra-

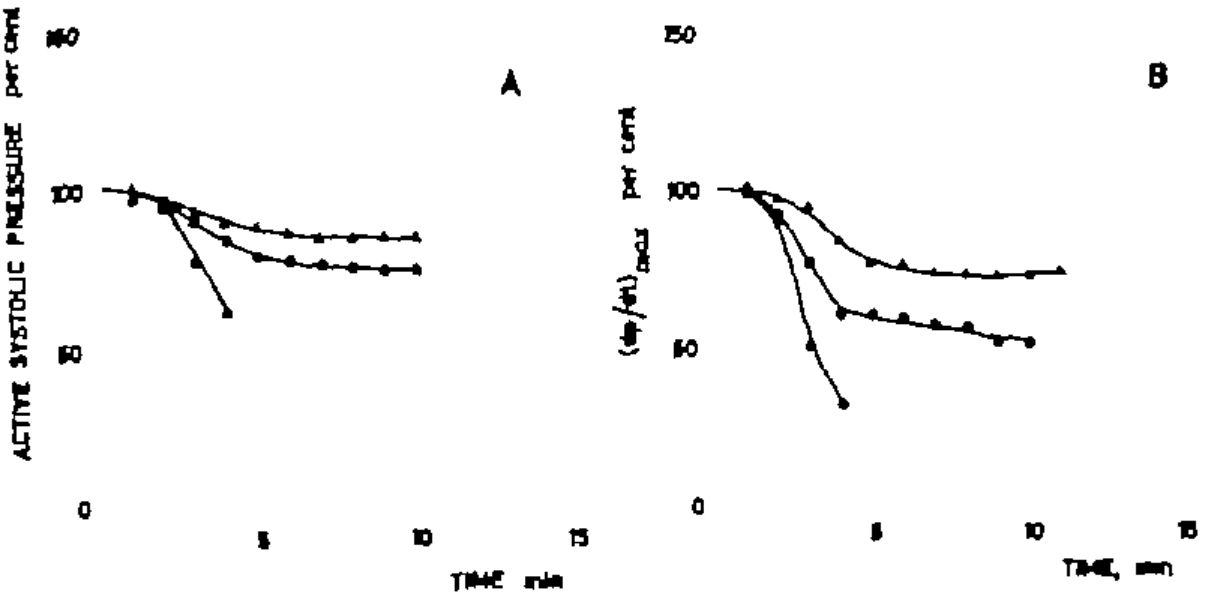

Fig. 2 A and B. Effects of three different concentrations of mepivacaine on activ systolic pressure (A) and $(dp/dt)_{max}$ (B) Constant stimulation frequency 128 stim./min. Same preparation and same symbols as in F g. 1 A—E. At the mepivacaine concentration 20 μg/ml A—V-conduction block occurred after four min perf sion.

tions of mepivacaine (10—20 μg/ml) Even at a concentration of 5 μg/ml, atrio-ventricular conduction block occurred at stimulation frequencies just above the spontaneous contraction rate in standard Ringer's solution.

I fluence f pH on the effects of mepivacaine

The effects of mepivacaine at pH 7.00 and 7.35 were compared in five spontaneously beating hearts the results are summarized in Table II The combination of mepivacaine and low pH caused a reduction of spontaneous contraction rate, active systolic pressure (Fig 3) and $(dp/dt)_{max}$ it also caused an increase in atrio-ventricular and intraventricular conduction time all these responses being more pronounced than to either intervention separately The negative inotropic effect of mepivacaine on electrically stimulated heart preparations was augmented by acidosis at all frequencies studied The ability of the preparations to respond to rapid frequencies of stimulation was reduced by mepivacaine and further diminished by a simultaneous lowering of extracellular pH (Fig. 4)

Concentrations f mepivacaine in heart tissue

Three heart preparations were perfused for 10 min with a Ringer s solution of pH 7 35 containing mepivacaine 10 μg/ml. After perfusion the hearts were immediately frozen and stored at −20 C. Their content of mepivacaine was analysed by gas-liquid chromatography The values obtained were 9 10, 7.36 and 8.91 μg/g wet heart tissue (mean 8.29 μg/g) Foetal hearts at midgestation contain approximately 850 g w ter per kg wet tissue (Widdowson and Dickerson 1960 Gemmer Johanson and

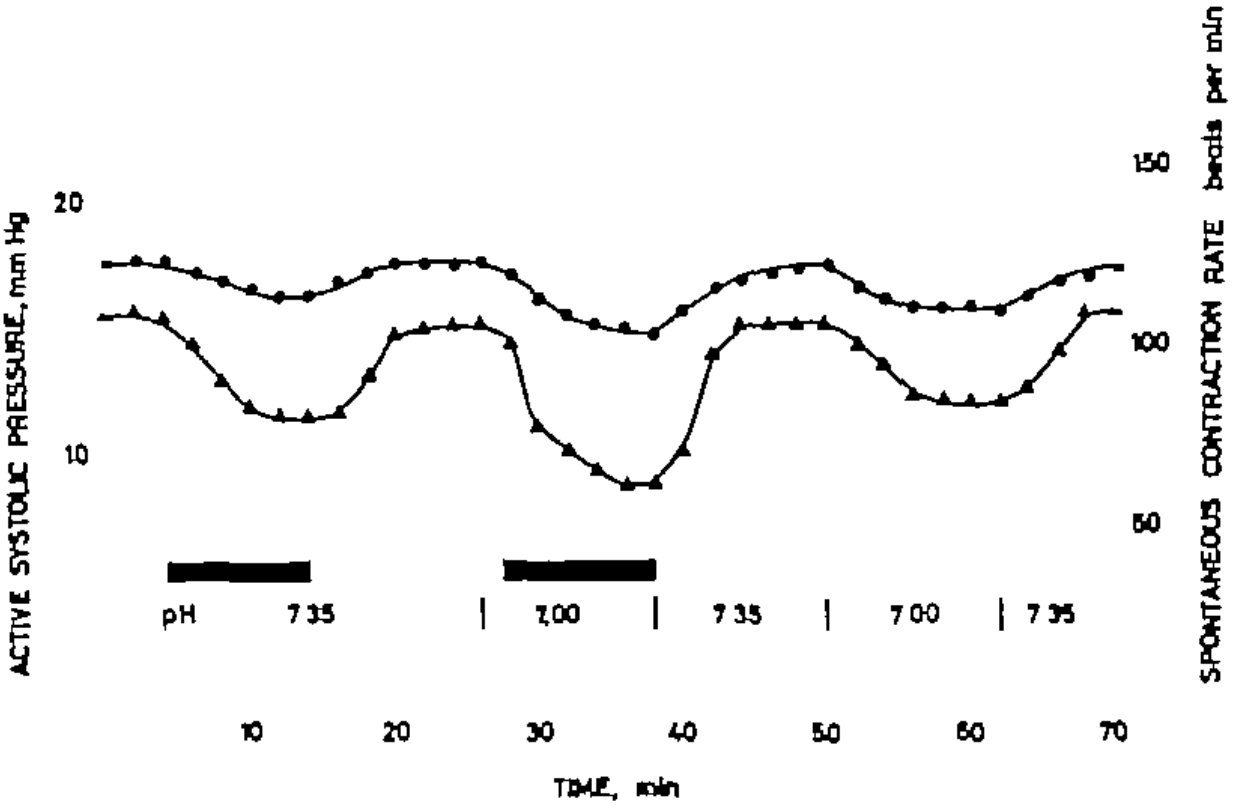

Fig. 3 Effects of mepivacaine at pH 7.35 and 7.00 on spontaneous contraction rate ( ) and active systolic pressure (▲) Black bars indicate perfusion with Ringer's solution containing mepivacaine 10 μg/ml. Heart preparation No. 2, see Table II

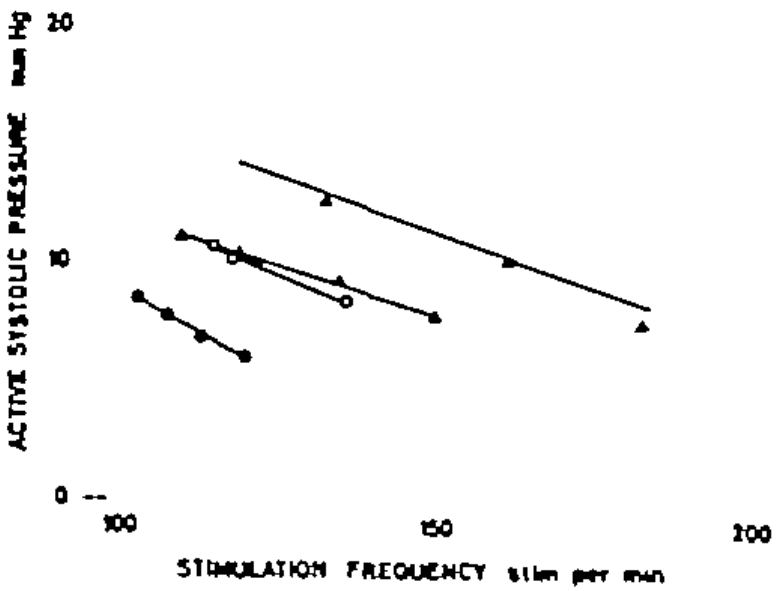

Fig. 4 Relation between active systolic pressure and stimulation frequency at pH 7.35 and 7.00 with and without mepivacaine in the perfusion fluid. Symbols: pH 7.35 (▲) pH 7.00 (△) pH 7.35 + mepivacaine 10 μg/ml ( ) pH 7.00 + mepivacaine 10 μg/ml ( ) Right ends of lines denote maximum contraction rate in response to stimulation. Same preparation as in Fig. 3

Kullander 1968). Assuming an even distribution of mepivacaine in total tissue water the intracellular concentration of mepivacaine would be very close to the concentration in the perfusion fluid. (A ratio of 0.98 for concentration in tissue water/concentration in perfusion fluid was obtained.)

Discussion

In the present study heart preparations from human foetuses at midgestation were used. There are reasons to assume that the results obtained are valid also for the human foetal heart at term. Organogenesis of the heart is considered to be complete before midgestation (Patten 1953) and it is possible that the human foetal heart at this stage of the gestation has developed an adrenergic innervation (Gennser and Owman, unpublished observation). It has also been shown (Gennser and Nilsson 1970) that human foetal heart cells from this period have resting membrane potentials of the same magnitude as and action potential characteristics similar to cells from adult mammalian hearts. Furthermore isometric tension developed by papillary muscle preparations from human foetal hearts at midgestation show a frequency dependence similar to that demonstrated in ventricular preparations from adult hearts of other mammalian species (Gennser and Nilsson 1972).

The mepivacaine concentrations used in the present investigation (5–10 μg/ml) are of the same magnitude as foetal blood levels of mepivacaine reported to have foetal bradycardia and/or foetal depression after paracervical block or epidural anaesthesia (Morishima et al. 1969, Gordon 1968, Hon 1970, Teramo and Rajamäki 1970).

Pacemaker activity

The results obtained have shown that mepivacaine produces a moderate slowing of the contraction rate by reducing the pacemaker activity of the sinus node. It is of interest to note that lidocaine which is chemically and pharmacologically similar to mepivacaine, has been demonstrated to depress the automaticity of the dog heart, primarily the ventricular but also the atrial (Lieberman *et al.* 1968 Sugimoto *et al.* 1969) However in several studies on adult man no consistent changes in heart rate have been observed at therapeutical concentration of lidocaine (plasma levels 1—4 μg/ml) (Harrison, Sprouse and Morrow 1963 Schumacher *et al.* 1968, Cullhed 1969) Initial tachycardia followed by bradycardia is seen as the typical pattern of *local anaesthetic toxicity (Steinhaus 1957) and a progressive bradycardia has been* noted during lidocaine infusion in dogs (maximum plasma levels 11.3±3.30 μg/ml mean and S.E.) (Binnion 1968, Binnion *et al.* 1969) In view of the moderate reduction in contraction rate obtained in the present study it seems unlikely that a direct effect of mepivacaine on the sinus node is the only cause of foetal bradycardia during PCB.

Electrogram changes

Large doses of lidocaine are known to prolong atrio-ventricular conduction time (Lieberman *et al.* 1968) This finding is in accordance with the present results for mepivacaine in which a concentration-dependent increase of the atrio-ventricular conduction time was noted. Also a broadening of the ventricular complexes could be demonstrated, which probably reflects an impaired intraventricular conduction. Both effects were more pronounced at high stimulation frequencies than at low The ability of the preparations to respond to rapid frequencies of stimulation was reduced by mepivacaine This is in accordance with results obtained in a recent electrophysiological study in which the lidocaine effects on Purkinje fibres and papillary muscles from dogs were analysed (Davis and Temte 1969)

Sinclair *et al* (1965) reported four cases of accidental injection of mepivacaine in the foetus in connection with PCB. In two of these cases (blood level determined in one 52 μg/ml) the electrogram showed an atrio-ventricular rhythm with ventricular conduction delay It is of interest that the same changes could be seen in two preparations of the present study (at concentrations 10 and 20 μg/ml, respectively)

Contractility

It is well known that high concentrations of local anaesthetics reduce the contractility of the heart, and the present results show that mepivacaine in all concentrations used reduced both $(dp/dt)_{max}$ and active systolic pressure Furthermore the results indicate that mepivacaine induces a direct negative inotropic effect independent of inotropic changes due to alterations in contraction rate

Mechanisms of mepivacaine effects

Mepivacaine at a concentration of 2.5 μg/ml or more caused a moderate slowing of the pacemaker activity of the sinus node, produced changes in the electrogram indicating a reduced conduction velocity and reduced the contractility of the hearts. The mechanisms behind these actions are not obvious. Local anaesthetics are known to "stabilize" excitable membranes raising the threshold for electrical excitation, suppressing the spontaneous pacemaker activity and slowing the propagation of action potentials. The rate of rise and the overshoot of the action potential are reduced but resting membrane potential is not consistently affected (Weidmann 1955 Ritchie and Greengard 1966). These actions are considered to be produced by a reduction in the conductance of sodium and possibly other ions in the cell membrane.

The negative inotropic action of mepivacaine may to some extent be ascribed to a reduction of intraventricular conduction velocity causing an asynchronous activation of the ventricles (cf. Andersson, Gennser and Nilsson 1970 a). It is also possible that mepivacaine directly interferes with the excitation-contraction coupling in the myocardial cell. Local anaesthetics have been shown to antagonize calcium movements across the cell membrane (Feinstein 1963) as well as across the internal membrane system of muscle cells, the sarcoplasmic reticulum (Feinstein 1963 Bianchi and Bolton 1967 Lüttgau and Oetliker 1968). These calcium movements are necessary for activation and relaxation of the contractile system (for references, see Langer 1968, Katz 1970). Furthermore, local anaesthetics have been shown to reduce the accumulation of calcium by the sarcoplasmic reticulum (Johnson and Inesi 1969). This ability might possibly be correlated with their negative inotropic action on the myocardium, as suggested by Gertz *et al.* (1967).

Mepivacaine and pH

The present results show a depressive effect on the spontaneous contraction rate and the myocardial contractility of both mepivacaine and a lowering of pH (cf. Andersson, Gennser and Nilsson 1970 b). The combined effect of these interventions may reflect a simple addition of the effects of mepivacaine and the increased proton activity in the external medium, but the present study was not aimed at a quantitative analysis of this point. It is not clear whether the cationic or the uncharged form of a local anaesthetic is responsible for its cardiac effects (see Ritchie Cohen and Dripps 1970). The pk_a of mepivacaine is 7.8 (Aberg, Friberger and Adler personal communication). Hence the relative amount of total anaesthetic in cationic form increases from 74 % at pH 7.35 to 86 % at pH 7.00. It seems unlikely that such a small change in the relation between the ionized and the non-ionized form of mepivacaine would have markedly affected the results of the present study.

Skilful technical assistance was given by Miss Margareta Olsson, Mrs Maria Wranitzky and Miss Karin Jönsson. Thanks are due to Professor K. U. P. Edman for valuable discussions during preparation of the manuscript and to fil. lic. G. Aberg, AB Bofors Nobel Pharma, Mölndal, for

presence in white adipose tissue of measurable amounts of noradrenaline metabolizing enzymes i.e. monoamineoxidase (Stock and Westermann 1963) and catechol-O-methyl transferase (Traiger and Calvert 1969 Horst *et al* 1969) has also been reported Inhibition of tyrosine hydroxylation, the rate limiting step in noradrenaline biosynthesis, in adipose tissue leads to a progressive decline in the transmitter content (Gessa *et al.* 1968) This indicates the presence in adipose tissue of a functioning noradrenaline biosynthesis. The release of noradrenaline from adipose tissue upon nerve stimulation, which would provide the final evidence for a transmitter function of noradrenaline in this tissue, has not been reported, however The fate of noradrenaline in intact adipose tissue is similarly unknown.

Electrical stimulation of nerves to rat and rabbit adipose tissue *in vitro* for prolonged periods of time and with high impulse frequencies (16—50 cps) has been reported to release FFA into the medium (Nash *et al.* 1961 Correll 1963) Recently an experimental technique permitting the study of vascular and metabolic reactions in dog subcutaneous adipose tissue was described (Orö Rosell and Wallenberg 1965 Rosell 1966) With this technique Rosell demonstrated the frequency-response characteristics of the FFA releasing effect of nerve stimulation. Maximal release rates during the stimulation were seen with 3 impulses/sec. At higher rates of stimulation the pronounced vasoconstriction apparently counteracted lipolysis during nerve stimulation. It has also been shown that electrical stimulation of certain diencephalic and mesencephalic areas connected to the sympathetic nervous system cause an elevation of plasma levels of FFA (Orö, Wallenberg and Bolme 1965)

Attempts to demonstrate adrenergic nerves by means of the fluorescence histochemical method of Falck and Hillarp (Falck 1962, Corrodi and Jonsson 1967) around individual fat cells in rat (Winsén 1965 Ballantyne and Raftery 1969) and dog (Fredholm and Hamberger unpublished) adipose tissue have proved unsuccessful. On the other hand, a rich supply of adrenergic nerves to the blood vessels has been shown. From this observation it has been suggested that the adrenergic nerves in adipose tissue regulate lipolysis by varying the blood flow through the tissue (Winsén 1965 Ballantyne 1968) However Rosell (1966) has shown that sympathetic nerve stimulation does cause mobilization of FFA even when the blood flow is kept constant.

The administration of the sympathetic neurotransmitter noradrenaline to intact animals and man increases the FFA and glycerol levels in plasma (cf Hagen 1967) This effect is probably due to a direct action on adipose tissue and not primarily to other factors, such as inhibition of insulin release (Porte 1967) This opinion is further strengthened by the massive collection of data showing that sympathomimetic amines are lipolytic when added to isolated

adipose tissue *in vitro* (see Steinberg and Vaughan 1965 Hagen 1967) and even to isolated fat cells from the rat (Rodbell 1964) Adrenaline and nor adrenaline cause an increase in the activity of the enzyme catalyzing the first step in triglyceride breakdown, which is probably rate-limiting in many situations (Gorin and Shafrir 1964 Strand, Vaughan and Steinberg 1964) The enzyme, hormone-sensitive triglyceride lipase exists in two forms (Vaughan *et al* 1965) and it appears that catecholamines are able to convert the inactive form into an active one. Moreover there is evidence that this conversion is brought about by adenosine 3',5'-monophosphate, cyclic AMP (Rizack 1964 Rizack 1965) possibly as a consequence of phosphorylation induced by a cyclic AMP-stimulated protein kinase (Corbin and Kreba 1969) The synthesis of cyclic AMP in adipose tissue is increased by catecholamines (Butcher *et al*, 1965 Butcher Baird and Sutherland 1968) The activity of the cyclic AMP synthesizing enzyme, adenyl cyclase also increased in adipose tissue following exposure to adrenaline (Vaughan and Murad 1969)

In accordance with the hypothesis of Ahlquist (1948) it is customary to divide the effects of catecholamines into two categories, α- and β- This classification is based on relative agonist potencies and the use of presumably specific receptor antagonists. Attempts to place the lipolytic response to catecholamines into this scheme have not been entirely successful (cf. Hagen 1967) This is particularly true with regard to the FFA and glycerol increases in plasma following the administration of sympathomimetic amines to intact animals and man. The usefulness of the classification in terms of "receptors" of the metabolic effects of adrenaline and noradrenaline in intact animals and man has been seriously questioned (Hagen 1967) On the other hand, a careful analysis of dose-response relationships of adrenomimetic amines with or without receptor blocking agents in epididymal fat pads *in vitro* led Wenke (1966) to conclude that the structure function relations agree extremely well with those for muscular β-effects. This conclusion was also reached by Stock and Westermann (1966a, 1966b)

Sympathetic nerve activity and catecholamines affect metabolic functions other than lipolysis both in intact animals (see Hagen 1967) and in isolated adipose tissue *in vitro* (see Ball and Jungas 1965 Flatt and Ball 1965 Lynn, Macleod and Brown 1960 Shafrir and Wertheimer 1965) The metabolic effect of sympathetic nerve activity in adipose tissue perfused with blood is not known, however Similarly the effect on adipose tissue of metabolic changes induced by sympathetic nerve activity elsewhere in the body such as increased blood lactate, is essentially unknown.

Adipose tissue is well vascularized (Gersh and Still 1945 Sheldon 1965) and clearcut vascular changes, such as arterial and venous vasoconstriction

and an increased hydrodynamic conductivity are seen when the nerves to adipose tissue of the dog are activated (Ngai, Rosell and Wallenberg 1966 Öberg and Rosell 1967) There are also indications that these vascular changes have some influence on the metabolic action of sympathetic nerve activity (Rosell 1966) this problem has not been studied in detail, however

The present experiments were undertaken to clarify the role played by sympathetic nerves in the regulation of circulation and metabolism in adipose tissue. The above mentioned experimental technique (Rosell 1966) permitting the study of the effects of nerve stimulation in isolated bloodperfused canine subcutaneous adipose tissue has been used. The release and fate of the adrenergic transmitter has been studied indirectly by following labelled nor adrenaline. The metabolic and vascular changes induced in adipose tissue by nerve stimulation have been studied in some detail. By pharmacological means attempts have been made to clarify the relative importance of different factors responsible for determining the overall response in adipose tissue to nerve stimulation. Particular emphasis has been put on the relationship between vascular changes and metabolic responses.

II. METHODOLOGY

a. Experimental procedure

Materials The studies were performed on female mongrel dogs weighing between 6 and 25 kg The dogs were fasted overnight (self-imposed) but no further caloric restrictions were imposed. Anaesthesia was induced by sodium pentobarbital (25—30 mg/kg) i.v with supplement during the experiment when necessary

Surgical procedure Subcutaneous adipose tissue (10—104 g) was isolated from all surrounding tissues, including skin, and scrupulous hemostasis was maintained (see Rosell 1966) In the majority of the experiments the right subcutaneous adipose tissue was used, but the left one appeared similar in every respect. An analysis of variance with regard to vascular resistance before and during nerve stimulation, glycerol and FFA release, and glucose uptake revealed no significant differences in ten dogs. Subcutaneous adipose tissue can be isolated and perfused in male dogs also (Ballard, Fredholm and Rosell, unpublished) Moreover from a qualitative point of view the responses are similar to those obtained in the female, but no quantitative comparisons have been carried out. The surgical procedure is considerably easier in the female.

Methods of perfusion The inguinal adipose tissue is supplied by one artery and drained by one vein (Rosell 1966) After canulation the tissue is therefore easily perfused. Three different types of perfusion have been used in these studies a) autoperfusion, b) constant flow perfusion using defibrinated blood and c) constant flow perfusion using heparinized blood. The different methods have been compared (a with b in papers V and VI b with c in paper IV) No significant differences with regard to the uptake or release of metabolites were found.

Constant flow perfusion was used in the majority of the experiments for three major reasons. First of all there have been proposals (Wirsén 1965 Ballantyne 1968) that the metabolic effects of nerve stimulation are mediated via changes in gross blood flow in adipose tissue. Secondly it was necessary to study the responses of the adipose tissue in complete isolation from the rest of the dog since it has been suggested that humoral factors (Wirsén 1965) play a major role in the response of white adipose tissue to an increased sympatho-adrenal tone. Finally it was hoped that by the use of an arterial

blood reservoir there would be no or at least more predictable, changes in the blood composition. In papers IV and V changes in the reservoir blood were reported (glucose concentration decreased and the lactate concentration increased) but it was found that these changes could be described by a linear change with time. It was thus possible to obtain a valid estimate of the blood composition at any given time during the course of the experiment.

In order to evaluate whether the constant flow perfusion caused any alterations in the activity of adipose tissue free flow experiments were also carried out. The basal metabolism was similar in autoperfused and constant flow perfused adipose tissue (papers V and VI) the similarity in the lipolytic response to nerve stimulation is documented below (section III e)

The vascular effects of drugs and of nerve stimulations were always studied with free flow perfusion. In some experiments the tissue was placed in a plethysmograph to measure volume changes and the capillary filtration coefficient CFC, as described in detail elsewhere (Folkow Lundgren and Wallentin 1963 Cobbold *et al* 1963 Öberg and Rosell 1967)

Nerve stimulation. The nerve to adipose tissue which runs together with the main artery and vein, was cut at the level of the external hiatus of the inguinal canal and placed on a bipolar electrode. The nerve was protected from moisture and air by Plastibase (Squibb) and stimulated electrically with approximately rectangular pulses delivered from a Grass stimulator

The pulses (2 msec duration, 8—15 V) were delivered at a rate of 3 to 10 cps. In most experiments 4 cps was used a frequency which is within the range considered by Folkow (1957) to be the physiological rate of firing in skeletal muscle adrenergic fibres. This frequency was known to give clearcut, although not maximal, vasoconstriction (Ngai, Rosell and Wallenberg 1966) and almost maximal rates of FFA release during a 30 min stimulation Rosell 1966)

Sampling procedure Samples of arterial and venous blood were collected. The sampling procedure varied between the series of experiments. The arterio-venous concentration difference was determined. If the concentration difference is negative there is considered to be a release of the metabolite in question, similarly a positive arterio-venous difference is in this report called uptake The uptake and "release of the metabolite is expressed as μmoles/min/100g by multiplying the concentration difference with the blood or plasma flow in ml/min/100g tissue.

b. Comments

Hahn (1943) found that heparin cleared lipemic plasma and Korn (1958) ascribed this phenomenon to the release of a lipase activity clearing factor lipase (CFL) by heparin. For this reason the use of heparin as an anticoagulant in a study of lipid metabolism deserves comment. Although CFL was at one time thought to be responsible for the mobilization of FFA from white adipose tissue (Gordon and Cherkes 1956 Olson and Vester 1960) this is not the current opinion (e.g. Ho Ho and Meng 1967) The administration of heparin causes release of lipase activity from canine subcutaneous adipose tissue (Ballard Fredholm Meng and Rosell 1970) but does not affect the release of FFA and glycerol therefrom induced by sympathetic nerve stimulation (Fredholm Meng, Öberg and Rosell 1968) Nerve stimulation did not release lipase activity into venous plasma (unpublished exp.) Therefore the two lipase activities, the one causing hydrolysis of intracellular triglycerides and that released by heparin, are in all probability dissociated There was no difference in the basal metabolism of adipose tissue perfused with defibrinated or heparinized blood (paper IV) Moreover heparin did not change the vascular resistance (Ballard *et al* 1970) For these reasons the use of heparin in the present studies appears justifiable.

The nerve to the adipose tissue is mixed in character as is evident from the fact that some, but not all, of the nerve fibres exhibit the specific catecholamine fluorescence after formaldehyde treatment according to Falck and Hillarp (Fredholm and Hamberger unpublished experiments) There is, however good reason to believe that the responses seen upon electrical activation of the nerves are secondary to the release of noradrenaline from nerve endings within the tissue. The responses to nerve stimulation could be mimicked by noradrenaline (paper II Ballard, Cobb and Rosell 1970) The vasoconstriction occurring upon nerve stimultaion can be converted to a vasodilatation by the use of an adrenergic α-receptor antagonist. Papers I III IV Ngai Rosell and Wallenberg 1966) This vasodilation is similar to that produced by isoprenaline (paper II) a relatively pure β-receptor agonist. There is also a close similarity between the lipolytic response to isoprenaline and to nerve stimulation after adrenergic α-blockade. The lipolysis, as well as the vasodilatation, can be inhibited by adrenergic β-receptor antagonists, including pronethalol, propranolol and INPEA (paper I) After dual adrenergic receptor blockade, nerve stimulation had neither vascular nor metabolic effects (paper I) Guanethidine (1.5 mg i.a.) blocked the vascular and metabolic effects of nerve stimulation (Fredholm, unpublished) Further evidence concerning the presence, uptake, release and metabolism of noradrenaline in

canine subcutaneous adipose tissue is summarized elsewhere (section III d)

Although histamine is present in appreciable amounts in canine subcutaneous adipose tissue and the release of endogenous histamine is accompanied by vasodilatation and lipolysis (Fredholm, Meng and Rosell 1968 Fredholm and Frisk Holmberg 1969) histamine release does not seem to be a factor in the responses to nerve stimulation (II) The possibility that prostaglandins play an important role in determining the responses to nerve stimulation in canine subcutaneous adipose tissue is discussed elsewhere (section III h)

c. Analytical methods

FFA were determined titrimetrically in plasma according to Dole (1956) as modified by Trout *et al.* (1960)

Glycerol was determined enzymatically as described by Laurell and Tibbling (1966)

Glucose was measured enzymatically using a commercial reagent (Glox, Kebo Stockholm Sweden) It was found that the sampling error was considerably lower (less than 2 per cent) when plasma was used instead of blood (about 4 per cent) Consequently glucose was measured in plasma in the majority of the experiments. As discussed in paper V plasma and blood glucose values covaried and the determination of glucose uptake with either of the two methods gave statistically indistinguishable results.

Lactate and *pyruvate* were measured according to Bücher *et al.* (1967) and Hohorst (1962) respectively using test kits obtainable from Boehringer and Sohne Mannheim, Germany

H no adrenaline and its metabolites The methods used for separation and determination have been described in detail in paper III

Noradrenaline was measured in 0 4 M perchloric acid extracts of adipose tissue according to the procedure of Bertler Carlsson and Rosengren (1958)

Glucos lactat and glycogen were determinated fluorimetrically (Karlsson, Diamant and Saltin 1970) in biopsy specimens (20—50 mg) excised before, during and after nerve stimulation and frozen in liquid nitrogen within 4 sec. The biopsies were cleansed from gross visible contaminants such as blood and connective tissue. The remainder was weighed, pulverized and mixed with frozen 3M perchloric acid (about 150 µl) After thawing the extract was titrated to pH 7.8—8 5 The supernatant after centrifugation was used for the determination of glucose and lactate The former was measured

as increase in NADPH after incubation with hexokinase and glucose-6-phosphate dehydrogenase in 0 1 M Tris buffer (pH 8 0) Lactate was measured as increase in NADH after incubation with heart lactic dehydrogenase in 0.2 M carbonate buffer (pH 9 7)

Triglycerides were determined according to Martinsson (1967)

Fatty acids in biopsy specimens (0.5—1 0 g) were determined titrimetrically (Trout *et al.* 1960) after homogenization in Dole s medium (25 ml)

Tissue water was determined in biopsy specimens (50—100 μg) by the weight decrease following freeze-drying for 14 days.

Na^+ *and* K^+*-ions* were determined in digests of adipose tissue with twice the weight of conc. HNO_3. After dilution and centrifugation, the ion concentration in samples were measured flame spectrophotometrically

III RESULTS AND DISCUSSION

a. Composition of adipose tissue

The composition of canine subcutaneous adipose tissue, as revealed by the present studies, is presented in Table 1

The extravascular ion contents could be calculated to be about 30 μEq Na^+/g tissue and 2.3 μEq K^+/g, since the plasma concentrations averaged 143 and 3 8 mM respectively The sodium space is calculated to average 21 per cent Using this estimate and assuming that the adipocyte potassium concentration is 110 mM (Denton, Yorke and Randle 1966) the intracellular water space is found to be 1 4 per cent. The values obtained are similar to those determined by Denton, Yorke and Randle (1966) in rat epididymal fat pads. Due to the variability in the ion determinations and the many approximations involved in the calculations the present estimate is very rough. Similarly the estimate of the extracellular water space from the determination of tissue glucose content (Ballard and Hanson 1969) is subject to considerable error One might conclude that the adipose tissue contains between 10 and 21 ml extracellular water per 100 g and that the intracellular water is one order of magnitude less.

b. The uptake and release of metabolites during basal conditions (I IV V IV)

During basal conditions (i.e. in unstimulated adipose tissue) the glycerol release rate averaged 0.24 μmoles/min/100 g The range was wide (0.0⁵— 0 71) This variation could not be explained on the basis of differences in the arterial concentrations. There was also no significant association between the rate of glycerol release and the fat weight, or the ratio between fat and dog weight, which might give a rough indication of the adiposity of the dog

Throughout this study the release of glycerol has been taken as an indicator of the rate of lipolysis The arguments in favour of this assumption were summarized by Steinberg and Vaughan (1965) Glycerol is utilized in adipose tissue (Lynn, MacLeod and Brown 1960 Antony White and Laudau 1969) but the rate is low This is probably due to the fact that the enzyme that phosphorylates glycerol glycerokinase is scarce in white adipose tissue.

TABLE 1 Composition of canine subcutaneous adipose tissue.
Numbers within parantheses represents number of determinations.

Glycogen (μmoles/100 g)	310 ± 120 (13)	P per IV
Triglycerides (g/100 g)	73 ± 3 (6)	
FFA (μmoles/100 g)	540 ± 100 (14)	
Glucose (μmoles/100 g)	50 ± 10 (14)	Paper IV
N (μEq/100 g)	3450 ± 450 (10)	
K (μEq/100 g)	450 ± 12 (10)	
Water (ml/100 g)	17 ± 4.5 (10)	Paper IV
Intravascular volume (ml/100 g	5	Öberg and Rosell (1967)
Extracellular water (ml/100 g)	21	(From N determination)
Extracellular water (ml/100 g)	11 ±	(From glucose determination)
Intracellular water (ml/100 g)	14	(From Na and K determination)

It was originally thought to be absent (Margolis and Vaughan 1962) but its presence was recently demonstrated (Robinson and Newsholme 1967) It is of importance that glycerol cannot by itself support triglyceride synthesis in otherwise suitably fortified homogenates of rat epididymal adipose tissue (Steinberg, Vaughan and Margolis 1961 Margolis and Vaughan 1962)

Basal FFA release was lower (0 12 μmoles/min/100 g) and the range was wider (—0.96 to 1.25) than the basal glycerol release. There was no correlation between the arterial FFA concentration and the net release rate. Similarly the fat weight and the adiposity did not correlate with the release rate.

The basal glucose uptake was extremely variable between dogs, but this variation can be ascribed, at least partly to an increased uptake with increasing arterial glucose concentration (V VI) The glucose uptake was weakly correlated ($p<0.05$) to an indicator of the re-esterification (3 x glycerol release — FFA release)

The uptake of lactate and pyruvate by adipose tissue was strongly dependent upon the arterial concentration (V) The dependence could be approximated by a straight line regression, the steepness of which was greater for pyruvate than for lactate. The lactate regression line intercepted with the arterial concentration between 1 and 2 mM the pyruvate regression line between 0.05 and 0.1 mM. These arterial concentration values are close to those found normally in the dogs. It might be concluded that the adipose tissue does not normally contribute significantly to the net uptake or release of these anions.

The oxygen extraction was found to be 2.4 ±0.6 μmoles/min/100 g and the carbon dioxide production 2.7 ± 1 7 μmoles/min/100 g. (IV)

c. Blood circulation in canine subcutaneous adipose tissue

1 *Resting conditions*

Blood circulation in canine subcutaneous adipose tissue has been studied extensively in this laboratory (see review by Rosell 1969). The resting blood flow was 8.4 ml/min/100 g (range 3.2—19) (Ngai, Rosell and Wallenberg 1966; Öberg and Rosell 1967 paper II). This value is of the same order of magnitude as that reported for resting skeletal muscle (Mellander and Johansson 1968). These authors also calculated that adipose tissue would take about 15 per cent of resting cardiac output in a 70 kg man, which is a larger proportion than any other organ system.

It was noted (II) that the highest blood flow values were generally seen in adipose tissues with the lowest weights. This finding indicates that increases in fat weight are not necessarily accompanied by corresponding increases in the magnitude of the vascular resistance section. Hausberger and Widelity (1963) in a study of the distribution of Cr tagged erythrocytes concluded that the size of the vascular bed decreased with ageing, when fat accumulation increased.

Blood flow measured by Xe^{133} clearance, in abdominal subcutaneous adipose tissue in man (Häggendal, Steen and Svanborg 1970) is similar to that obtained in the abdominal subcutaneous adipose tissue in dogs. On the other hand blood flow values in other depots of subcutaneous adipose tissue in man, similarly determined by Xe^{133} or Kr^{85} clearance, are generally somewhat lower (2.6 ml/min/100 g, Larsen, Lassen Quaade 1966; 2.3 ml/min/100 g Nielsen *et al* 1968; 2.1 ml/min/100 g Lesser and Deutsch 1967). The flow in canine subcutaneous adipose tissue is similar to that in rat as measured directly (5.3 ml/min/100 g) and by Rb^{86} clearance (5.7 ml/min/100 g) (Mayerle and Havel 1969 a) or by clearance of H DDT (10—25 ml/min/100 g, Herd Goodman and Grose 1968) and also similar to rabbit epigastric adipose tissue (Lewis and Matthews 1968 8.1 ml/min/100 g).

There is considerable evidence that blood flow may in some conditions, such as fasting diabetes and glukagon administration, increase with lipolysis in man (Nielsen *et al* 1968; Häggendal *et al* 1970) rat (Mayerle and Havel 1969 b) and rabbit (Lewis and Matthews 1968).

The results of Scow *et al* (1965) studying the release of FFA from perfused rat parametrial fat, do not suggest such a good correlation, however. Thus ACTH which strongly stimulated lipolysis and FFA release had no effect on blood flow and adrenaline decreased blood flow in lipolytic concentrations. Our own results (see below) also indicate that there is not always a correlation between lipolysis and blood flow.

The maximal blood flow rate in canine subcutaneous adipose tissue, which might give an indication of the dimension of the resistance section, ranged between 25 and 45 ml/min/100 g tissue (Ngai *et al.* 1966 Öberg and Rosell 1967 paper II) This suggests that the resistance section is less well developed than in skeletal muscle for example.

The regional blood content in adipose tissue was estimated by Öberg and Rosell (1967) to be 5 ml/100 g tissue, which is 1.5—2 times higher than the corresponding value in skeletal muscle. Hausberger and Widelitz (1963) reported a regional blood content of one to eight ml/100 g tissue in white adipose tissue from various locations in the rat. This value was similar to that of skeletal muscle in the same study

The capillary filtration coefficient, CFC, which gives a measure of the total surface area available for filtration of water indicated a richer capillary supply than that present in skeletal muscle (0.024 ml/mm/100 g/mmHg as compared to 0.010—0.015 ml/min/100 g/mmHg in skeletal muscle) On the other hand Gerah and Still (1954) in a morphological study concluded that adipose tissue was less well capillarized than skeletal muscle, but yet, for purposes of metabolism, the capillary bed of adipose tissue was far richer than that of muscle.

2. *The effect of drugs.* A brief summary is given in Table 2.

Table 2. Vascular effects of drugs in canine subcutaneous adipose tissue.

Drug	Dose	% change in flow	% change in CFC	% change in reg. blood vol.
Acetylcholine	10^{-6}—10^{-5}	107	20	4
Bradykinin	10^{-6}	46	114	15
Histamine	10^{-7}—10^{-6}	113	82	6
5-hydroxytryptamine	10^{-6}	23	9	— 3
Isoprenaline	10^{-6}	151	15	3
Noradrenaline	10^{-5} —10^{-4}	—68	63	—14
PGE_1	10^{-5}	127	27	8
Theophylline	10^{-5}	165	122	9
I. a.				
K^+	5×10^{-5}	30		
Ca^{++}	5×10^{-4}	—20	12	— 2
Mg^{++}	3×10^{-4}	10		
Ba^{++}	5×10^{-5}	—30		
Na-EDTA	3×10^{-5}	190	25	4
L(+)-lactate	-20×10^{-4}	— 3		
D(—)-lactate	10^{-5}	0		
Pyruvate	5×10^{-5}	18		
Vag. *stimulation*	3—8 cps	—66	73	—14

Acetylcholine, isoprenaline 5-hydroxytryptamine and prostaglandin E all increased blood flow in adipose tissue (paper II) The most potent of these drugs on a molar basis was PGE_1 PGE_2 was 2 to 10 times less effective (Fredholm, Öberg and Rosell, unpublished) These drugs also caused a small (5—10 per cent) increase in CFC. Histamine and bradykinin also increased blood flow but produced larger increases in CFC (paper II) per unit increase in blood flow Noradrenaline (II) and adrenaline (Ballard, Cobb and Rosell 1970) are predominantly vasoconstrictor in subcutaneous adipose tissue. The former drug gives vascular changes, including CFC increase, identical to those given by nerve stimulation (Table 2)

Of the anions studied in paper V only pyruvate produced a significant vasodilatation. This is in agreement with earlier observations (see Haddy and Scott 1968)

3 *The effect of nerve stimulation. Earlier studies*

The nervous control of adipose tissue has been studied in some detail in this laboratory (Ordö Rosell and Wallenberg 1965 Ngai, Rosell and Wallenberg 1966, Öberg and Rosell 1967 paper II Fredholm, Linde, Öberg and Rosell 1969 Rosell 1969) The blood flow through canine subcutaneous adipose tissue decreases during electrical activation of the nerve to the tissue or the lumbar sympathetic chain. The rate of the resistance increase as well as the "steady state" level of the constrictor response is frequency dependent. Maximal vasoconstriction is obtained with frequencies between 10 and 20 cps. Stimulation with 4 cps, the frequency most commonly used in the present experiments, gave 70 per cent of maximal vasoconstriction (Ngai Rosell and Wallenberg 1966)

Comparative studies on the sympathetic regulation of circulation in adipose tissue from other species are lacking. On the other hand, studies of circulation in canine adipose tissue from other locations, have revealed differences from subcutaneous adipose tissue (Ballard and Rosell 1969 1970)

During nerve stimulation about one third of the blood contained in adipose tissue is expelled (Öberg and Rosell 1967) This is similar to skeletal muscle (Mellander and Johansson 1968)

Nerve stimulation, moreover increased CFC markedly This response appears to be unique. The CFC has been regarded as an indication of the capillary surface area and/or the capillary porosity (Cobbold *et al.* 1963) The morphological basis for the increase in adipose tissue is as yet unclear *In skeletal muscle CFC increases somewhat, although much less than in* adipose tissue, during prolonged nerve stimulation. This phenomenon has been ascribed to a sphincter relaxing effect of metabolites accumulating in

the tissue. It does not seem possible to explain the CFC increase in adipose tissue similarly. Thus metabolism in adipose tissue is stimulated by a mechanism that can be inhibited by adrenergic β-receptor antagonists (I) yet the administration of propranolol will not abolish the CFC increase during nerve stimulation in adipose tissue. Moreover Linde and Rosell (unpublished) have found that the clearance of locally injected radioisotopes is decreased in adipose tissue during nerve stimulation, in situations where CFC increases, even if the blood flow is kept constant by artificial means.

4. The effect of nerve stimulation. Own studies (II)

In order to obtain further evidence on the background to these apparently conflicting findings the studies reported in paper II were performed. It was noted that the effect of nerve stimulation could be mimicked by noradrenaline and after α-receptor blockade it could be imitated by isoprenaline. The CFC increases seen during nerve stimulation were larger than those produced by acetylcholine, isoprenaline and PGE_1 in concentrations giving apparently maximal relaxation of the resistance section in adipose tissue (Table 2). Since procedures which maximally increase blood flow are generally capable of opening all capillaries, mere relaxation of precapillary sphincters was apparently not capable of allowing CFC rises comparable to those seen with nerve stimulation. On the other hand, histamine and bradykinin, which are generally supposed to increase capillary permeability (Elliott, Horton and Lewis 1960, Spector 1958) did give CFC values comparable to those seen with nerve stimulation (Table 2). When nerve stimulation was superimposed upon infusion of acetylcholine, isoprenaline or PGE_1 a further increase in CFC was obtained even if blood flow was kept constant. Nerve stimulation during infusion of histamine or bradykinin, however rather decreased CFC.

These results, those obtained by Linde and Rosell (unpublished) and others can possibly be unified, as discussed earlier (Fredholm *et al.* 1969, Rosell 1969) by assuming that nerve stimulation induces a closure of pre capillary sphincters and an increase in the permeability of the capillaries left open. Such a mechanism would give increased diffusion distances, leading to a decreased clearance of radioisotopes, and simultaneously an increased CFC.

d. Adrenergic transmission in canine subcutaneous adipose tissue (III)

Canine subcutaneous adipose tissue contained 37 $\pm$10 ng noradrenaline/g (n=10). This value is in the lower range reported for white adipose tissue (see Introduction).

During prolonged sympathetic nerve stimulation there was a net production of lactate seen as a net outflow of lactate and an accumulation of lactate in the tissue (IV) The tissue lactate level during stimulation was approximately 2.5 μmoles/g. Assuming distribution solely in tissue water this would correspond to a concentration above 10 mM. On the other hand, shorter nerve stimulation had no significant effect on the net lactate release by adipose tissue (V)

f. Modification of metabolic effects of nerve stimulation by adrenergic receptor antagonists (I IV)

There is general agreement that catecholamines stimulate lipolysis mainly by activating receptors which are similar to muscle β receptors (Havel 1965 Stock and Westermann 1966 a, Wenke 1966) On the other hand, in the two published reports concerning the effect of nerve stimulation on lipolysis dibenamine an adrenergic α-receptor antagonist, inhibited lipolysis induced by nerve stimulation (Nash *et al.* 1961 Correll 1963)

In contrast in our experiments (paper I) the lipolytic effect of nerve stimulation was potentiated by adrenergic α-receptor blockade induced by dihydroergotamine or phentolamine. Administration of β receptor antagonists such as pronethalol, propranolol or INPEA (D( ) N isopropyl-p-nitrophenyl-ethanolamine) inhibited the lipolytic effect as well as the vasodilatation occurring during nerve stimulation after dihydroergotamine or phentolamine. The fact that Correll (1963) was able to produce inhibition of lipolysis might be due to the high concentration of dibenamine (0.5 mg/ml) he used, since it has been shown that α-blocking agents in concentrations of this magnitude cause unspecific inhibition of lipolysis (Stock and Westermann 1966 b)

Oxygen uptake increased during nerve stimulation after dihydroergotamine pretreatment, but decreased after propranolol as it did when no receptor antagonist was given. The oxygen uptake appeared to vary inversely with vascular resistance (IV)

The glycogenolysis during nerve stimulation was unaffected by dihydroergotamine, but was inhibited by propranolol It appears that glycogenolysis as well as lipolysis is activated by stimulating fat cell receptors which are similar to muscular β-receptors.

Lactate production during nerve stimulation was inhibited by both propranolol and dihydroergotamine (IV) It seems reasonable to assume that the lactate production is a consequence of both a stimulation of metabolism effected by β-receptor activation and a decreased transport of metabolites, including oxygen, secondary to vasoconstriction caused by stimulation of α-receptors.

g. Evidence for the participation of cyclic AMP in the regulation of lipolysis in canine subcutaneous adipose tissue

The evidence for a role of cyclic adenosine 3',5'-monophosphate (cyclic AMP) in the activation of lipolysis by different lipolytic hormones, including sympathomimetic monoamines, was briefly summarized in the Introduction. Methyl xanthines, including caffeine and theophylline, can be used as tools to evaluate the role of cyclic AMP in lipolysis as discussed by Brodie and coworkers (Hynie, Krishna and Brodie 1966, Weiss, Davies and Brodie 1966). These substances are known to inhibit the enzymatic degradation of cyclic nucleotides (Butcher and Sutherland 1962).

In a series of experiments theophylline-1-aminopropanol (a kind gift from AB Astra, Södertälje, Sweden) was infused in graded amounts (0.05—10 mM in blood). Theophylline above 0.1 mM was found to increase the rate

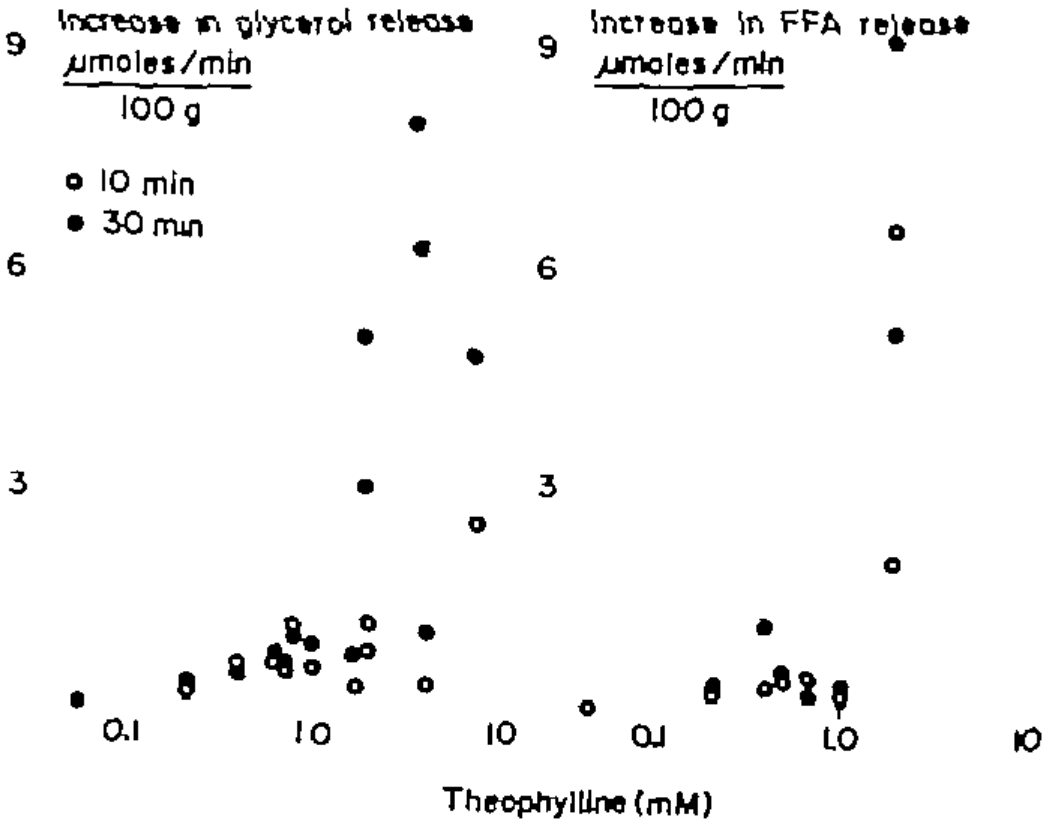

Fig. 3. Increase in glycerol and FFA 10 (○) and 30 min (●) after the start of an infusion of theophylline-1-aminopropanol in graded amounts. Each point represents results from one experiment.

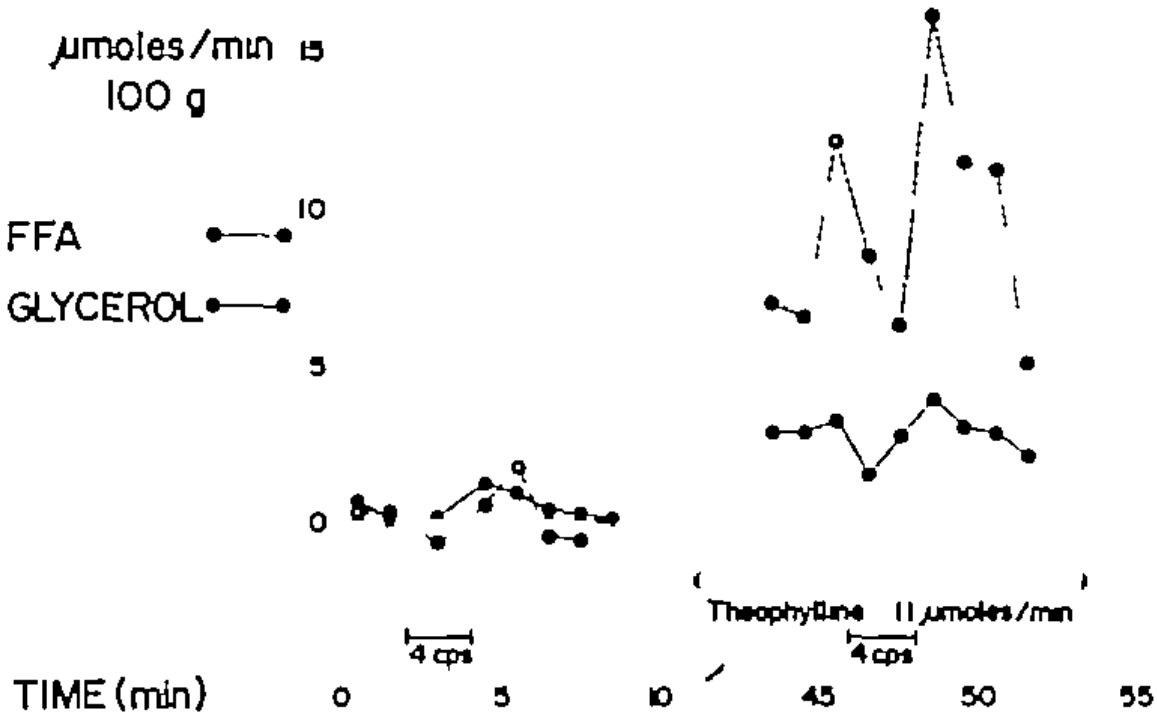

Fig. 4 The effect of a min sympathetic nerv stimulation on the release of FFA and glycerol before and during an infusion of theophylline-1-aminopropanol (11 µmoles/min) Adipose tissue weight 24 g Mean systemic blood pressure 110—100 mmHg PCV 40.0.

of glycerol and FFA efflux from adipose tissue (Fig 3) 0 1 mM was threshold for producing lipolysis, increasing cyclic AMP levels and significantly inhibiting phosphodiesterase in rat epididymal adipose tissue and isolated fat cells (Weiss, Davies and Brodie 1966 Hynie, Krishna and Brodie 1966) Theophylline above 2 mM produced marked increases in FFA and glycerol release (Fig 3) These concentrations produced apparently maximal stimulation of lipolysis in the rat and human adipose tissue *in vitro* (Hynie, Krishna and Brodie 1966, Weiss, Davies and Brodie 1966, Carlson, Hallberg and Michell 1969) Nerve stimulation during infusion of these high concentrations of theophylline had little if any further stimulatory effect on lipolysis (Fig 4) This indicates that these concentrations of theophylline had indeed caused a maximal stimulation of lipolysis in canine subcutaneous adipose tissue *in situ* The fact that theophylline by itself can markedly increase lipolysis can be taken as evidence that cyclic AMP is rapidly synthesized and broken down even in unstimulated adipose tissue (Weiss, Davies and Brodie 1966) at least if it is assumed that theophylline only inhibits phosphodiesterase

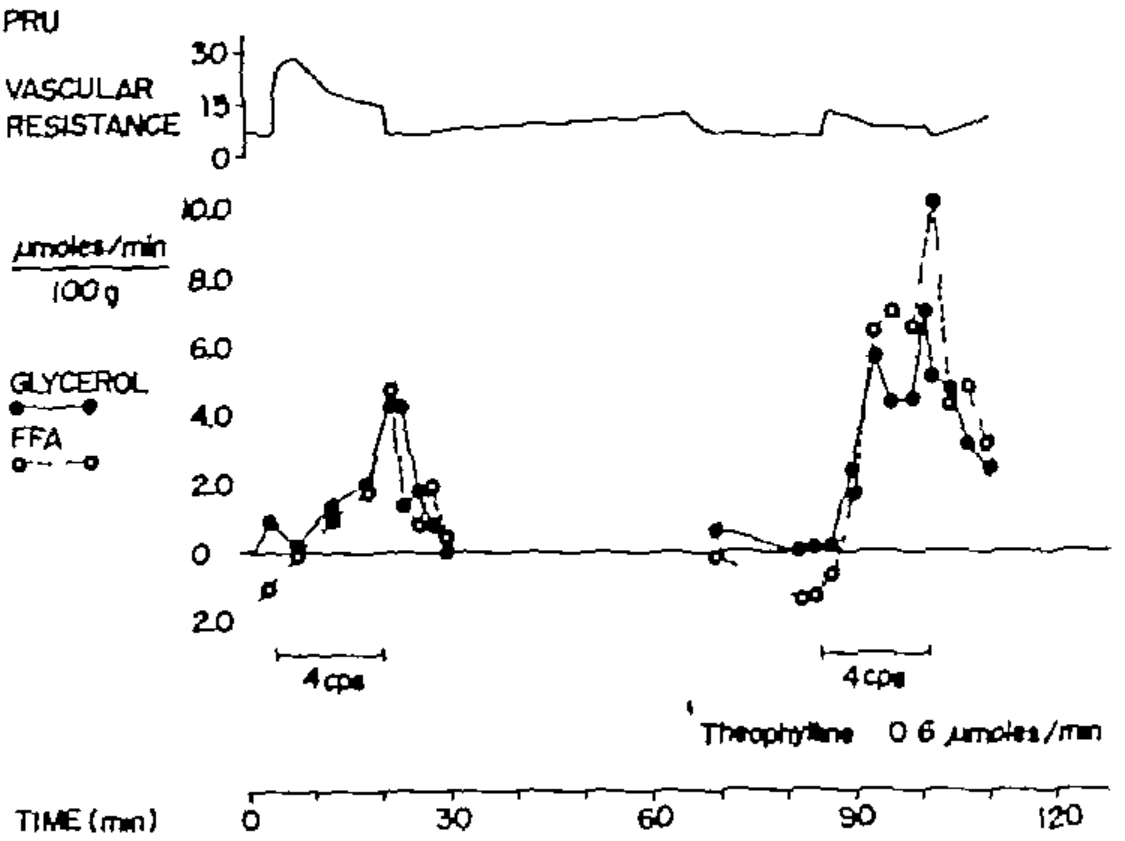

Fig. 5. Potentiation of the release of glycerol and FFA evoked by nerve stimulation by theophylline-1-aminopropanol (0.6 µmoles/min). Adipose tissue 16 g. PCV 34 0. Mean systemic blood pressure 140—120 mm Hg.

The lipolytic effect of nerve stimulation was potentiated by theophylline in low (0 1—1 mM) concentrations (Fig 5) Noradrenaline induced lipolysis is potentiated by low amounts of theophylline in rat epididymal fat pads in *vit o* (Vaughan and Steinberg 1963 Weiss, Da ies and Brodie 1966) The increase in cyclic AMP after adrenaline is considerably enhanced by methyl xanthines in rat epididymal fat pads (Butcher Ho Meng and Sutherland 1965) and isolated fat cells therefrom (Butcher Baird and Sutherland 1968) Therefore the present data might indicate that nerve stimulation in canine subcutaneous adipose tissue *in situ* increases the rate of cyclic AMP formation.

It can be seen in Fig 5 that the vasoconstriction induced by nerve stimulation is reduced by theophylline. (0.1—1 mM theophylline inhibited the vasoconstriction by 34 per cent 1—10 mM by 66 per cent) The lipolytic response to nerve stimulation is affected by the vasoconstriction (section *III j*) Therefore the interaction between theophylline and α-receptor stimulation on blood circulation might contribute to the potentiation.

h. *Effects of prostaglandins on lipolysis during nerve stimulation (VI)*

The prostaglandins are a group of acidic lipids found in many tissues and body fluids. Prostaglandins, especially E-compounds, decrease lipolysis in adipose tissue *in vitro* (see Bergström, Carlson and Weeks 1968) presumably by inhibiting the formation of cyclic AMP (Stock, Aulich and Westermann 1968 Butcher and Baird 1968) Stimulation of the nerve to rat epididymal fat pads *in vitro* was recently found to cause an increased prostaglandin formation and release of prostaglandin-like material into the medium (Shaw and Ramwell 1968) The possibility that prostaglandins act as feed-back inhibitors of stimulated lipolysis has therefore been proposed (Shaw and Ramwell 1968 Bergström, Carlson and Weeks 1968 Horton 1969)

Studies on the isolated dog spleen revealed that prostaglandin-like material could be released during nerve stimulation and that the release was inhibited by adrenergic α-receptor antagonists (Davies, Horton and Withrington 1968) Since it was found in the course of the present work (paper I) that α-receptor blockade potentiated the release of glycerol and FFA we were interested to see whether this was mainly due to removal of inhibition of lipolysis by prostaglandins, released by α-receptor stimulation. Efendic (1970) concluded from a series of studies on human adipose tissue *in vitro* that stimulation of adrenergic α-receptors inhibits lipolysis.

In a recent study (Fredholm Rosell and Strandberg 1970) we were able to confirm the results of Shaw and Ramwell (1968) by showing that sympathetic nerve stimulation at "physiological" frequencies caused an increased outflow of acidic lipids, resembling prostaglandins chromatographically from blood perfused canine subcutaneous adipose tissue. In general less than 1 ng prostaglandin like activity (in PGE units) was found in the venous effluent per ml. There was no detectable increase in extractable prostaglandin-like material in stimulated adipose tissue relative to control. We were unable to find inhibition of prostaglandin release by dihydroergotamine. Recently it was reported that prostaglandin release from the diaphragm is actually increased by α-receptor blockade (Laity 1969) which indicates that the findings of Davies, Horton and Withrington (1968) may not be representative of all tissues from all species. Therefore the possibility that the potentiation of lipolysis by dihydroergotamine or phentolamine was due to removal of inhibition secondary to prostaglandin release, as also suggested by Bergström, Carlson and Weeks (1968) appeared less attractive.

In paper VI prostaglandin E — the most potent inhibitor of lipolysis in rat epididymal fat pads *in vitro* (Bergström, Carlson and Weeks 1968) was infused in graded amounts into adipose tissue and its effect on the glycerol and

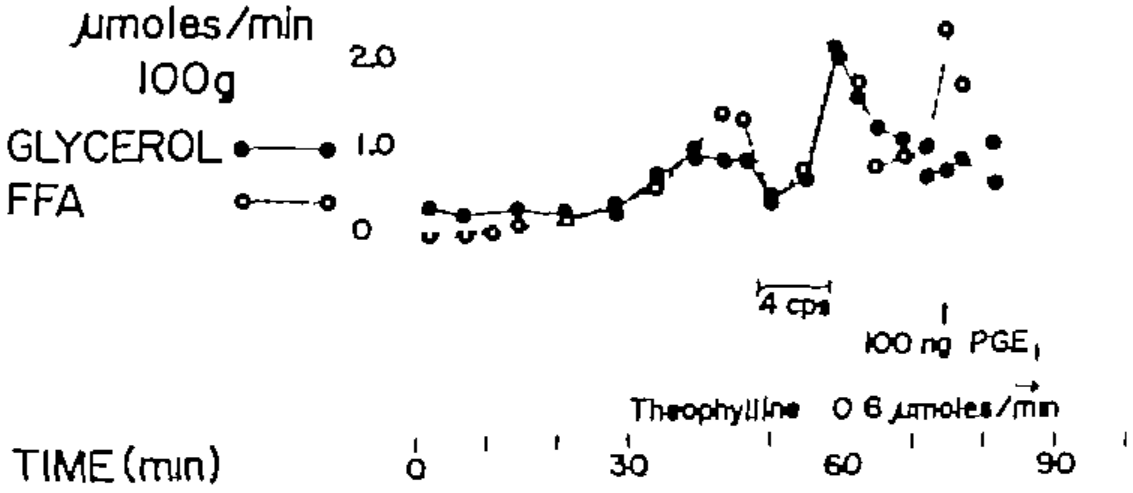

Fig. 6. The effect of nerve stimulation (10 min, 4 cps, 12 V 2 msec) and PGE_1 (100 ng i.a.) during infusion of theophylline (0.6 μmoles/min) after pretreatment of the tissue with propranolol (400 μg i.a.) on FFA and glycerol release. Adipose tissue 35 g. PCV 40.0. Mean systemic blood pressure 105—100 mm Hg.

FFA release induced by nerve stimulation determined. It was found that lipolysis induced by nerve stimulation was inhibited dose-dependently by PGE_1 (ID_{50} appr 1.2×10^{-7} M). The concentrations needed to produce significant inhibition of lipolysis were considerably larger than those found in the venous effluent after nerve stimulation (10—100 times). Thus it would appear that the amounts of prostaglandin released are insufficient to significantly affect lipolysis during nerve stimulation. It was, however found (Fredholm, Rosell and Strandberg 1970) that the rate of inactivation of infused PGE was considerable. It is consequently possible that a small pool of prostaglandin, with a very rapid turnover might regulate lipolysis, although it can not be shown by merely analyzing for total tissue prostaglandin content.

PGE_1 was also found to produce a very marked increase in the rate of glucose uptake by adipose tissue, as described earlier *in vitro* by Böhle *et al.* (1966). On the other hand, nerve stimulation did not cause an increased uptake of glucose (papers IV, V, VI).

PGE was found to be a powerful vasodilator (II). It did not produce the very marked increase in CFC as seen after nerve stimulation, however. It is difficult to ascribe any of the vascular reactions during nerve stimulation to the release of prostaglandins in adipose tissue (II).

Polyphloretinphosphate has recently been shown to antagonize the action of prostaglandin on many smooth muscle preparations (Eakins, Karim and Miller 1970). Polyphloretinphosphate (10—20 mg/ml) did not, however

affect the basal or nervously stimulated lipolysis in canine subcutaneous adipose tissue (unpublished)

Finally in a series of six experiments no evidence for the presence in canine subcutaneous adipose tissue of an inhibitory α-receptor mechanism was obtained. Stimulation after propranolol administration, leaving only the α-receptors intact caused a decrease in the release rate during the stimulation period, but afterwards there was a compensatory increase (Fig 6) In the same experiment and in three others PGE actually increased the release of glycerol as was seen occasionally when lipolysis had not been previously stimulated by theophylline (VI) The results did not support the opinion that prostaglandins, released by adrenergic α-receptor stimulation, are important inhibitors of lipolysis activated by nerve stimulation.

To summarize We have been able to confirm the *in vitro* observation that PGE_1 inhibits lipolysis stimulated by nerve activity (Berti and Usardi 1964) and extended it by demonstrating dose response characteristics in a blood perfused organ stimulated with frequencies more similar to those occurring physiologically We have also confirmed the results of Shaw and Ramwell (1968) that prostaglandin-like material is released from adipose tissue upon nerve stimulation. It is, however difficult to define the part played by prostaglandins in the lipolytic response to nerve stimulation in canine subcutaneous adipose tissue and none of the vascular responses could be directly attributable to prostaglandin release. Whether prostaglandins play a role in the long-term regulation of adipose tissue metabolism in the dog cannot be determined from these experiments.

5. Changes in re-esterification (V)

When triglycerides in adipose tissue are hydrolysed three moles of fatty acid are formed per mole of glycerol. It has been found repeatedly in *in vitro* experiments (see Steinberg and Vaughan 1965) that less than three moles of fatty acids are released per mole of glycerol even if corrections are made for the contents of free fatty acids and of glycerol in the incubated tissue Steinberg and Vaughan (1965) discussed this phenomenon at length and concluded that the most reasonable explanation is that fatty acids are re esterified.

In the present experiments there was often a net uptake of FFA in spite of a definite net release of glycerol during basal (i.e. unstimulated) conditions. Since no estimate of the fluxes of fatty acids in adipose tissue were made conclusions about re-esterification and esterification could not be

drawn in the basal state. For this reason studies of the changes of the re esterification were made on the basis of differences in the amounts of FFA and glycerol released upon nerve stimulation. The increase in FFA and glycerol release over the basal rate were considered to be due to increased release and not to decreased uptake.

Increasing the arterial L(+) lactate concentration decreased the mobilization of FFA upon nerve stimulation, while the release of glycerol was essentially unchanged. On the other hand, infusion of Na-pyruvate in very high amounts had the opposite effect more FFA were mobilized but the glycerol release was significantly lowered. This implies that lactate increased re-esterification and pyruvate decreased it. Before discussing possible mechanisms behind this effect some of what is known about adipose tissue intermediary metabolism will be briefly reviewed (Fig 7)

The rate of triglyceride synthesis in defatted homogenates of rat epididymal adipose tissue was found to be strongly dependent upon the concentration of α-glycerol phosphate and fatty acid (Steinberg, Vaughan and Margolis 1961 Angel and Rondel 1967) Many authors have proposed a control for α-glycerol phosphate in the regulation of triglyceride biosynthesis *in vivo* (e.g. Leveille 1967) On the other hand attempts to correlate the contents of α-glycerol phosphate or long-chain fatty acyl-CoA with *observed rates of glyceride biosynthesis* have not been successful (Denton and Randle 1967 Denton and Halperin 1968)

Although less effective than glucose, pyruvate can be a substrate for synthesis of glyceride-glycerol (Ballard, Hanson and Leveille 1967 Leveille 1967 Reshef Hanson and Ballard 1969 Wieegrad and Renold 1958) This is presumably true also for lactate. *Adipose tissue contains pyruvate carboxylase (Ballard and Hanson 1967)* and phosphoenolpyruvate carboxykinase (Ballard, Hanson and Leveille 1967) These findings indicate that pyruvate carbon can be incorporated into triglycerides via a pathway essentially similar to gluconeogenesis in liver Pyruvate carboxylase and citrate synthetase activities are higher in mitochondria from white adipose tissue than from liver (Patel and Hanson 1970) which supports the view that this route might be of physiological significance. Adipose tissue apparently lacks the enzymes fructose 1,6-phosphatase and glucose 6-phosphatase (Weber *et al.* 1965) and glucose and glycogen cannot be synthesized from e.g. pyruvate. Instead, fructose 1,6-diphosphate and the triosephosphates, including dihydroxyacetonephosphate, the immediate precursor to α-glycerol phosphate, would accumulate. The physiological significance of the pathway might be the production of glycerol necessary to keep up with triglyceride turnover in conditions such as fasting, when the supply of glucose is limited (Steinberg, Vaughan and Margolis 1961) Evidence supporting this view was recently provided (Reshef Ballard and Hanson 1969) Pyruvate kinase in adipose tissue is converted *to* a less active form upon fasting (Pogson 1968) and the conversion of oxaloacetate to malate decreases during fasting (Gorin, Tal-Or and Shafrir 1969) Both these changes would enable more pyruvate to form glyceride-glycerol in fasting.

When the animal is fed the conversion of oxaloacetate to malate is presumably of great importance, since *this step is crucial in a cyclic process in adipose tissue with the*

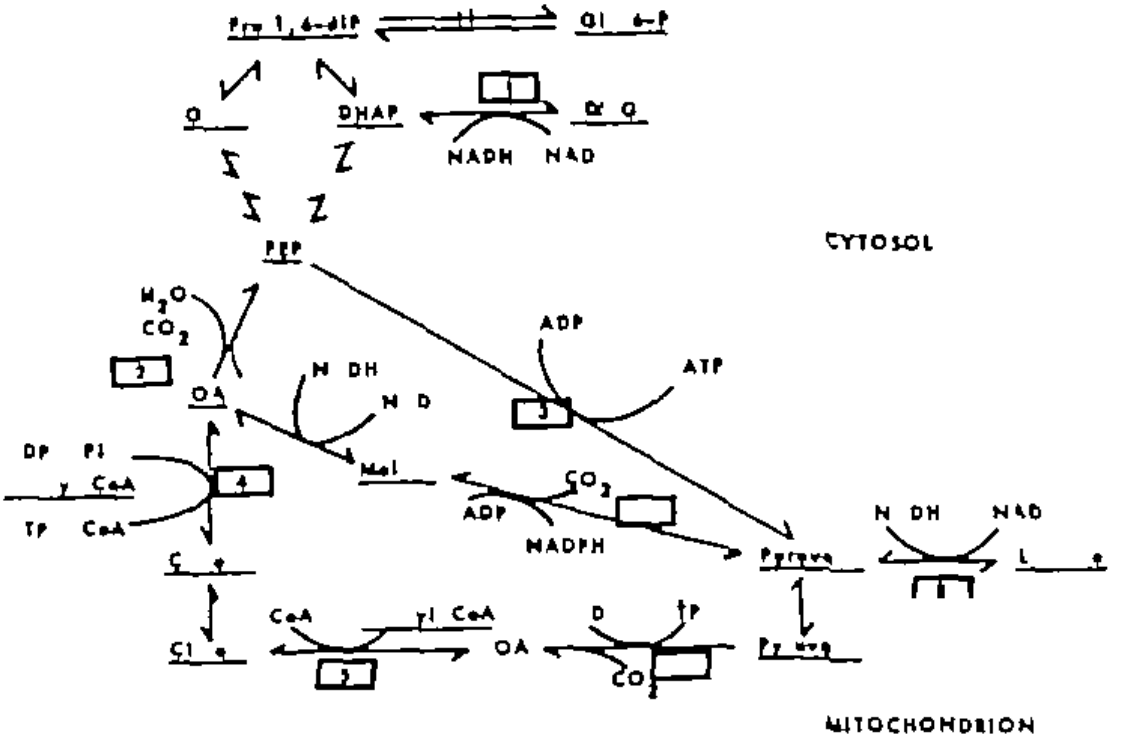

Fig. 7 Schematic representation of pathways involved in glucose and pyruvate metabolism relevant to a discussion of the regulation of re-esterification in adipose tissue. Glu-6-P = glucose 6-phosphate Fru 1,6-di P = fructose 1,6-diphosphate GADP = glyceraldehyde 3-phosphate DHAP = dihydroxyacetone phosphate α-GP = glycerol 3-phosphate PEP = phosphoenolpyruvate OA = oxaloacetate.

Reaction 1) is catalyzed by glycerolphosphate dehydrogenase (1.1.1.8) 2) by phosphoenolpyruvate carboxykinase (4.1.1.3) 3) by pyruvate kinase (2.7.1.40) 4) by ATP citrate lyase (citrate cleavage enzyme) (4.1.3.8) 5) citrate synthetase (4.1.3.7) 6) Pyruvate carboxylase (6.4.1.1) 7) Malate dehydrogenase-decarboxylating enzyme (1.1.1.40) and 8) by lactate dehydrogenase (1.1.1.8)

twofold purpose of transferring acetyl-CoA from the mitochondria to the cytosol and transhydrogenation of NADH to NADPH both essential processes in lipogenesis (Young, Shrago and Lardy 1961 Wise and Ball 1964 Rognstad and Katz 1968 Leveille and Hanson 1966) This cycle, which found experimental support by Rognstad (1969) involves the transfer of pyruvate into the mitochondria, carboxylation to oxaloacetate, oxaloacetate and acetyl-CoA forming citrate which flows out of the mitochondrion and is split by citrate cleavage enzyme into oxaloacetate and acetyl CoA. The oxaloacetate is reduced to malate with NADH and the malate converted back to pyruvate generating NADPH. Since the first steps in the pyruvate cycle and the pathway leading from pyruvate to glyceride-glycerol are identical there should be competition between glyceride and fatty acid formation from pyruvate as discussed for liver (Ballard, Hanson and Kronfeld 1969) and found experimentally in rat epididymal fat pad (Gorin, Tal-Or and Shafrir 1969) In fed animals, which have been used throughout this study the cyclic process might be the quantitatively more important one.

If prevalon of glycerol equivalents for triglyceride biosynthesis was the only explanation for the observed increase in re-esterification during lactate infusion it is surprising that pyruvate does not have the same effect. Indeed one would expect that pyruvate would be a more efficient substrate for α-glycerolphosphate biosynthesis since lactate would tend to shift the oxaloacetate-malate reaction towards malate, thus providing less phosphoenolpyruvate.

The final step in the conversion of glucose — or for that matter pyruvate — into glycerol phosphate involves the reduction of dihydroxyacetone-phosphate. This reaction it is generally accepted, is strongly dependent upon the ratio between reduced and oxidized NAD (Bücher and Klingenberg 1958, Hohorst *et al* 1965) Another tentative explanation for the observed actions of lactate and pyruvate on the re-esterification can be stated. It is possible that lactate and pyruvate change the concentration of α-glycerolphosphate less by themselves being the substrate than by changing the utilization of glucose for glycerol synthesis. When lactate is infused a certain proportion of the anion is oxidized to pyruvate, furnishing reduced nucleotides in the process. The reduced nucleotides shift the dihydroxyacetonephosphate—α-glycerolphosphate equilibrium to the right. The converse could be true during pyruvate infusion. Cahill Leboeuf and Flinn (1960) found that 5 mM pyruvate significantly decreased the incorporation of ^{14}C-label from glucose into glyceride glycerol. Incubation of rat epididymal fat with adrenaline increased both lactate production and triglyceride synthesis (Flatt and Ball 1965 Landau *et al* 1965) Similarly lactate production and re-esterification seemed to increase in parallel during prolonged sympathetic stimulation (IV) and it was shown by Peterson and co-workers (1964) that pyruvate and dihydroxyacetonephosphate compete for NADH in skeletal muscle.

Evidence for an inhibition of FFA release by lactate has appeared earlier Thus Mueller (1961) found that lactate inhibited the FFA increase in plasma of dogs after systemic 2-deoxy-D-glucose administration. Issekutz and Miller (1962) found that infusion of Na-lactate in amounts similar to those produced in exercise and giving the same blood concentrations decreased plasma FFA levels. This finding was confirmed by Miller *et al.* (1964) who also found that the effect was stereospecific for L(+)-lactate. These authors concluded that the effect was presumably due to an increased re-esterification secondary to an increased availability of α-glycerolphosphate, but could not prove this, since glycerol turnover rates in the dog were not determined. Björntorp (1965 1966) investigated the effect of Li-lactate on glycerol production in rat epididymal fat pads *in vitro* He found that already at a concentration of 3 mM lactate caused a significant inhibition of glycerol production and lipo-

lytic activity and that this effect was not clearly dose-dependent since 30 mM lactate had the same effect.

The results (V) with infusion of lactate and pyruvate clearly demonstrate that the mobilization of FFA can be varied independently of the mobilization of glycerol, i.e. of lipolysis. Moreover it appears that such modification could occur under physiological conditions. Decreased mobilization of metabolizable fat by increasing re-esterification would seem to be a rapid and efficient means of adjusting the substrate availability in conditions such as heavy exercise, when the need for FFA is small, and yet a high sympathoadrenal tone is present

j Modification of the metabolic responses by vasoconstriction.

It was essential to clarify the metabolic consequences of vasoconstriction and the other vascular effects of nerve stimulation (see section III c) In paper IV the metabolic consequences of nerve stimulation were studied after administration of propranolol in amounts sufficient to inhibit adrenergic activation of lipolysis. The vasoconstrictor response was essentially the same as without propranolol. During such pure α receptor stimulation the glycerol release rate decreased, but immediately after the cessation of the stimulation the release rate increased. This pattern of response resembled the disappearance of radioactive xenon or iodide from canine subcutaneous adipose tissue during and after α-receptor stimulation (Linde and Rosell unpublished) Similarly as illustrated in Fig 6, a decreased rate of glycerol release was seen *during α-receptor stimulation, and a compensatory increase afterwards*, even when the level of glycerol release was increased by theophylline. The findings are best explained by assuming that vasoconstriction caused trapping of glycerol and FFA in the tissue and that the excess is free to diffuse out when the stimulation is terminated.

In paper III it was suggested that vascular responses might actually modify the adrenergic transmission between nerve endings and fat cells. It is possible that the vascular responses might delay the onset of lipolysis stimulation owing to hindrance of transmitter transport from nerve endings to fat cells. The possibility that the lipolysis is delayed in its onset when nerve stimulation produces vasoconstriction received circumstantial support (see above section III d)

Vasoconstriction might therefore affect the lipolytic response in two ways The products of lipolysis formed upon stimulation of triglyceride breakdown are to some extent trapped in the tissue and the onset of lipolytic stimulation apparently also delayed, possibly due to inhibition of noradrenaline transport

The vascular effects of nerve stimulation seem to have other metabolic consequences as well. Some of these might be secondary to the accumulation of products of lipolysis, especially fatty acids in adipose tissue. The oxygen uptake decreases during stimulation. This is most likely due to a diminished capillary surface area available for diffusion of oxygen. Accumulated fatty acids might play a role since it has been shown that they decrease oxygen utilization in adipose tissue *in vitro* (Hagen and Ball 1961). On the other hand, the failure of nerve stimulation to increase glucose uptake, which was expected from available *in vitro* data (Hagen 1967), can probably not be explained similarly since nerve stimulation did not increase glucose uptake after dihydroergotamine pretreatment either. The accumulation of lactate in adipose tissue upon prolonged nerve stimulation appears to depend upon the vasoconstrictor response, since it was blocked by α-receptor antagonists.

Finally, we must consider the possibility that the observed potentiation of the lipolytic response to nerve stimulation after adrenergic α receptor blockade could depend upon the abolishment of vasoconstrictor response. Two principally different mechanism are conceivable. Firstly it is known (Bally *et al.* 1965, Rodbell 1965) that fatty acids function as feed-back inhibitors of lipolysis. Accumulation of excessive amounts of fatty acids might thus inhibit lipolysis. Secondly it is possible that abolishment of vasoconstriction in adipose tissue makes more of the released transmitter substance available for stimulation of lipolysis. α-Receptor antagonists abolish vasoconstrictor responses facilitating the diffusion of noradrenaline thereby producing smaller concentrations of transmitter near the nerve ending. This could lead to a smaller re-uptake of the transmitter into the nerve ending (Iversen 1968). It is also known that different α-receptor blocking agents have a direct inhibitory effect on the neuronal uptake process as well as effects on the granular storage mechanism.

IV SUMMARY

The present results have elucidated several aspects of the sympathetic regulation of circulation and metabolism in canine subcutaneous adipose tissue.

1 Noradrenaline is present in canine subcutaneous adipose tissue in measurable amounts. H-noradrenaline is taken up into cell structures in the tissue and released by nerve stimulation. The released transmitter is metabolized the same way as in organs known to have a functioning adrenergic innervation.

2. Nerve stimulation causes an arteriolar vasoconstriction, an increased hydrodynamic conductivity (CFC increase) and an expulsion of blood. These effects are mimicked by noradrenaline and are abolished by adrenergic α-receptor antagonists. The ensuing arteriolar vasodilatation, limited increase in CFC and venodilatation are all mimicked by the β-receptor agonist isoprenaline. The possibility is discussed that the CFC increase during nerve stimulation is due to an increased capillary permeability simultaneously with a decrease in the number of open capillaries.

3 The rate of free fatty acid (FFA) and glycerol release increased during and after nerve stimulation. This lipolytic effect was inhibited by β-receptor blocking agents. The maximal release rates were generally seen after the cessation of the nerve stimulation. After adrenergic α-blockade totally more glycerol and FFA were released and the maximal release rates were generally observed already during the stimulation period. α Receptor blockade apparently brought about a similar change in the magnitude and time course of the evoked transmitter overflow to judge from the efflux of radioactivity from H-noradrenaline

It appears that vasoconstriction influences the mobilization of FFA and glycerol in two major ways it delays the stimulation of the fat cells by released noradrenaline and it causes a trapping in the tissue of lipolytic products already formed.

4 Glycogenolysis is activated by nerve stimulation, presumably via a β receptor mechanism On the other hand, net glucose uptake in adipose tissue in unaffected by nervous activity Oxygen extraction in adipose tissue decreased during nerve stimulation provided vasoconstriction occurred. If vasoconstriction was prevented by dihydroergotamine oxygen uptake increased. Pro-

longed sympathetic nerve stimulation caused a net production of lactate which also accumulated in the tissue. This effect was prevented by adrenergic α- or β-blockade.

5 Lactate, in concentrations present in blood during severe muscular exercise or in shock or calculated to occur in adipose tissue during prolonged sympathetic nerve stimulation, inhibited the mobilization of FFA. Since the glycerol release was not significantly affected, this implies an increased re esterification during lactate administration. Pyruvate had the opposite effect. It appears that alterations in the degree of re-esterification could be an efficient means of regulating the mobilization of fat from adipose tissue, and also that the cytoplasmatic red-ox state might be a factor in this regulation.

6. Prostaglandins are released from canine subcutaneous adipose tissue by nerve stimulation and administered PGE inhibits its lipolytic effect. The amounts recovered in venous blood following nerve stimulation are lower than those necessary to produce inhibition, however There is no effect of nerve stimulation that can be directly attributed to prostaglandin release and formation.

ACKNOWLEDGEMENTS

My sincere thanks are due to

Associate Professor Sune Rosell, who introduced me to this field of research and who has aided me in every way conceivable throughout this work.

Professor Börje Uvnäs, who has provided facilities for my work and together with Docent Erik Anggård read all manuscripts. Their criticism and suggestions have been of great value.

My co-authors Docent Bengt Öberg and Fil. Lic. Jan Karlsson for very stimulating discussions in front of dogs and manuscripts.

Miss Mona Engqvist and Miss Gunilla Wickberg without whose competence, interest and responsibility this work would not have been realized

Miss Anita Söderberg for her patience over manuscripts in various states of completion.

The entire staff of the Department of Pharmacology who have helped me in numerous ways and also created an atmosphere that is most rewarding to work in.

This work has been supported by the Swedish Medical Research Council (Grants 40X 2553 No 01—03) which also supported me personally (Grants 40P 2631 No 01—03) and by Karolinska Institutet.

ACKNOWLEDGEMENTS

The main part of the present study was carried out in 1966—1969 at the Wihuri Research Institute. To my respected teacher Professor Pentti I. Halonen, M.D. Head of the Institute and also Head of the First Department of Medicine, University of Helsinki, I wish to express my cordial gratitude. His wide knowledge and jovial personality have created the inspiring and unique atmosphere of the Institute. Without his never failing trust and encouragement the present work would not have been possible.

My sincere gratitude is also due to my mentor Dr Simo Salminen, M.D. Lecturer in Medical Chemistry University of Helsinki. He introduced me to the field of membrane physiology and guided my work during all its stages without sparing his time.

Dr Aarne Ekman, Associate Professor in Physical Chemistry Helsinki University of Technology has been the steady foundation in theoretical problems. I am deeply indebted to him.

I wish to thank Professors Herman Adlercreutz, M.D. and Matti Paasonen, M.D., Heads of the Departments of Clinical Chemistry and Pharmacology University of Helsinki, for kindly putting the facilities of their Institutes at my disposal. My thanks are also offered to Mr Erkka Solatunturi, M.Sc., for his help in liquid scintillation measurements.

My warm thanks are due to Mrs Rauni Saarinen and Ritva Sirkiä for their skilful technical assistance.

For kindly revising the English text, I wish to thank Miss Anne Cross, Ph.D.

This study has been supported by grants from the Paavo Nurmi Foundation and from the Sigrid Juselius Foundation.

Last but not least I wish to thank the volunteer blood donors, many of whom are my colleagues and friends. Their readiness and patience towards my insect like behaviour has been astonishing.

Helsinki, April 1970.

Vesa Manninen

INTRODUCTION

General features of red cells in studies of transport phenomena

At present the literature concerning erythrocyte membrane transport phenomena is so voluminous, and not without conflicts of opinion, that attempts to try to understand even a bit of it are difficult. The reviews of Ponder (1948) Harris (1960), Prankerd (1961) Passow (1964) Whittam (1964) and Nims (1967 a) are helpful and give comprehensive data.

The mature mammalian red cell is structurally one of the simplest cells, oversimplified it is a parcel of haemoglobin enveloped by a thin membrane. The cell weight is made up of about 33 % haemoglobin, 1 % lipids and lipoproteins, 1 % alkali salts, and the rest is water The lipids and lipoproteins are almost totally confined to the cell membrane. Mature mammalian red cells have few of the properties of other cells with specialized functions, such as secretion, absorption, and protein synthesis. Red cells, however have the common fundamental characteristics of all living cells they have a finite life span, and as a result of metabolic reactions they are capable of maintaining concentration gradients of permeable compounds across the cell membrane.

Isolated red cells maintain their stationary state even in artificial medium, probably because of their simple metabolic requirements. The main metabolic pathway of the mature mammalian red cells is the anaerobic glycolysis of glucose to lactic acid. Human red cells convert about 2 mmoles of glucose to lactic acid per litre of cells per hour (Bartlett and Marlow 1953, De Loecker and Prankerd 1961 Murphy 1963) About 6 % of the glucose is consumed via the hexose monophosphate pathway (De Loecker and Prankerd 1961 Szeinberg and Marks 1961). Red cells cannot metabolize fatty acids and the tricarboxylic acid cycle is not functioning in mature mammalian red cells (Rubinstein and Denstedt 1953, Dejani and Orten 1958, Bishop 1964).

Due to their availability as single cells and ease with which they can be maintained in a stationary state, even in laboratory conditions, mature mammalian red cells have become widely used as tools in transport studies. The amount of medium trapped between packed red cells is about 2—3 % (Beilin et al. 1966, Funder and Wieth 1967), while the interspace volume in skeletal muscle is about 10—20 % and in cardiac muscle 20—25 % (Harris 1960) The rate of movement of material across the red

cell membrane is often slow enough to allow the cells to be washed with cold saline, which in many cases makes consideration of the effect of interspace volume unnecessary

The surface area of the human red cell is about 150 μm^2 and the cell volume is 90 μm^3 (Whittam 1964). One litre of human red cells consists of 1.1×10^{13} cells. From these values it follows that the total membrane area per litre of cells is as high as 1650 m^2. The thickness of the red cell membrane is 8—10 nm (Robertson 1967). Due to the biconcave disc shape of the human red cell its surface/volume ratio is nine times that of a sphere of equal volume. One consequence is that the membrane can be considered to be the main limiting factor in the transfer of material between the cell and the medium. Thus a red cell suspension, when slowly stirred, can with reasonable accuracy be considered to be composed of two compartments the cell or cell interior and the medium. This allows general two-compartment analysis, solvable in an exact form, to be used in the kinetic treatment of the flow of material across the membrane. In the case of ion transport with radioactive tracers the most widely used method of analysis is that developed by Sheppard and Martin (1950). It is based on changes on each side of the membrane in the specific activities of the ions studied. A still more convenient method for the calculation of the tracer rate constants both in the stationary and the non-stationary state was presented by Ekman, Manninen and Salminen (1969). This treatment makes use of the changes of the concentration ratios in the two compartments.

Red cells contain about 5 mmole of haemoglobin per litre of cells. Haemoglobin is retained inside the cell, and, depending on the pH, may provide an anion concentration as high as 50 mEq/litre cells (Adair 1925, Harris 1960). If a system like red cells that contains small anions and cations capable of passing through the membrane were in Donnan equilibrium, the intracellular osmolality would be expected to exceed that of the medium by 25—30 mOsm/kg H_2O and the water pressure excess to be about 6000 mm H_2O. These values are far greater than the experimental estimates. We can conclude that red cells have the ability, with the aid of metabolism, to cancel out the effect of colloid *osmotic accumulation of water (Tosteson and Hoffman 1960, Tosteson 1964)*. In fact, when determined by freezing point depression, the intracellular and extracellular water activities are the same (Appelboom et al. 1958, Maffly and Leaf 1958) and the internal water pressure excess over that outside is 2 mm H_2O (Rand and Burton 1964).

Some earlier observations on the transfer of material across the red cell membrane

After the introduction of the concept of haematocrit (Hedin 1890), changes in red cell volumes in various circumstances were measured in the first

systematic studies of red cell permeability at the turn of the century Gryns (1896), Hedin (1897 1898) and Hamburger (1902) incubated red cells in isotonic solutions of solutes such as urea, ethylene glycol and glycerol, and found that the red cell volumes and water contents increased. In hypertonic solutions of sucrose, mannitol, and sodium or potassium chloride the red cells shrank, while in hypotonic solutions the cell volume increased. It was concluded that the red cell membrane was permeable to water and certain other substances, but impermeable to some others, such as sucrose, mannitol, and alkali salts.

The very rapid movement of water across the red cell membrane was demonstrated later in several studies (Parpart 1935 Paganelli and Solomon 1957 Villegas, Barton and Solomon 1958). The half-exchange time of tritiated water is about 4 msec.

Soon it became evident that the red cell membrane was easily permeable to small anions, such as chloride and bicarbonate ions (Hamburger 1902, van Slyke, Wu and McLean 1923) The half-exchange time of radioactive chloride ions in red cells has been found to be 0.2 sec (Tosteson 1959). This shows that chloride ions can rapidly pass through the membrane, but that the friction in their movement is greater than in that of water

Until the 1940 s the intact red cell membrane was believed to be impermeable to sodium and potassium ions. Then it was found that red cells that had lost potassium and gained sodium during cold storage at 4 C, could reverse these ion shifts after *in vivo* transfusion or after rewarming the cell suspension *in vitro* (Maizels and Paterson 1940 Danowski 1941 Harris 1941). Simultaneously it was shown with radioactive isotopes that the red cell membrane was permable to sodium and potassium ions (Hahn, Hevesy and Rebbe 1939 Dean *et al.* 1941 Hahn and Hevesy 1941 Mullins *et al.* 1941) Detailed studies with tracers of the red cell permeability to sodium and potassium ions were first carried out by Solomon (1952) He found that the half-exchange times for sodium and potassium tracers were about 20 hr and 30 hr respectively Thus the small anions pass through the red cell membrane at a rate 10^4 times higher than that of the small cations, while the water permeability is still 10^4 times higher than that of the small anions.

Theories of the distribution of ions across the red cell membrane

The high permeability of the red cell membrane to chloride and bicarbonate ions allows their rapid equilibration between the cells and the external environment. Their distribution is related to the difference in pH across the membrane and does not significantly differ from that predicted by the Donnan equilibrium theory (van Slyke *et al.* 1923 Passow 1965 Funder and Wieth 1966)

In the stationary state the cell to medium concentration ratios of potassium and sodium ions are 20 and 0 05 respectively Clearly some force is needed to sustain such a high deviation from equilibrium. Two different approaches to this problem are reviewed here. One connects the metabolic reactions and cation movements with a special »pump At the expense of ATP which is split to ADP and inorganic phosphate, potassium and sodium ions are believed to be transported to different sides of the membrane. The other predicts that the non-equilibrium distribution of potassium and sodium ions follows from their different friction with the transmembrane flows of metabolites.

Danowski (1941) and Harris (1941) in their pioneering experiments found that the uptake of potassium and outflow of sodium in cold-stored red cells after rewarming depended on glycolysis. The connection between glycolysis and cation transport was later studied in detail by several authors. Since metabolism was needed for the uphill transport of cations from a lower to a higher concentration, and the downhill movements from a higher to a lower concentration occurred in the absence of metabolism, the cation transport process was divided into two parts an actively pumped uphill transport and a non metabolically driven passive downhill leak (Maizels 1949 Solomon 1952, Shaw 1955 Glynn 1956, Solomon, Gill and Gold 1956) The leak is thought to be parallel to the pump, but independent of it and not representing a backwash through the pump (Post, Albright and Dayani 1967 Post 1968).

Schatzmann (1953) contributed to progress towards the active cation pump concept by first using cardiac glycosides, of which ouabain has been the most popular to study the mechanism of the selectivity between sodium and potassium ions by the red cell membrane. Cardiac glycosides were found to reduce the rate of uptake of potassium ions in cells rewarmed after cold-storage Glynn (1957) used alkali ion tracers. He found that inward unidirec tional flux of potassium and outward unidirectional flux of sodium were greatly diminished by cardiac glycosides, whereas outward unidirectional potassium flux was only slightly reduced, and inward unidirectional sodium flux was almost unaffected. Thus the main effect of cardiac glycosides was ascribed to inhibition of the active transport of potassium and sodium ions. As a consequence, cardiac glycosides have been used to separate the ion flows into the actively pumped flows and the passive diffusing or leaking ones.

Cardiac glycosides were originally found not to affect the rate of glucose conversion to lactic acid (Schatzmann 1953 Glynn 1964) Later it became evident that ouabain decreases the lactic acid production rate by 15—50 % (Murphy 1963 Minakami, Kakinuma and Yoshikawa 1964 Whittam and Ager 1965 Minakami and Yoshikawa 1966).

Cardiac glycosides in relatively high concentrations reduce the rate of ATP breakdown to ADP and inorganic phosphate in whole red cells (Whittam 1958

1964) and in isolated red cell membrane stroma or red cell ghosts (Post *et al.* 1960 Dunham and Glynn 1961) This was believed to be the only metabolic alteration in red cells caused by administration of cardiac glycosides (Glynn 1964). The enzyme especially inhibited by cardiac glycosides is a special $(Na^+ + K^+)$-activated, Mg^{++}-dependent, ATPase (see e.g Skou 1965 a or Katz and Epstein 1968 for a detailed review). Since cardiac glycosides were found to inhibit both the active uphill movements of sodium and potassium ions and the activity of the $(Na^+ + K^+)$-activated ATPase without affecting overall cell metabolism, the $(Na^+ + K^+)$-ATPase enzyme system is commonly considered somehow to be connected with the cation pump. This enzyme system has been detected in a large variety of cells.

The other approach reviewed here to the problem of transfer and distribution of material across biological membranes is based on the principles of thermodynamics of irreversible processes. The fundamental characteristics are that all reactions and processes occurring in the system are coupled, and the flow of material is a linearly dependent function of all forces, such as chemical potential and temperature gradients, in the system, provided that the system is observed from one point inside the membrane. If the phenomenological coefficients expressing the linear dependence are known as functions of concentrations, it is possible to solve the flows of components as functions of concentrations on each side of the membrane. It then becomes evident that the flow of a substance does not only depend on its own concentration, but also depends on the concentrations of all the other substances. It is possible that a given substance can flow across the membrane against its concentration gradient. According to the Curie principle the chemical reactions, being scalar processes, cannot be directly coupled to the flow of material, but affect the flows across the membrane because of the stationary state coupling (Prigogine 1955 Nims 1961 1967 a and b).

This approach is independent of the molecular mechanism of the transport process, and its principles can be applied generally In a living cell nutrients and metabolic end products are continually flowing in and out. These flows may lead to non-equilibrium stationary state distribution of compounds for which the system is closed, such as alkali ions. Indeed, Thurber and Thompson (1967) and Coster George and Rogers (1968) could demonstrate that the logarithm of the deviation of potassium and sodium ions from the equilibrium distribution is in a predictable way linearly dependent on the rate of flow of reactants. Thus potassium and sodium ions, without participating in the chemical reaction, were supposed to be separated and brought to a non equilibrium distribution across the membrane by their different friction with the flows of reactants. Coupling of certain flows has been found to lead to movement of some other substances against their concentration gradients in nerves (Baker *et al.* 1969 Blaustein and Hodgkin 1969) and ascites-tumour cells

(Eddy 1968 a and b). In these cases uphill movement of calcium ions and glycine was achieved by a downhill movement of potassium and/or sodium ions.

In living cells there are far too many components to allow an exact mathematical analysis of the transport processes. However simple models may be illustrative. Salminen (1963) and Ekman, Rastas and Salminen (1963) separated potassium and sodium ions by their different friction against the flow of water and acid, the end products of oxidative metabolism. Across a homogeneous porous membrane it was possible to keep potassium predominantly in one compartment and sodium in the other and to solve the system mathemati cally A still more sophisticated model has been constructed by Nims (1968). In his model the energy source needed for the non-equilibrium distribution of cations was an enzyme-induced chemical reaction, the hydrolysis of urea to ammonia and carbon dioxide.

If the membrane is non-homogeneous some component may circulate across the membrane even though there is no net flow Then it could act as a »carrier» for substances whose flows are coupled to it. This differs from the traditional carriers in that the formation of a chemical compound from the carrier and the substance to be transported would not be necessary The selectivity is achieved by different frictional coefficients in the membrane. Such a system has been studied in a model where circulation of water induced by electric current was found to lead to non-equilibrium distribution and accelerated exchange of various test substances across a non-homogeneous membrane (Salminen and Ekman 1970) The stationary state distribution ratios and the isotopically-determined exchange rates differed greatly from those obtained with the same current across a homogeneous membrane.

The water permeability of red cells is high and if the red cell membrane properties are different at different sites, circulation of water inwards and outwards across the cell membrane would be possible as a result of flows of metabolites. Salminen, Ekman and Manninen (1968) proposed that coupling the potassium and sodium ions to the water circulation could lead to their non-equilibrium distribution in red cells.

It is evident that, on the basis of the thermodynamics of irreversible processes, it is difficult to separate transport processes into active and passive systems. If active transport means movement of a substance against its chemical potential gradient, it can be brought about by coupling simultaneous flows of several components. Such coupling may arise from chemical reac tions of the components, or only from friction between various molecules. The situation in the membrane at a given time determines the direction of movement of an individual component. There is no fundamental difference between flows along or against the chemical potential gradient. If active transport means a flow of material connected to some chemical reaction the following points have to be taken into account maintaining a stationary

non-equilibrium state in living cells needs continuous inflow of some compounds, and simultaneous outflow of others. This means that the transport process predicts a chemical reaction to occur in the system. On the other hand there cannot be direct coupling of the chemical reaction and the flow of material according to the Curie principle: the coupling is the indirect stationary state coupling. In principle it is not possible to resolve a flow coupled to a given reaction: the whole system has to be considered as a single entity.

Various chemical modifiers of ion permeability of the red cell membrane

Many chemically unrelated substances have been found to cause the human red cell membrane to leak alkali ions. Since the cells usually begin to lyse at higher concentrations, the effect is called pro-lytic (Davson and Danielli 1938, Ponder 1948). It is characteristic that certain agents can induce a selective leakage of potassium ions, while some other agents affect both sodium and potassium ions. Propranolol and pronethalol (Ekman *et al.* 1969), lead salts (Ørskov 1935, Joyce, Moore and Weatherall 1954, Grigarzik and Passow 1958, Vincent and Blackburn 1958, Hasan *et al.* 1967), fluoride in certain concentrations (Wilbrandt 1940, Eckel 1958, Gardos 1959, Lepke and Passow 1960), valinomycin and certain other cyclic polypeptides and polyethers (Tosteson *et al.* 1967, Lardy 1968, Tosteson 1968, Henderson, McGivan and Chappell 1969) induce a greatly increased net flow and exchange of potassium or rubidium ions. However they have little effect on the movements of sodium ions. Butydrine induces a flow of potassium twice as great as that of sodium (Manninen 1969). On the other hand primaquine (Weed, Eber and Rothstein 1961) and alprenolol (Manninen 1969) increase the flows of potassium and sodium ions to similar extents, while chlorpromazine increases the flow of sodium ions somewhat more than that of potassium ions (Kwant and Stevenínck 1968).

Valinomycin and a number of its natural and synthetic analogues also selectively increase potassium and rubidium permeabilities in mitochrondria and artificial bimolecular lipid leaflets (Pressman 1965, 1968, Andreoli, Tieffenberg and Tosteson 1967, Lev and Buzhinsky 1967, Henderson et al. 1969).

In certain cases the changes in ion behaviour induced by chemical agents are not restricted to cations. For example dinitrofluorobenzene is known to decrease permeability to anions and increase that to cations (Berg, Diamond and Marfey 1965, Passow 1969). Others like benzote and dinitrophenol, have little if any effect on cation movements but effectively decrease movements of anions (Passow and Schnell 1969).

Review of the biological effects of propranolol

In the last few years propranolol (Fig. 1) has been widely used in clinical research because of its favourable effects in certain cardiac dysfunctions. Pharmacologically propranolol is classified as a potent beta-adrenergic blocking agent, which selectively suppresses the so-called beta receptor effects (as described by Ahlquist 1948) without having any sympathomimetic intrinsic activity (Shanks 1966) Propranolol effectively suppresses adrenaline-induced cardiac arrhythmias in animals (Shanks 1966). In man propranolol has also proved useful in controlling those cardiac arrhythmias exacerbated or induced by sympathetic activity (Besterman and Friedlander 1965, Irons, Ginn and Orgain 1966). Propranolol effectively blocks many catecholamine-induced metabolic effects (Zoter et al. 1966, Hunninghake, Azarnoff and Waxman 1967 Sailer et al. 1967) It has also been used to lower the cardiac work and to supress cardiac pain in patients with ischaemic heart disease (Epstein and Braunwald 1966, Glanelly et al. 1967 Mason and Braunwald 1967)

Propranolol has many other effects. It is a potent local anaesthetic, its potency being twice that of procaine (Morales-Aquiléra and Vaughan Williams 1965). Propranolol has an effect similar to quinidine on cardiac muscle action potentials (Vaughan Williams 1966). Propranolol can protect animals and humans from cardiac arrhythmias induced by cardiac glycosides (Howe and Shanks 1966 Irons et al. 1966 Turner 1966, Dohadwalla, Freedberg and Vaughan Williams 1969). These effects have been called the non-specific actions of propranolol. Alterations in membrane properties might be involved in some of them, such as those connected with cardiac glycosides, whose effects on electrical phenomena in cardiac muscle are believed to be based on altered transport of potassium ions in cardiac muscle membranes (Lyon and DeGraff 1966, Weatherall 1966).

In an organ like cardiac muscle, which is capable of carrying out complicated functions, it may be difficult to decide between pure membrane effects and effects mediated by a changed metabolic state in other parts of the cells (Bülbring 1960). If experiments are carried out in situ connections between different organs also have to be considered. For example adrenaline is known to elevate the plasma potassium concentration, the source of potassium being the liver (Ellis and Beckett 1963) while in cardiac and skeletal muscle potassium uptake may be enhanced (Powell and Skinner 1966, Stafford 1969) Increased plasma potassium concentration may per se change cardiac function. Similarly propranolol by inhibiting catecholamine-induced lipolysis (Zoter et al. 1966 Hunninghake et al. 1967 Sailer et al. 1967) might secondarily lead to changes in the behaviour of potassium and sodium ions in remote organs in the body As Jacob (1967 1968) and Cooper and Jandl (1968) showed lipids are in some unknown way linked to cation tranport even in red cells.

When studying the direct membrane effects of propranolol it may be advantageous that mature human red cells do not contain the adenylcyclase and 3'5' AMP system (Sutherland and Robison 1966). Many probably all, of the beta-receptor effects are believed somehow to be mediated through this system (Robison, Butcher and Sutherland 1967). As stated earlier adrenaline leads to cation shifts in certain organs, but does not influence the movements of sodium and potassium ions in red cells (Kahn and Acheson 1955).

Isolated rat diaphragm as an object for transport studies

Rat diaphragm is one of the most suitable objects for studying transport in the complicated cell systems. It is mammalian skeletal muscle naturally thin enough provided that small animals are used (Creese 1960) Potassium and sodium ions in rat diaphragm have been extensively studied by several authors (Creese 1954, Flückiger and Verzár 1954 Lüllman 1958 Rixon and Stevenson 1958, Creese and Northover 1961, Fozzard and Kipnis 1967). The diaphragm is capable of gaining potassium and expelling sodium in a way comparable to other cell systems.

OUTLINES OF THE PRESENT INVESTIGATION

Propranolol induces a massive outflow of bulk potassium ions from human red cells. Against the outflow of bulk potassium ions, tracer potassium ions are rapidly taken up into the cells. Their intracellular concentration transiently reaches much higher levels than that in the final propranolol induced stationary state. The rate of exchange of sodium tracer ions is also somewhat increased, but the concomitant net uptake of bulk sodium ions is small. The net loss of potassium salts is associated with a loss of water and the cell volume decreases. These phenomena were first investigated by Ekman *et al.* (1969). Now an attempt has been made to investigate these effects in more detail, for instance by changing to composition of the incubation medium, and simultaneously adding other membrane active compounds. The kinetics of propranolol uptake and outflow especially in relation to the cation flows, was studied using ^{14}C-labelled propranolol. The effectiveness of different optical isomers of propranolol was compared. Since cation transport and ATP breakdown to ADP and inorganic phosphate are generally believed to be causally connected, the effect of propranolol on ATP content and ATPase activities in red cells and isolated red cell membrane stroma was measured. Finally an attempt was made to compare the phenomena observed in red cells with those in other more complicated systems using isolated rat diaphragm.

MATERIALS AND METHODS

Experiments with red cells

General arrangements

Freshly drawn blood from apparently healthy human donors of both sexes, aged 20—53 years, was used. About 100—150 ml of blood was drawn at a time. There was at least a month between successive bleedings of one donor. Heparin (0.5 mg/ml blood) was used as anticoagulant. The blood was centrifuged at 3000 g for 15 min, then plasma, buffy coat, and the topmost cell layer were discarded. The cells were then washed 2—3 times with a twofold volume of buffered saline of the composition described below. About 90 % of the original white cells were removed by the washing. The cells were subsequently resuspended in the buffer to give, unless otherwise stated, a packed red cell volume of about 55 %.

The cells were incubated in a water bath at 38°C, mixed gently and usually equilibrated with humidified gas containing 95 % of O_2 and 5 % of CO_2.

The medium used in most experiments contained (mmole per litre) NaCl 115, $MgCl_2$ 1.0, $CaCl_2$ 0.5, $NaHCO_3$ 30, Na_2HPO_4 1.7 KH_2PO_4 0.4, KCl 4.3, and glucose 14. The pH of the medium during the experiments was 7.4.

To study the effect of calcium or magnesium ions their concentrations in the medium were either increased to 20 mM, or alternatively both were first omitted and later added in appropriate amounts to the cell suspension with the drugs and tracers. In some experiments enough disodium ethylenediaminetetra-acetate (EDTA Na_2) was added to chelate calcium and magnesium in the medium.

To study the effect of increased sodium ion concentration on the propranolol induced non-stationary state the cells were first suspended in the usual medium to give a packed cell volume of 50 %. Then the suspension was divided into three portions, to one 5 M NaCl was added to bring the sodium concentration to 310 mM, to another 0.35 M of sucrose was added, the third was a control. The packed red cell volumes were reduced by the NaCl and sucrose additions to 29 %. In the sucrose-treated cell suspension the pH was reduced to 7.15. Enough 0.2 N NaOH was added to bring the pH to 7.4.

When the potassium concentration was increased a corresponding amount of sodium was withdrawn, so that the osmolality remained unchanged.

For experiments of pH 7.0 and 8.0 the pH of the suspension was adjusted by adding 0.2 N HCl or NaOH in small amounts and thoroughly mixing the suspension between successive additions. With this treatment the cells were not lysed.

The pH was measured with a glass capillary electrode system (Radiometer Copenhagen).

When the reversibility of normal cation permeability in the propranolol treated cells was studied the cells were suspended in a fractional cell volume of 0.5 in a medium containing 100 mM potassium and 45 mM sodium. Propranolol (0.5 mM) was added and the suspension was incubated at 38°C for 1 hr Then the cells were first washed 3 times in a threefold volume of the KCl medium, resuspended in a tenfold volume of this medium and stored overnight. After that the cells were washed twice in the KCl and at last twice in the usual medium, to which they were subsequently resuspended. Control cells without propranolol were treated as above.

Bulk ion and tracer ion concentrations

Drugs and tracers were usually added simultaneously in saline to intact red cell suspensions. In most experiments the initial packed red cell volume after addition of the drugs and tracers was about 50 /i. From time to time an aliquot of 2.0 ml of the cell suspension was pipetted into an isotope counting tube and centrifuged at 3000 g for 5 min A 0.5 ml sample of the supernatant was carefully removed. After discarding the remaining supernatant without disturbing the cell column, the cells were washed once with a fiftoenfold volume of ice-cold buffer To determine the cell volume in the sample the relative packed red cell volume of the suspension was measured separately using microcapillary haemotocrit centrifugation at 12,000 g for 5 min with Hawskley & Sons (London) centrifuge.

The radioactive tracers were determined with an automatic dual channel well type crystal scintillation spectrometer (Nuclear Chicago, 874., or Wallac Decem). In most experiments ^{42}K and ^{22}Na isotopes were simultaneously present, and they were separated by their different half-lives and radiation energies. In some experiments ^{86}Rb was used and then sodium tracer was not present. The ^{22}Na and ^{86}Rb tracers were supplied by the Radiochemical Centre (Amersham) and ^{42}K by the Reactor Laboratory Helsinki University of Technology The specific activity of ^{86}Rb was high, so that the system contained very low concentrations of non-radioactive rubidium ions.

Non-radioactive potassium and sodium ions were determined with an internal standard flame photometer (Beckman 105).

Experiments with ^{14}C sucrose

Universally labelled sucrose was obtained from the Radiochemical Centre (Amersham) It was dissol ed in saline before use. The incubation and sample preparation procedures were as in experiments with alkali ion tracers. After separating the cells, they were lysed in a fivefold volume of distilled water

Round pieces of lens paper were placed so as to cover the bottom of the counting planchets. Test samples were pipetted onto the lens paper and dried at 22°C. The counts were measured with a gaiger gas flow counting apparatus (Beckman, Lowbeta II) The counts were corrected for dead times and self-absorption.

Experiments with ^{14}C p opranolol

The ^{14}C propranolol was was dissolved in saline before use. The basic principles were as described a lier for experiments with alkali ion tracers, except that the

packed red cell volume in the final incubation mixture was usually 10 /. Aliquots of 0.5 ml of the whole suspension and the medium, and the sedimented cells from samples of 2.0 ml of the suspension were used to determine the radioactivities.

A great deal of radioactivity was lost from the cells even in one wash in ice-cold buffer. Therefore the cellular ^{14}C-propranolol concentrations in the inflow experiments had to be calculated from those of the whole suspension and the medium with the aid of the packed red cell volume.

When the outflow of propranolol was studied, the cells were preincubated for 30 min in a medium containing either 1 / M or 0.4 mM propranolol including the ^{14}C-propranolol tracer. Then the cells were either washed 1—6 times with a fiftyfold volume of cold propranolol free buffer or the tracer outflow was followed against time after suspending the cells in the usual medium in a fractional cell volume of 0.1 with various concentrations of propranolol. The initial cellular radioactivities were calculated as before, the remaining activity after each wash was counted directly from the cell samples.

Red cell membrane stroma were prepared as described later in the ATPase experiments. The final incubation medium contained (mmole per litre) NaCl 100, KCl 10, $MgCl_2$ 5, $CaCl_2$ 5, imidazole Cl 5, tris Cl 6, adjusted to pH 7.5. The fractional stroma volume was 0.1. The suspension was incubated with ^{14}C-propranolol for an hour at 38 C, pH 7.5. Aliquots (0.5 ml) of the suspension and the medium, and 0.2 ml of the sedimented stroma after centrifugation at 20,000 g for 10 min were used to determine radioactivities.

In alkaline solutions propranolol can be quantitatively extracted as a free amine in heptane or in other non-polar solvents. The procedure used for extracting propranolol was a modification of those described by Black, Duncan and Shanks (1965) and Potter (1967). Aliquots of 4 ml of 1 N NaOH were added to the samples, and they were allowed to stand at least for an hour. Then 4.0 ml of n-heptane was added, and the tubes were gently shaken for 15 min. The phases were separated by centrifugation at 2000 g for 10 min. Aliquots of 2.0 ml of the heptane phase were added to 10 ml of scintillator containing 4 g of 2,5-diphenyloxazole (PPO) and 100 mg of 1,4,-di(2,5-phenyloxazolyl)-benzene (POPOP) dissolved in a mixture of equal volumes (500 ml) of toluene and ethyleneglycolmonoethylether.

The radioactivities in the samples were counted with a dual channel automatic liquid scintillation apparatus (Wallac Decem 314). The recoveries of various concentrations of ^{14}C-propranolol added together with different amounts of non-radioactive propranolol to the cell, medium and whole suspension samples were found to vary from 96 / to 100.5 / with the heptane extracting procedure. For correction of quenching the external standard channels ratio method was used.

Adenosine triphosphate (ATP) concentration

The cells were handled as above except that after discarding the buffy coat and the topmost cell layer the remaining cells were resuspended in a medium containing 50 / of their own plasma and 50 /o of the usual buffered saline. Aliquots of 2.0 ml were taken immediately and after 60 min. They were then deproteinized in equal volume of cold 0.6 N $HClO_4$. After centrifugation at 3000 g for 10 min, the ATP concentration was determined enzymatically from the clear supernatant using reagent kits of Boehringer & Soehne (Mannheim).

Adenosine triphosphatase (ATPase) activity

Red cells were washed three times in the usual medium, from which calcium had been omitted. They were then resuspended in the same medium at 38 C to give a packed red cell volume of 20 /o. The drugs, ATP (4 mM) and in some cases $CaCl_2$ (5mM), were added simultaneously. Aliquots of the suspension were withdrawn immediately and after 60 min, and were deproteinized by adding 0.2 vol. of cold 60 (w/w) $HClO_4$. After centrifugation at 3000 g for 10 min inorganic phosphate (Pi) was determined immediately from the clear supernatant according to Fiske and Subbarow (1925). ATPase activity was calculated from the increase in Pi content in the suspension during the first hour. The method used to determine Pi did not cause any significant hydrolysis of ATP as revealed by adding ATP and 0.2 vol 60 % $HClO_4$ to the buffer, determining the Pi and comparing the result to that obtained after heating the same ATP-containing solution with an equal volume of 1 N H_2SO_4 at 160°C for 3 hr.

The method used to prepare red cell membrane stroma was a modification of that used by Wiley (1969). Red cells were washed three times with 0.145 M NaCl. Centrifugation time was 10 min at 3000 g. The buffy coat and topmost cell layer were discarded. The cells were then lysed at room temperature in a tenfold volume of 6 mM tris Cl, adjusted to pH 7.5. The lysate was allowed to stand about 10 min, then the stroma were separated by centrifugation at 2°C at 20,000 g for 15 min. All visible traces of haemoglobin were removed by four further washes in this medium. The white stroma were suspended in 5 mM tris Cl, pH 7.5, at a concentration of 1.5—2 mg protein/ml solution. The stroma were preincubated at 38 C for 10 min with the tested drugs before the reaction was initiated by adding ATP and co-factors in 0.2 vol. to give final concentrations (mmole per litre) of NaCl 100, KCl 10, $MgCl_2$ 5, imidazole Cl 5 and ATP 1.5. In some cases 5 mM $CaCl_2$ was added. Aliquots were withdrawn at 0 min and 60 min. They were deproteinized in 0.5 vol of cold 1 N $HClO_4$, and the Pi was determined from the clear supernatant after centrifugation at 3000 g for 10 min. Protein in the incubation mixture was determined by the Biuret method (Gornall, Bardawill and David 1949). A commercial protein standard (Lab-Trol, Dade, Evanstown), diluted to the protein concentration of the incubation mixture, was used as a reference.

Experiments with isolated rat diaphragm

Diaphragms of Sprague-Dawley rats of both sexes weighing 150—200 grams were used. For the tracer outflow experiments the diaphragms were loaded with ^{22}Na, ^{42}K, and ^{86}Rb tracer ions in vivo. Amounts of the tracers that would give enough counts in the hemidiaphragms for reliable measurement were given intraperitoneally in 2—3 ml of 0.145 N NaCl in one or two injections 12—36 hr before the experiment. Only one isotope was given to each rat. The rats were anaesthetized with ether and exsanguinated by cutting the abdominal aorta. The diaphragms were rapidly rinsed in 0.145 M NaCl, and the tracer outflow was followed by incubating isolated hemidiaphragms at 38 C in a succession of about 10 tubes containing 3 ml non-radioactive buffered saline as used in red cell experiments except that the $CaCl_2$ concentration was 1 mM. The diaphragms were soaked 5—10 min in one tube, the contents of which were mixed with a vigorous bubbling of gas containing 95 / O_2 and 5 /o CO_2. The radioactivities released in the tubes, and the remaining activity in the diaphragm after soaking, were counted with a well-type automatic gamma spectrometer as described in experiments with red cells.

For the ion inflow experiments pieces of diaphragm weighing about 100 mg were removed rapidly and dissected radially to minimize fibre damage. They were incubated at 38°C in a two hundredfold volume of the buffered saline. The volume was large enough to maintain a practically constant composition. Propranolol and ^{42}K and ^{22}Na tracers were added to the medium beforehand.

From time to times pieces of muscle were removed, rapidly rinsed with 0.145 M NaCl, dried with blotting-paper and weighed. The radioactivities were counted as previously. To determine bulk potassium and sodium ion concentrations, the muscle pieces were digested by heating in 2 ml of 30 % HNO_3 at 80°C for 6 hrs. The whole muscle samples except for a little fat piece were digested. Potassium and sodium ion concentrations were then determined as in experiments with red cells.

The water content of the muscles was measured by calculating the loss of weight after drying to constant weight (24 hr at 100°C).

The extracellular space was determined by measuring the distribution of ^{14}C-sucrose between the muscle and the medium. Experimental procedure was as above. Activity of ^{14}C was counted in the medium and digested muscle samples with a gas flow geiger tube (Beckman Lowbeta II).

Chemicals

Propranolol (1-isopropylamino-3-(1-naphthyloxy)-propan-2-ol hydrochloride (Fig. 1) both different optical isomers and the ^{14}C labelled propranolol, were kindly supplied

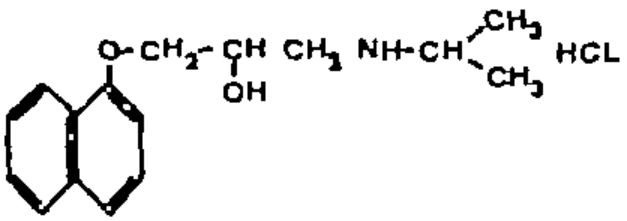

Fig. 1. Structure of propranolol.

by Drs J. D. Fitzgerald and A. Hayes (I.C.I., Macclesfield). Propranolol was dissolved in distilled water to which NaCl was added to bring the solution to 300 mOsm/kg H_2O. Unless otherwise stated, racemic propranolol was used. Ouabain was obtained from Fluka (Buchs). Protamine sulphate was obtained from Orion (Helsinki) as a 1 % solution in hydrochloric acid, and was neutralized before use. ATP was obtained from Boehringer Soehne (Mannheim).

Concentrations of the drugs are expressed, if not otherwise stated, as moles per litre of the whole suspension.

Calculation of the tracer rate constants

The tracer rat constants, k_{in} and k_{out}, give the fraction of the tracer that moves in one direction per unit time. The tracer rate constants do depend on the concentrations of all bulk substances, but are independent of the low tracer concentrations.

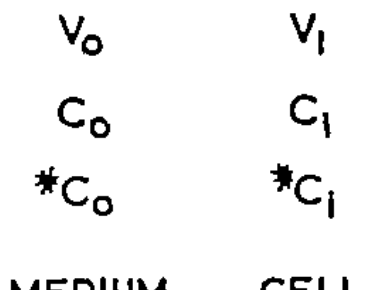

Fig. — Two compartment model system. V and V_i denote the volumes of the compartments and c and *c the concentrations of two isotopes of the same species.

The following equations follow from this general principle of the tracer experiments. Calculation of the tracer rate constants in a two-compartment system composed of the »cell or inside« and the medium« or »outside« separated by a thin membrane (Fig. ") are described by the following equations. A general case, during which all properties of the system may change with time, and a stationary state case are presented. This approach conforms to the analyzing method suggested by Ekman et al. (1969) and Ekman (personal communication 1970).

General case

The inside and outside volumes of the two compartments are denoted by V_i and V_o. The system contains two isotopes of the same species, so that their behaviour is similar but they can be separated analytically One is a tracer and the other may be another tracer or the corresponding bulk substance. The concentrations inside are denoted by c_i and $^*c_i$ and outside by c_o and $^*c_o$.

The flow of the first isotope through the membrane from one compartment to be other is given by

$$J = k_{in} C_o - k_{out} C_i \tag{1}$$

J is the flow into the cell in moles/litre cells/min.

The flow of the other isotope at the same time is

$$J = k_{in} {}^*C_o - k_{out} {}^*C_i \tag{2}$$

with the same rate constants.

The flow of the first isotope into the cell is equal to the rate of change of the concentration in the cell

$$J = \frac{dC_i}{dt} \tag{3}$$

The flow of the other isotope is

$$J = \frac{d^*C_i}{dt} = -\frac{V}{V_i}\frac{d^*C_o}{dt} \tag{4}$$

The ratios of concentrations are denoted by

$$r = \frac{C_i}{C_o} \qquad \text{and} \qquad {}^*r = \frac{{}^*C_o}{{}^*C_i} \tag{5}$$

and the ratios of the total amounts of the isotopes in the compartments are denoted by

$$R = \frac{V_i}{V}\,\frac{C_i}{C_e} \qquad \text{and} \qquad {}^*R = \frac{V}{V_i}\,\frac{{}^*C_i}{{}^*C_i} \tag{6}$$

By taking the derivatives with respect to time we get

$$\frac{dR}{dt} = \frac{V_i}{V}\,\frac{1}{C_e}\left(\frac{dC_i}{dt} - \frac{C_i}{C_e}\,\frac{dC_e}{dt}\right) \tag{7}$$

and

$$\frac{d^*R}{dt} = \frac{V_e}{V_i}\,\frac{1}{{}^*C_i}\left(\frac{d^*C_e}{dt} - \frac{C_e}{{}^*C_i}\,\frac{d^*C_i}{dt}\right) \tag{8}$$

Because the total amount of the isotopes in the system is constant, we have

$$V_e\frac{dC_e}{dt} + V_i\frac{dC_i}{dt} = 0 \quad \text{and} \quad V\,\frac{d^*C_e}{dt} + V\,\frac{d^*C_i}{dt} = 0 \tag{9}$$

Thus equations (7) and (8) may be written

$$\frac{dR}{dt} = \frac{V_i}{V}\,\frac{1}{C_e}(1+R)\frac{dC_i}{dt} \tag{10}$$

$$\frac{d^*R}{dt} = \frac{V}{V_i}\,\frac{1}{{}^*C_i}(1+{}^*R)\frac{d^*C_e}{dt} \tag{11}$$

From equations (1—4), (10) and (11) follow that

$$\frac{C_e V}{V_i(1+R)}\,\frac{dR}{dt} = k_{in}C_e - k_{out}C_i \tag{12}$$

and

$$-\frac{C_i V_i}{V\ (1+\ R)}\,\frac{d\ R}{dt} = k_{in}{}^*C_e - k_{out}{}^*C_i \tag{13}$$

By dividing equation (12) by (13) we get

$$\frac{k_{in} - k_{out}\,r}{k_{out} - k_{in}\,{}^*r} = \frac{V}{V_i}\,\frac{\dfrac{1}{1+R}\,\dfrac{dR}{dt}}{\dfrac{1}{1+\ R}\,\dfrac{d^*R}{dt}} = A \tag{14}$$

where definitions from equation (5) have been used.

From equation (14) the ratio k_{in}/k_{out} can be solved

$$\frac{k_{in}}{k_{out}} = \frac{A + r}{1 + A^*r} \tag{15}$$

k_{in}/k_{out} is the cell/medium concentration ratio that the tracer tends to attain at time t.

The rate constant k_{out} can be calculated from

$$k_{out} = \frac{V}{V_i}\,\frac{1}{1+R}\,\frac{\dfrac{dR}{dt}}{\dfrac{k_{in}}{k_{out}} - } \tag{16}$$

which is obtained from equations (1), (3) and (10).

The k_{in} can be calculated from the values of k_{out} and k_{in}/k_{out}. The values of k_{in} and k_{out} are the same for all isotopes, so that the flow of any isotope or the total flow of the species can be calculated from equation (1) by substituting the concentrations c_e and c_i by the inside and outside concentrations in question.

Stationary state

When the system is in a stationary state with respect to the bulk concentrations, the tracer rate constants are independent of time. The time derivative of r is, according to equations (5) and (9)

$$\frac{d^*r}{dt} = \frac{1}{C_o}\left(1 + r\,\frac{V_1}{V}\right)\frac{dC_1}{dt} \tag{17}$$

Equations (1), (3) and (17) yield

$$\frac{d^*r}{dt} = (k_{in} - k_{out}\,{}^*r)\left(1 + {}^*r\,\frac{V_1}{V}\right) \tag{18}$$

The variables can be separated by integrating from $^*r = 0$ to $^*r = {}^*r$ and $t = 0$ to $t = t$

$$k_{in}\,t = \frac{1}{\frac{V_1}{V} + \frac{k_{out}}{k_{in}}}\ln\frac{1 + {}^*r\frac{V_1}{V_o}}{1 - \frac{k_{out}}{k_{in}}\,{}^*r} \tag{19}$$

By infinite time the tracer flow stops and we may write

$$\frac{{}^*C_1^{\infty}}{C^{\infty}} = {}^*r^{\infty} = \frac{k_{in}}{k_{out}} \tag{20}$$

Thus equation (19) takes the form

$$k_{in} = k_{out}\,{}^*r^{\infty} = \frac{B/t}{1/{}^*r^{\infty} + V_1/V} \tag{21}$$

where

$$B = \ln\frac{1 + {}^*r\,V_1/V}{1 - {}^*r/{}^*r^{\infty}} \tag{22}$$

When the system is in the stationary state with respect to the bulk component, the tracer tends to attain the same cell/medium concentration ratio as the corresponding bulk substance, so that $^*r^{\infty} = r^{\infty}$. When the corresponding bulk substance is not present, or its distribution is not known, the ratio $^*r^{\infty}$ can be obtained by choosing by trial and error a value of $^*r^{\infty}$ that gives a straight line in the plot of the term B against time. When the tracer movement is slow so that its distribution is still far from the stationary state at the end of the experiment, only large errors in the value of $^*r^{\infty}$ will lead to a visible deviation from the straight line in the plot. In such cases the most accurate method of obtaining the right value for $^*r^{\infty}$ is to examine the rates of tracer movements both inwards and outwards.

Practical arrangements

The calculations were performed with a small digital computer (Olivetti, Programma 101). In equations (15 and 16) the tangents dR/dt and d*R/dt can be determined, if the time-interval $t_2 - t_1$ is short enough, as follows

$$\frac{dR}{dt} = \frac{\frac{V_{11}}{V_1}r_1 - \frac{V_{12}}{V_2}r_2}{t_2 - t_1} \quad \text{and} \quad \frac{d\,{}^*R}{dt} = \frac{\frac{V_1}{V_{11}}\,{}^*r_1 - \frac{V_2}{V_{12}}\,{}^*r_2}{t_2 - t_1} \tag{23}$$

in which 1 and 2 denote the measured parameters at times t_1 and t_2. So the rate constants could be calculated with the available computer

In the calculations of the stationary state rate constants the term B in equation (22) was calculated with different values of "r" When plotted against time, the one that showed the least deviation from the straight line was chosen by the least square method.

Calculations of the diaphragm inward tracer rate constants were based on the above treatment. The diaphragms were incubated in a large volume of medium so that the composition of this other compartment remained constant. This made it possible to leave the volume parameter out of the equations.

In outflow experiments the standard technique for one compartment analysis was used. The radioactivities in the diaphragm at a given time, after replacing the the outer compartment often enough with non-radioactive medium, were plotted semi-logarithmically against time. The half-exchange time ($T_{½}$) was then calculated graphically The tracer outward rate constant, $k_{out} = \ln 2/T_{½}$, was then calculated.

RESULTS

Inflow and outflow of ^{14}C propranolol

Accumulation by whole red cells

Fig 3 shows that propranolol added initially to the medium was rapidly taken up by the cells. The cell/medium concentration ratios of the ^{14}C-propranolol varied from 7 to 10 in the first sample (5 min). With low propranolol concentrations (1 μM and 10 μM) the stationary distribution ratio between the cells and the medium was reached at that time, while with higher concentrations the tracer continued to accumulate in the cells. With 0 1 mM of propranolol the approximate stationary distribution was reached after 90 min, the cell/medium concentration ratio of ^{14}C-propranolol being 28. When the propranolol concentration was still higher 0 4 mM, the tracer transiently reached an intracellular concentration higher than that at the end of the experiment.

The rate of inflow of ^{14}C-propranolol in cells treated with 0 4 mM propranolol was decreased when the pH of the medium was lowered from .5 to 7 0 After increasing the pH to 8.0 the uptake rate was enhanced

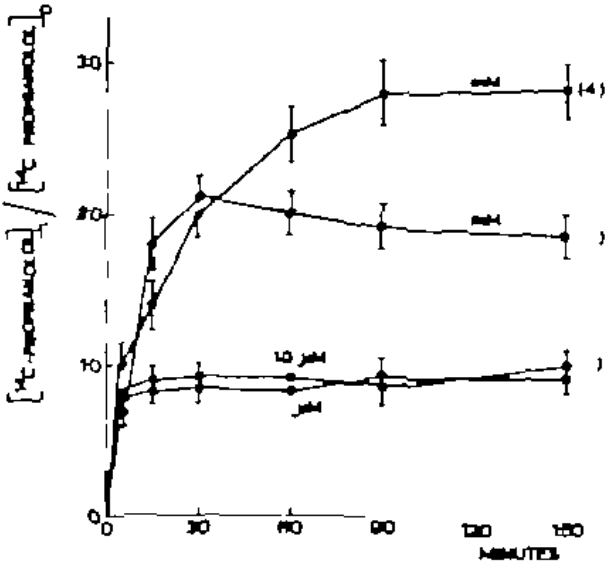

Fig. 3 Cell ( )/medium ( ) concentration ratios of ^{14}C-propranolol added to red cell suspension t 0 min with various total propranolol concentrations Numbers of experiments and means ± S.D

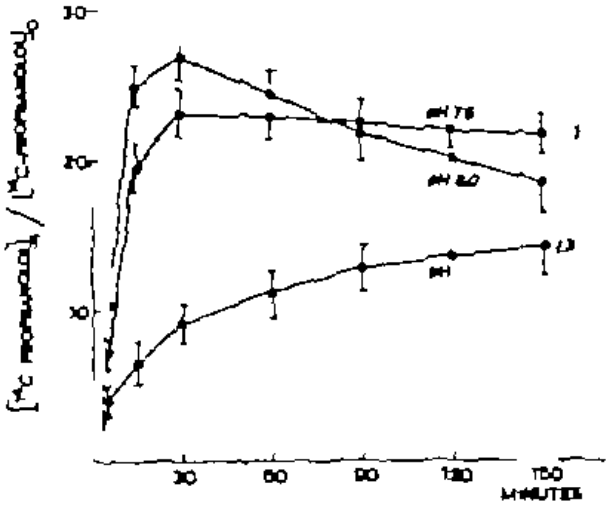

Fig. 4. Effect of the pH of the medium on the cell (i)/medium (o) concentration ratios of ^{14}C propranolol added to the cell suspension at 0 min with 0.4 mM non radioactive propranolol.

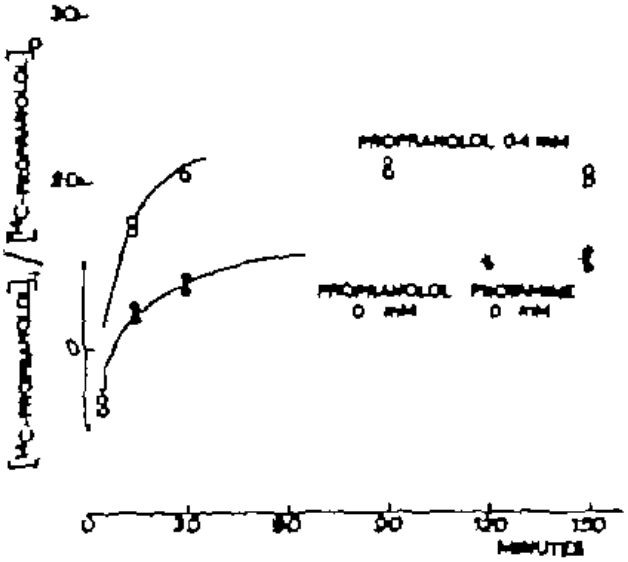

Fig. 5. Effect of protamine on the uptake of ^{14}C propranolol.

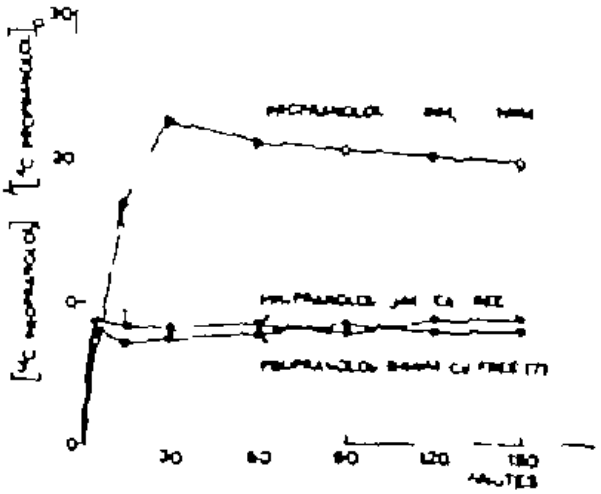

Fig. 6. Effect of calcium ions on the uptake of ^{14}C-propranolol.

(Fig 4). The height of the transient cellular accumulation as compared to that at the end of the experiment was also greater at pH 8.0

Addition of an equimolar amount of protamine reduced both the rate of ^{14}C-propranolol uptake and its stationary distribution ratio between the cells and the medium in cells with 0 4 mM propranolol (Fig 5)

When calcium ions were omitted from the medium there was no increased cellular accumulation of ^{14}C-propranolol when high concentrations of propranolol were present (Fig 6).

Outflow and binding by whole red cells

The cells were loaded with propranolol by incubation for 30 min in a medium containing 0 4 mM bulk propranolol and the propranolol tracer The fraction of the initial radioactivity remaining in the cells after washing for various times with propranolol free saline is shown semilogarithmically against time in Fig 7 Cells that were loaded with propranolol in medium containing calcium ions, contained 12 /o of their initial radioactivity after 6 washes in Ca-medium. The same cells when washed in Ca-free medium contained only 1.5 ^{0}/$_{0}$ of their initial radioactivity In Ca free medium the total cellular radioactivity as disintegrations per min per ml of cells accumulated during the 30 min loading procedure,

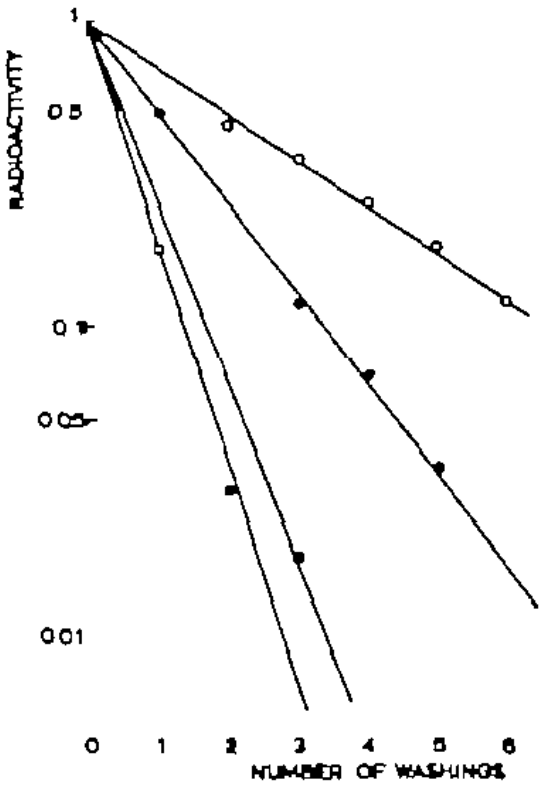

Fig. 7 Fraction f ^{14}C propranolol remaining in the cells after washing for various times in saline without propranolol The cells were initially loaded by the tracer with 0 4 mM propranolol. ○ cells loaded and washed in medium containing 0.5 mM calcium, ● loaded in Ca-containing and washed in Ca free medium, □ loaded in Ca free medium and washed in Ca-containing medium, ■ loaded and washed in Ca-free medium.

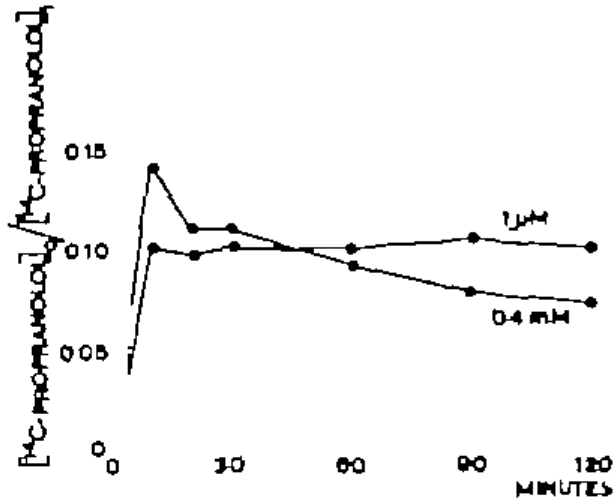

Fig. 8. Outflow of ^{14}C-propranolol from cells loaded at a propranolol concentration of 1 μM. The fractional cell volume during the experiment was 0.1.

was about 0.4 of that in cells incubated with calcium ions. In this case the tracer could easily be washed out irrespective of the calcium content of the medium.

The effective time for ^{14}C-propranolol outflow in each wash was 4 min. With its aid the outward rate constants, k_{out}, for ^{14}C-propranolol efflux could be calculated. For cells loaded with propranolol in the presence of calcium ions they were 5.2 hr^{-1} and 10.3 hr^{-1} in Ca-containing and Ca free washing media respectively. Those for cells loaded in Ca free medium were 20 hr^{-1} and 21 hr^{-1}.

In the other kind of experiments cells were loaded with propranolol tracer with a low (1 μM) total propranolol concentration. The outflow of ^{14}C-propranolol was then followed from cells suspended in a fractional cell volume of 0.1 in the usual medium containing 1 μM or 0.4 mM bulk propranolol. With the higher propranolol concentration the medium/cell concentration ratio of the propranolol tracer transiently attained a higher value than that at the end of the experiment (Fig. 8). The inward and outward rate

TABLE I. Rate constants of propranolol tracer and the initial total inflow of propranolol, 5 min after addition of propranolol to cell suspensions.

	Propranolol concentration	
	1 μM	0.4 mM
k_{in}, hr^{-1}	65	340
k_{out}, hr^{-1}	7.0	20
k_{in} [propranolol] — k_{out} [propranolol] mmole/litre cells/hr	0.063	85

constants for the propranolol tracer flow at the 5 min point, and the initial inflow of propranolol, are given in Table I. Interestingly the total inflow of propranolol by the higher propranolol concentration was enhanced more than in linear relation to the increase in propranolol concentration. The outward rate constant for the ^{14}C-propranolol efflux with 1 μM external propranolol was 7 0 hr^{-1} which fits fairly well with the rate constant of 5.2 hr^{-1} obtained earlier by a different method.

Uptake by red cell membrane stroma

After 30 min incubation with 1 μM or 0.3 mM propranolol red cell membrane stroma had ^{14}C-propranolol concentrations 2.48 ± 0.20 or 1.80 ± 0.17 times higher than the medium (means of five determinations ± S E.).

In one series of experiments where samples were taken after 5, 30 and 60 min, the ^{14}C-propranolol distribution ratios between stroma and medium were similar in all samples regardless of incubation time. Adding 1.5 mM ATP to the medium made the stroma viscous, but did not change the ^{14}C propranolol distribution ratio. Omission of calcium ions from the medium did not lead to visible changes in the distribution ratio of ^{14}C propranolol.

Movements of non radioactive potassium and sodium ions and their tracers in red cells during the propranolol induced non-stationary state

Different optical isomers of propranolol

Initially the mean cell and medium sodium concentrations were 7 mM and 145 mM, and those of potassium 95 mM and 4.8 mM respectively corresponding to a cell/medium concentration ratio of 0 05 for sodium and 20 for potassium. Adding 0.5 mM (±)-propranolol to the cell suspension increased the cell/medium concentration ratio of sodium and decreased that of potassium until a new time-independent state was reached (Fig. 9) The decrease in the cell/medium concentration ratio of potassium was even greater with (+)-propranolol than with (±)-propranolol, while with (—)-propranolol the decrease was less. Changes in the cell/medium concentration ratios of sodium were smaller than those of potassium with all the different optical isomers of propranolol.

At the end of the experiments the cell/medium concentration ratios of bulk potassium ions were 1 4, 2.6, and 1 6 with (+), (—) and (±)-propranolol (0 5 mM). Those of sodium were 0.20 0 16, and 0 19 respectively

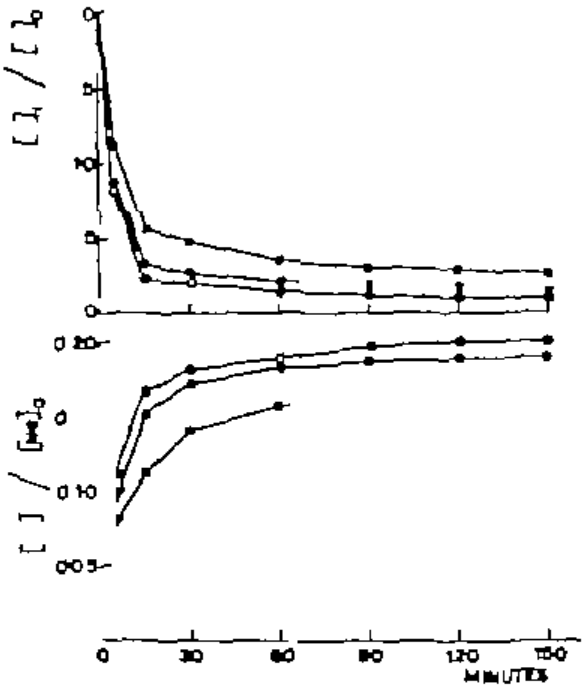

Fig. 9. Cell (i)/medium (o) concentration ratios of bulk potassium and sodium ions after addition of 0.5 mM propranolol of various optical forms to red cell suspension. ○ (+), ■ (−) and ● (±)-propranolol. In controls without propranolol the cell/medium concentration ratios of potassium and sodium bulk ions remained unchanged and were 20 and 0.03 respectively

The packed red cell volumes were reduced, and were 0.78, 0.88 and 0.80 times the initial volumes with (+), (−), and (±)-propranolol.

In the controls without propranolol the cell/medium concentration ratios of bulk potassium and sodium ions and the packed red cell volumes did not change noticeably during incubation.

The flows of bulk potassium and sodium ions as mmole/litre initial cells are shown as a function of time in Fig. 10. At the end of the experiments, when the flows were ceased, the outflow of potassium was 50 mmole/litre cells after treatment with 0.5 mM (+)-propranolol. The corresponding

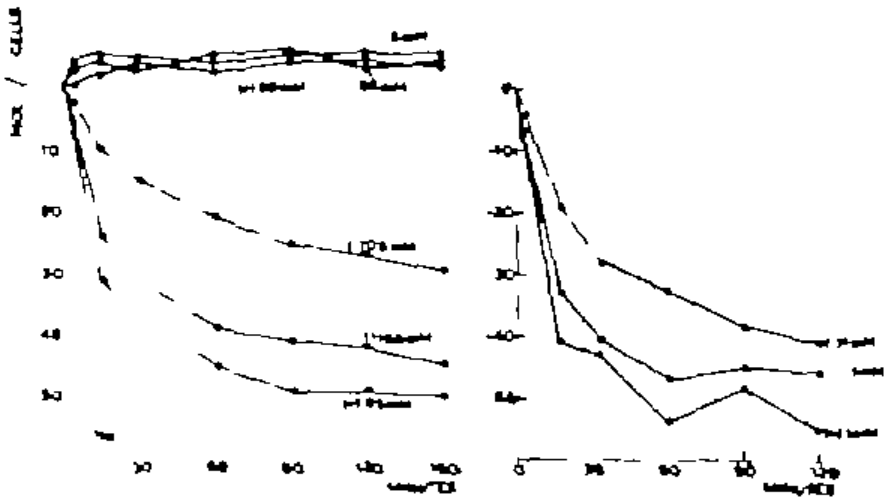

Fig. 10. Flows of bulk potassium and sodium ions as mmole/litre initial cells after exposure to various optical isomers of propranolol.

potassium flow produced by (—)-propranolol was much lower (27 mmole/litre cells) while that with (+)-propranolol was intermediate (45 mmole/litre cells). The concomitant inflow of sodium ions was low about 5 mmole/litre cells after 2.5 hr and no differences between the various forms of propranolol could be discerned.

The outflow of bulk potassium ions with 1 mM (—)-propranolol was similar to that with 0.5 mM (±)-propranolol (Fig 10) With 0.3 mM (—)-propranolol almost no shift of potassium ions was produced, while a clear outflow was observed when the (+)-propranolol concentration was 0.1 mM. Smaller concentrations down to 0.1 μM had no noticeable effect.

The rates of increases of the cell/medium concentration ratios of ^{42}K and ^{22}Na tracer ions were accelerated by all the forms of propranolol when the tracers were added together with 0.5 mM propranolol to the red cell suspension (Fig 11). With (+) and (±)-propranolol the potassium tracer transiently attained an intracellular concentration much higher than that at the end of the experiments. After 5 min the cell/medium concentration ratios of ^{42}K were 3.2 (+) and 2.7 (±), whilst the corresponding ratio for (—)-propranolol was 0 6, and 0 03 for controls without propranolol. The ^{42}K tracer then began to flow out of cells treated with (+)- or (±)-propranolol, and reached an

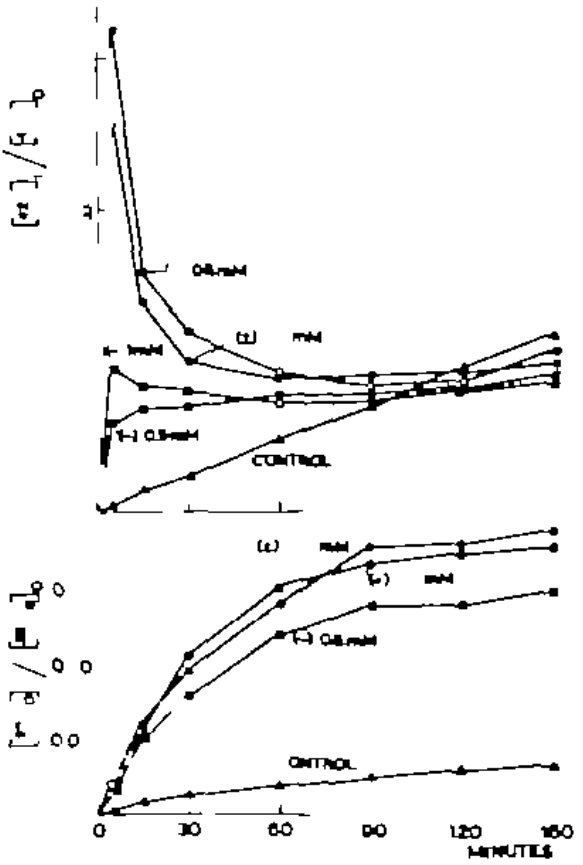

Fig. 11. Cell (*i*)/medium (*o*) concentration ratios of ^{42}K and ^{22}Na tracer ions added to the medium simultaneously with various optical isomers of propranolol.

approximate stationary state after about 60 min, when the cell/medium concentration ratios were near unity

Increasing the (—)-propranolol concentration from 0.5 mM to 1 mM somewhat accelerated the rate of uptake of the ^{42}K tracer However the cell/medium concentration ratio of ^{42}K did not exceed unity and in the first sample (5 min) it was almost the same as at the end of the experiment. With 0.3 mM (—)-propranolol the potassium distribution ratio during the experiments was near that of the controls. Even 0.1 mM (+)-propranolol was able to change the rate of ^{42}K uptake lower concentrations down to 0.1 μM had no noticeable effect

With 0.5 mM propranolol-treated cells the cell/medium concentration ratios of ^{22}Na tracer ions, measured simultaneously with ^{42}K, were somewhat lower with (—)-propranolol than with (+)- or (±)-propranolol (Fig. 11). However if the different shrinkage of the cells is taken into account, approximately the same amounts of ^{22}Na tracer were accumulated in all cases. At the end of the experiment the cell/medium ratios of the total amounts of ^{22}Na were 0.11 0 10 and 0 11 with (+)- (—)- and (±)-propranolol respectively while that of the controls without propranolol was 0.03.

The calculated potassium tracer rate constants and bulk ion flows 2.5 min after addition of 0.5 mM propranolol are given in Table II. The rate constants changed rapidly with time. In cells treated with (±)-propranolol the inward rate constant was reduced from 18 hr^{-1} to 4.5 hr^{-1} after 5 min, and the outward rate constant from 2.5 hr^{-1} to 2.3 hr^{-1} After 3 hr the respectiv rate constants are 0.66 hr^{-1} and 0.66 hr^{-1} (Ekman *et al.* 1969)

TABLE II. Rate constants of tracer potassium, concentrations and flows of bulk potassium ions in propranolol (0.5 mM)-induced non-stationary state 2.5 min after addition of various optical isomers of propranolol. Corresponding stationary state values of the control cells are given.

	Propranolol			Control

Effect of the pH of the medium

The outflow of bulk potassium ions induced by 0.5 mM (±)-propranolol at pH 7.0 was about half of that at pH 7.5 or 8.0 (Fig. 12). The inflow of bulk sodium ions was small at each pH tested and no significant differences could be discerned.

By the end of the experiments the packed red cell volumes had decreased to 0.89, 0.78, and 0.79 times the initial volumes at the three pH values increasing from pH 7.0 to pH 8.0.

After adding ^{42}K and ^{22}Na tracer ions with 0.5 mM propranolol to intact red cell suspensions the initial rate of ^{42}K uptake was high at pH 7.5 and 8.0 and the tracer transiently attained a higher intracellular concentration than the final one (Fig. 13). At pH 7.0 the uptake rate of ^{42}K was low. After 2.5 min the tracer potassium inward rate constants were 1.1 hr^{-1}, 17 hr^{-1}, and 19 hr^{-1} at pH 7.0, 7.5, and 8.0. The corresponding outward rate constants were 0.28 hr^{-1}, 2.2 hr^{-1}, and 2.5 hr^{-1}.

The rate of increase, and the stationary state cell/medium concentration ratio of ^{22}Na in the propranolol treated cells were lower at pH 7.0 than at pH 7.5 or 8.0 (Fig. 13).

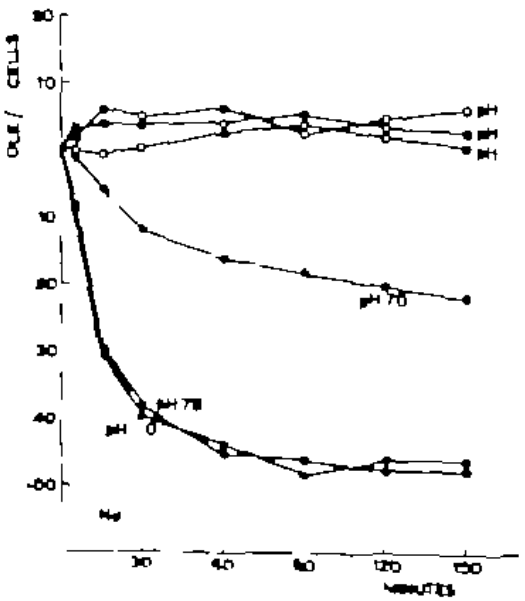

Fig. 12. Effect of pH on flows of bulk potassium and sodium ions in 0.5 mM propranolol treated cells.

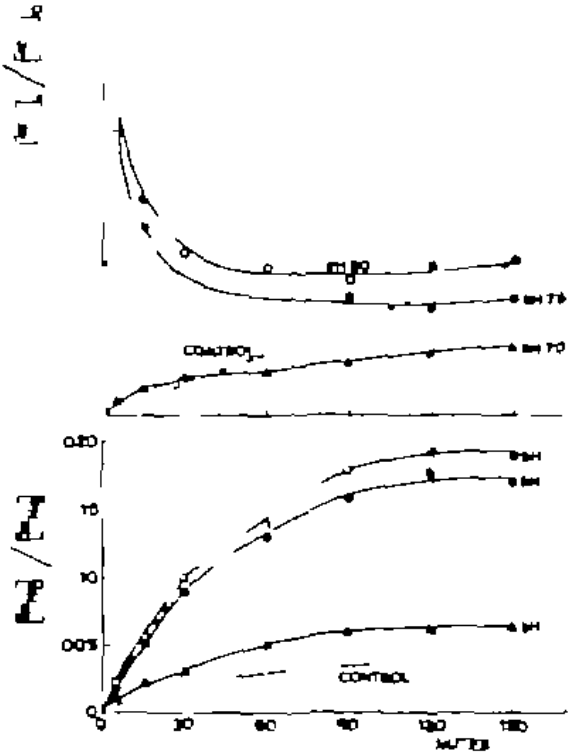

Fig. 13. Effect of pH on cell (I)/medium (o) concentration ratios of ^{42}K and ^{22}Na tracer ions added to the medium simultaneously with 0.5 mM propranolol. Control lines denote tracer uptakes at pH 7.5 in cells without propranolol.

In the control cells changing the pH had little effect on the behaviour of bulk potassium and sodium ions. At pH 7.0 the rate of uptake of both ^{42}K and ^{22}Na tracers was about 0.8 times that at pH 7.5. At pH 8.0 uptake of ^{22}Na was 1.5 times higher than at pH 7.5 whereas the uptake rate of ^{42}K was as low as at pH 7.0. The results obtained here for intact cells are in agreement with those at various pH values found by Pfleger, Rummel and Seifen (1967).

Effect of potassium and sodium ions

The height of the 0.5 mM propranolol induced rapid transient cellular accumulation peak of ^{42}K tracer ions above the final stationary concentration was sensitive to the bulk potassium ion concentration of the medium (Fig. 14). Table III shows the calculated potassium tracer rate constants and the

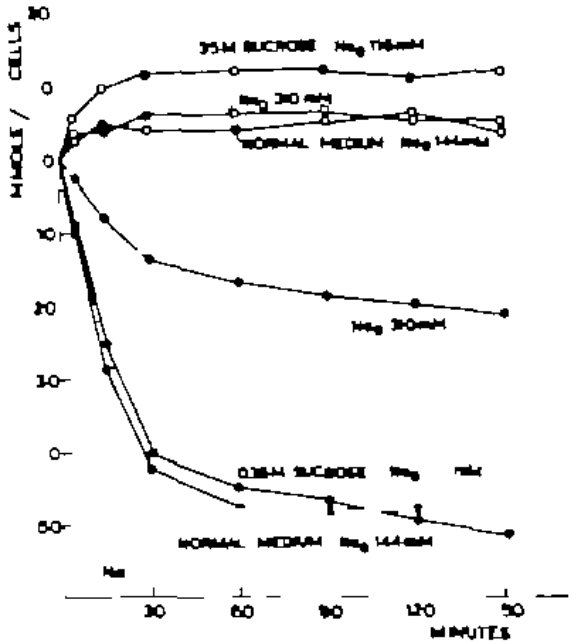

Fig. 15. Flows of bulk potassium and sodium ions in cells treated with 0.5 mM propranolol after increasing the medium sodium concentration to 310 mM, or adding sucrose to give a medium osmolality similar to that with 310 mM sodium.

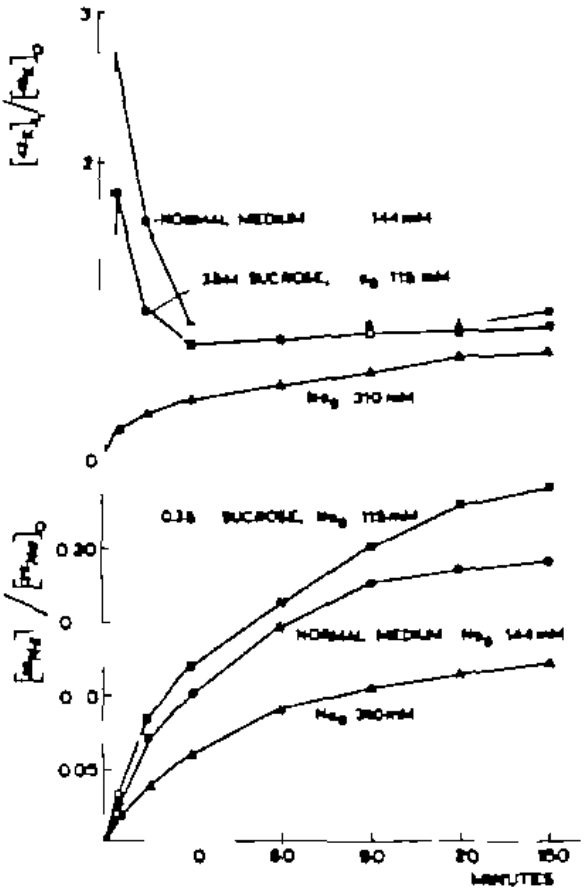

Fig. 16. Cell (i)/medium (o) concentration ratios of ^{42}K and ^{22}Na tracer ions in the same cells as in Fig. 15. Tracer ions were added at 0 min to the medium.

unidirectional fluxes of potassium ion. During the non-stationary state the inward and outward unidirectional fluxes of potassium ions were rather constant at different concentrations of external potassium ions.

When the sodium concentration of the medium was increased to 310 mM, the 0.5 mM propranolol-induced leakage of potassium ions was reduced (Fig 15) In the usual medium (144 mM sodium) the outflow of potassium ions was 46 mmole/litre cells after 2.5 hr while in the high sodium medium it was 21 mmole/litre cells. Where 0.35 M sucrose was added to make the osmolality of the medium the same as in the high sodium medium, the flow of potassium ions was about the same as that produced by propranolol in the usual medium without sucrose. Sucrose alone, without propranolol, induced a rather high outflow of potassium. The flow was 16 mmole/litre cells after 2.5 hr and was accompanied by a corresponding inflow of sodium ions. The inflow of sodium was small in propranolol treated cells suspended either

TABLE IV Rate constants of tracer potassium, concentrations and flows of bulk potassium ions 2.5 min after addition of 0.5 mM propranolol to usual, high sodium or sucrose-containing media.

	Medium

in the usual or the high sodium medium. In the sucrose-treated cells propranolol did not increase the flow of sodium ions above that induced by sucrose alone.

After propranolol treatment the initial rate of uptake of ^{42}K tracer ions from the medium was somewhat lower after sucrose treatment than in the cells suspended in the usual medium (Fig. 16). In the high sodium medium the rate of uptake of ^{42}K tracer was much lower than in the other two groups and was near that of the control cells without propranolol. Table IV gives the rate constants of potassium tracer and flows of bulk potassium ions 2.5 min after addition of propranolol.

In control cells the uptake rate of ^{42}K was decreased by sucrose treatment, the cell/medium concentration ratios after 2.5 hr being 1.2 and 0.76 in the usual and sucrose-containing media respectively

Sucrose treatment increased the cell/medium concentration ratio of ^{22}Na in 0.5 mM propranolol treated cells, while in cells suspended in the high sodium medium the ratio was lower about half of that in the usual medium (Fig. 16) Without propranolol the cell/medium concentration rations of ^{22}Na at the end of the experiments were 0.092, 0.045, and 0.022 in sucrose-containing, usual and high sodium media respectively

Effect of calcium and magnesium ions

The outflow of bulk potassium ions produced by 0.5 mM propranolol was reduced when magnesium ion concentration in the medium was raised to 20 mM (Fig. 17). On the other hand, similar increase in the calcium ion con-

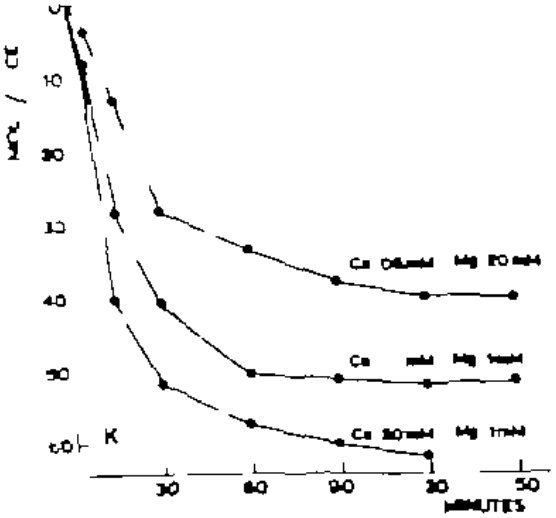

Fig. 17 Flows of bulk potassium ions after adding 0.5 mM propranolol to cell suspensions with different external calcium and magnesium ion concentrations.

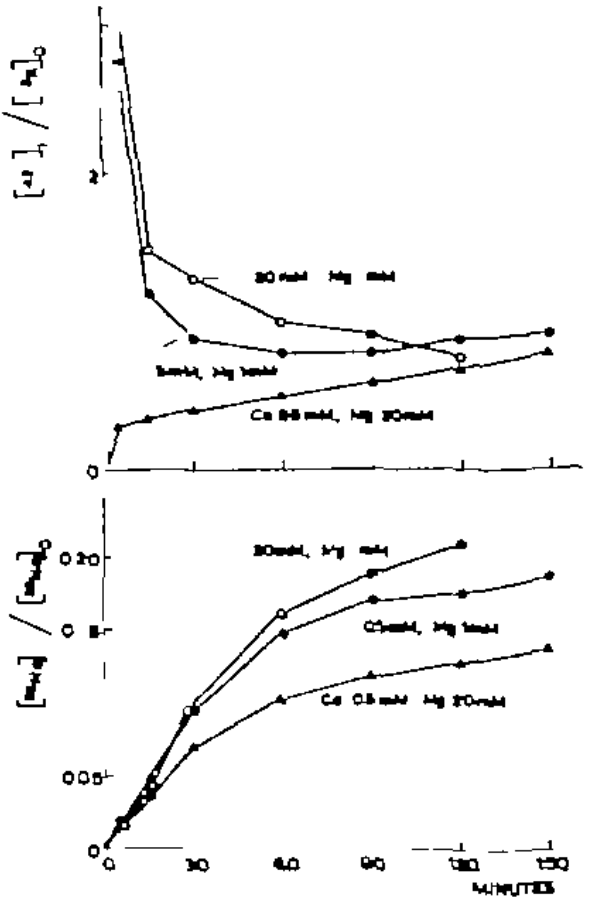

Fig. 18. Cell (I)/medium ( ) concentration ratios of ^{42}K and ^{22}Na tracer ions added simultaneously with 0.5 mM propranolol to cell suspensions with different external calcium and magnesium ion concentrations.

centration enhanced this flow The mean flows of bulk potassium after 2 hr were 52, 40 and 62 mmole/litre cells in the usual, high magnesium and high calcium media respectively The flows of bulk sodium ions were small, and were only slightly if at all, changed by increasing the calcium or magnesium ion concentrations in the medium. The corresponding packed red cell volumes after 2 hr were 0.81 0 86 and 0 75 times the initial ones.

Experiments with the high calcium medium were only continued for 2 hr since after that time considerable amounts of haemoglobin were released.

The increased initial cellular uptake of ^{42}K tracer ions produced 0.5 mM propranolol was greatly reduced when the magnesium ion concentration was raised to 20 mM (Fig 18). In high calcium medium the observed transient accumulation peak of ^{42}K at the beginning of the experiments was somewhat increased. After exposure to propranolol an approximate stationary distribution of ^{42}K between the cells and the medium was reached after 60 min in cells suspended in the usual medium. In the high calcium medium the cell/medium concentration ratio of ^{42}K continued to decrease even at the end of the experiment.

Increasing the medium magnesium concentration slightly decreased the cell/medium concentration ratios of ^{22}Na in propranolol-treated cells (Fig. 18).

However if the smaller shrinkage of these cells is taken into account, approximately the same amounts of ^{22}Na tracer were accumulated as in cells suspended in the usual medium. In high calcium medium the cell/medium concentration ratios of ^{22}Na were higher than those of cells in the usual medium. This elevation may be related to the increased tendency for cellular breakdown allowing a more free permeation of sodium ions. This was also manifested by the outflow of haemoglobin and potassium tracer

In control experiments without propranolol 20 mM magnesium did not influence the behaviour of bulk potassium and sodium ions or ^{42}K and ^{22}Na tracer ions, as compared to cells suspended in the usual medium, while in the high calcium medium there was some outflow of bulk potassium ions, and later of haemoglobin.

When the cells were initially suspended in a Ca, Mg-free medium the outflow of bulk potassium ions produced by 0.5 mM propranolol was only 14 mmole/litre cells at the end of the experiments, and there was a concomitant inflow of an equal amount (13 mmole/litre cells) of bulk sodium ions (Fig. 19) Addition of 1 mM magnesium had little effect on the flows of bulk potassium and sodium ions, but after addition of 1 mM calcium the characteristic rapid great selective outflow of bulk potassium ions (60 mmole/litre cells after 2 hr) became evident. The simultaneous inflow of

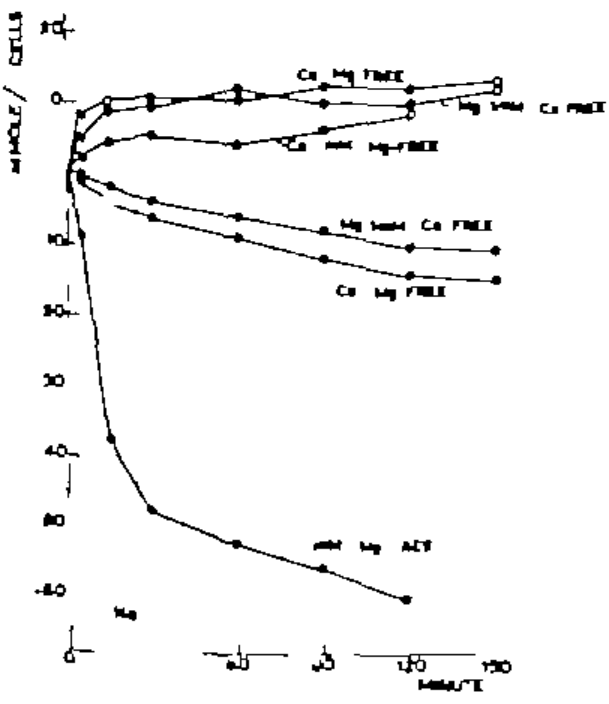

Fig. 18. Flows of bulk potassium and sodium ions in cells suspended in Ca, Mg free and Ca or Mg-containing medium after adding 0.5 mM propranolol.

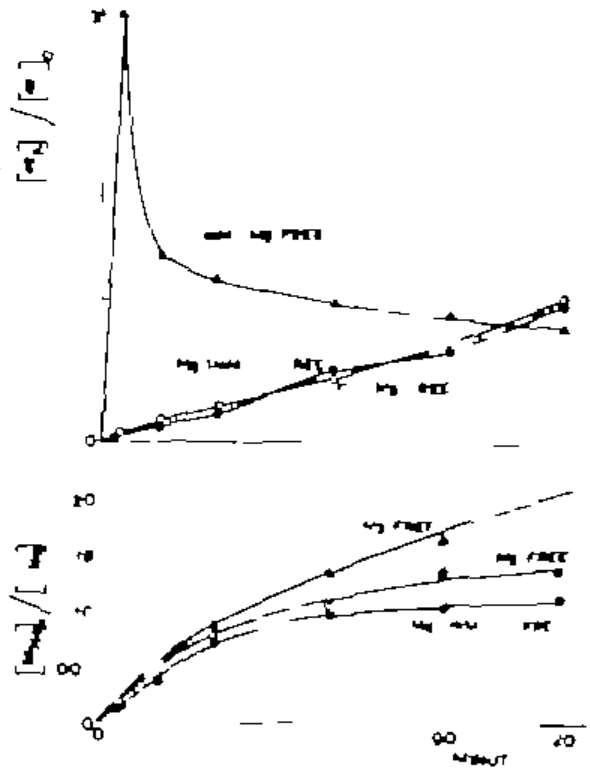

Fig. 20. Cell (i)/medium (o) concentration ratios of ^{42}K and ^{22}Na tracer ions added simultaneously with 0.5 mM propranolol to Ca, Mg free, and Ca or Mg-containing medium.

TABLE V Rate constants of tracer potassium, concentrations and flows of bulk potassium ions 2.5 min after addition of 0.5 mM propranolol to cell suspensions with varying external calcium and magnesium ion concentrations.

	Ca, Mg free	Ca 1 mM No Mg	No Ca Mg 1 mM	Ca 0.5 mM Mg 1 mM	Ca 20 mM Mg 1 mM	Ca 0.5 mM Mg 20 mM
k_{in}, hr^{-1}	0.24	19	0.24	18	20	3.1
k_{out}, hr^{-1}	0.092	2.5	0.050	2.3	2.7	0.68
[K+] mmole/litre cells	96	94	95	94	93	95
$[K^+]_o$ mmole/litre cells	4.9	7.3	4.8	7.3	7.5	6.1
$k_{in}[K^+]_o$ mmole/litre cells/hr	1.2	140	1.2	130	150	19
k_{out} [K+] mmole/litre cells/hr	8.7	240	4.6	220	250	65
Bulk ion flow k_{in} [K+] — k_{out}[K+] mmole/litre cells/hr	—7.5	—100	—3.4	—90	—100	—46

bulk sodium ions was only about 5 mmole/litre cells at 2 hr but later increased when the cells began to lyse. The packed red cell volumes after 2 hr were 1.0 1.0 and 0.74 times the initial volumes in Ca, Mg free, 1 mM Mg or 1 mM Ca-containing media.

The rapid initial uptake of ^{42}K tracer ions produced by 0.5 mM propranolol was abolished in a Ca, Mg-free medium or in Ca free medium with 1 mM magnesium but became evident in the presence of 1 mM calcium (Fig. 20) In this case, as with 20 mM Ca and 1 mM Mg, no stationary state for cell and medium ^{42}K ions was reached at the end of the experiments. These cells were prone to lysis at the time.

Table V shows the potassium tracer rate constants 2.5 min after adding 0.5 mM propranolol to cell suspensions with differing external calcium and magnesium ion concentrations.

The cell/medium concentration ratios of ^{22}Na are shown in the lower part of Fig. 20 In propranolol-treated (0.5 mM) cells the least ^{22}Na was accumulated at first in cells suspended in medium containing 1 mM calcium (Fig. 21) Together with the greatly accelerated exchange of potassium this shows that the initial selectivity between potassium and sodium ions was greatest in Ca-containing medium.

When enough EDTA Na_2 was added to chelate the magnesium and calcium ions in the usual medium, bulk potassium and sodium ions and ^{42}K and ^{22}Na tracer ions behaved, after treatment with 0.5 mM of propranolol, as they did in a Ca, Mg-free medium.

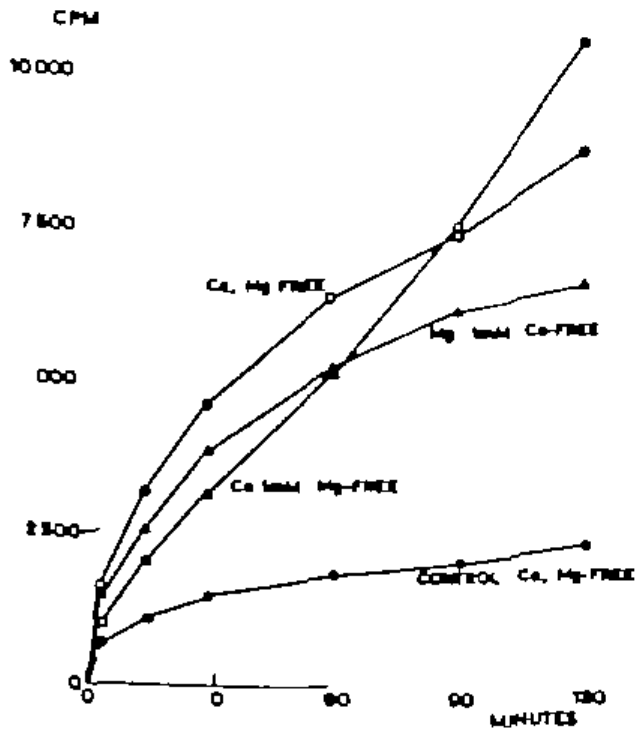

Fig. 21 Cellular ^{22}Na radioactivities (counts per minute per ml of cells) after adding ^{22}Na tracer ions to the medium at 0 min with 0.5 mM propranolol.

In experiments without propranolol omitting the calcium of magnesium ions from the medium (or chelation with EDTA Na_2) did not change the behaviour of bulk potassium and sodium ions or their tracer ions.

Ouabain and propranolol

After 2.5 hr incubation with 0 01 μM or 1 μM ouabain the outflow of bulk potassium ions was 3 0 mmole/litre cells or 3.4 mmole/litre cells. The corresponding inflow of bulk sodium ions was 2.5 mmole/litre cells or 3.7 mmole/litre cells (n = 10) The packed red cell volumes did not change from the initial ones.

Ouabain drastically reduced the rate of increase of the cell/medium concentration ratio of ^{42}K added simultaneously with ouabain to the cell suspension (Fig 22) At the end of the 2.5 hr experiment this ratio was 1 15 in the controls without ouabain, but 0.35 and 0.21 with 0.01 μM and 1 μM ouabain respectively Table VI shows the potassium rate constants and unidirectional fluxes in cells treated with 1 μM ouabain. Both the inward rate constant and unidirectional flux of potassium was markedly reduced by ouabain.

The uptake rate for ^{22}Na was only slightly influenced by ouabain (Fig 22) With 0 01 μM ouabain no differences between controls and ouabain-treated cells could be detected. In cells treated with 1 μM ouabain the cell/medium concentration ratios at the end of the experiments were slightly higher than in the controls.

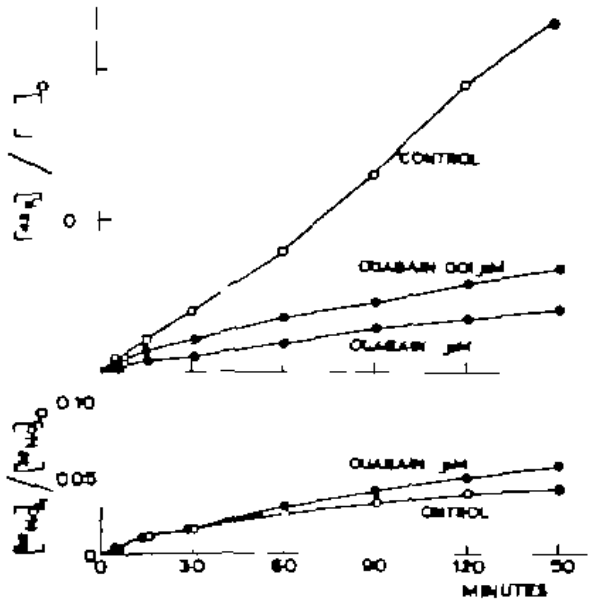

Fig. 22. Cell (i)/medium (o) concentration ratios of ^{42}K and ^{22}Na tracer ions added to the medium at 0 min simultaneously with ouabain.

TABLE VI Rate constants of tracer potassium, concentrations and flows of bulk potassium ions in ouabain-treated and control cells during the whol exper iment, and after 2.5 min in cells treated with propranolol alone or with propranolol and ouabain.

	Control	Ouabain (1 μM)	Propranolol (0.5 mM)	Ouabain+Propranolol (1 μM) (0.5 mM)
k_{in}, hr^{-1}	0.37	0.075	18	18
k_{out}, hr^{-1}	0.019	0.019	2.4	2.5
[K+] mmole/litre cells	95	94	94	94
$[K+]_e$, *mmole/litre cells*	4.8	5.2	7.5	7.5
$k_{in}[K+]_e$ mmole/litre cells/hr	1.8	0.39	135	135
k_{out} $[K+]_i$ mmole/litre cells/hr	1.8	1.8	230	235
Bulk ion flow k_{in} [K+] — k_{out} [K+] mmole/litre cells/hr	0	—1.4	— 95	—100

Adding 0.01 μM or 1 μM ouabain did not change the 0.3 mM or 0.5 mM propranolol-induced flow of bulk potassium ions (Fig 23). That of sodium was somewhat increased, for instance the inflow of bulk sodium after 2.5 hr was 4 mmole/litre cells with 0.5 mM propranolol and 10 mmole/ litre cells with 0.5 mM propranolol and 1 μM ouabain. The above difference, though small, seemed to be valid since it occurred in all six experiments performed. Ouabain did not change the propranolol induced shrinkage of the cells.

Neither did ouabain change the propranolol-induced rapid initial cellular uptake of ^{42}K tracer ions (Fig. 24) Table VI shows that the calculated potas-

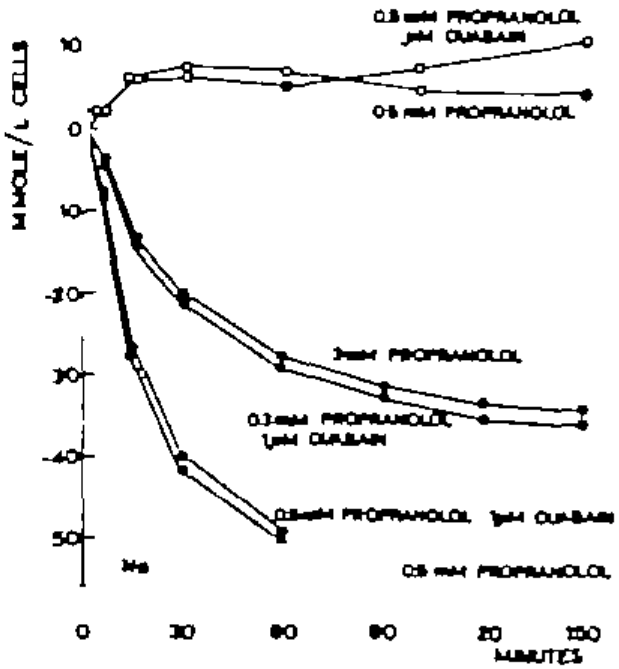

Fig. 23. Flows of bulk potassium and sodium ions in cells treated with propranolol and ouabain.

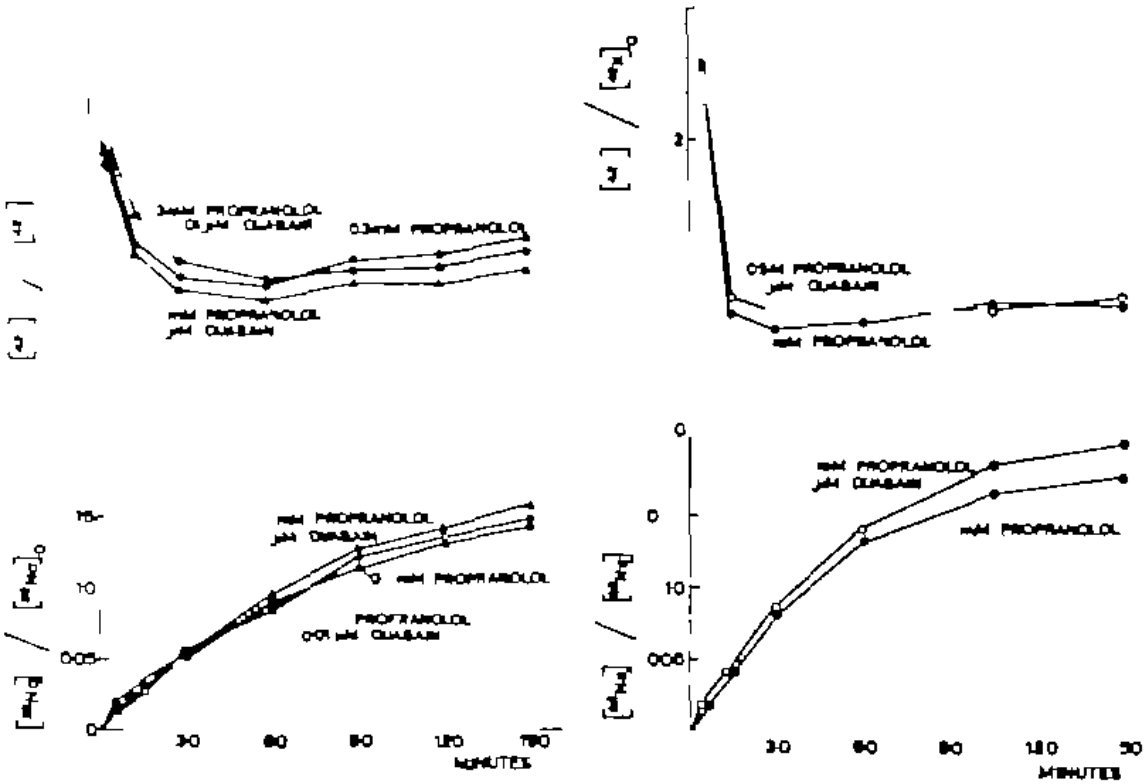

Fig. 24. Cell (i)/medium (o) concentration ratios of ^{42}K and ^{22}Na tracer ions added to the medium at 0 min with propranolol and ouabain.

sium rate constants and unidirectional fluxes were equal in cells treated either with propranolol alone or with propranolol and ouabain.

At the end of the experiments the cell/medium concentration ratios of ^{22}Na tracer ions were slightly higher when the cells were simultaneously trated with 0.5 mM propranolol and 1 μM ouabain than when only 0.5 mM propranolol was used (Fig. 24).

Effect of protamine

The outflow of bulk potassium induced by 0.5 mM propranolol was reduced when the cells were treated with equimolar protamine at the same time (Fig 25) The inflow of bulk sodium was slightly enhanced by protamine, but the difference may be erroneous since the uptake of ^{22}Na was not increased by simultaneous treatment with propranolol and protamine. The packed red cell volumes at the end of the experiment were 0 79 and 0.87 times the initial volumes in cells treated with propranolol alone and with propranolol plus protamine. The rate of the cell shrinkage was also lowered after treat ment with protamine.

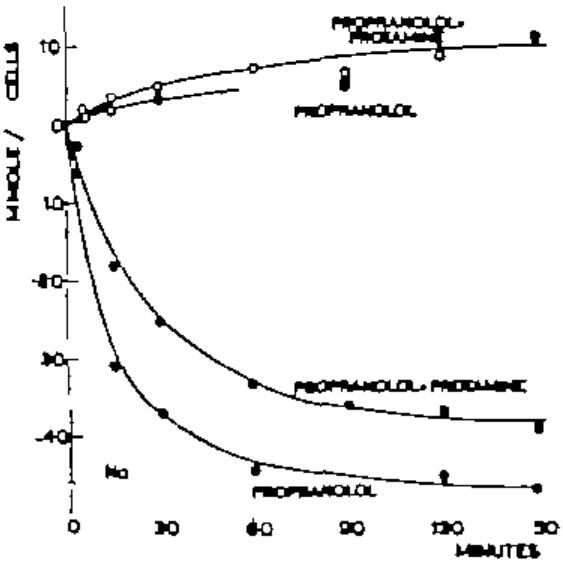

Fig. 25. Flows of bulk potassium and sodium ions after treatment with 0.5 mM propranolol and 0.5 mM protamine.

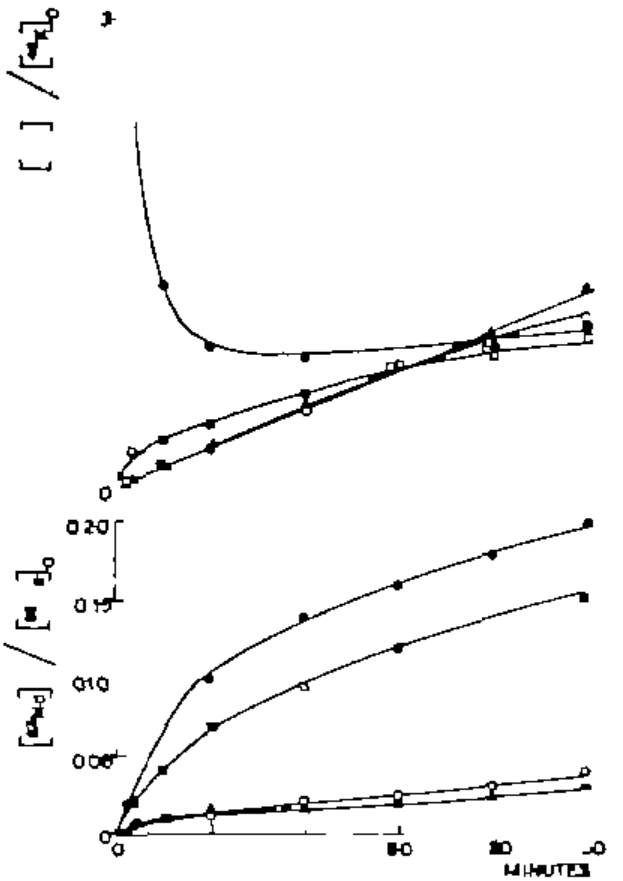

Fig. 26 Cell (i)/medium (o) concentration ratios of ^{42}K and ^{22}Na tracer ions added to the medium at 0 min with propranolol and protamine. ● propranolol 0.5 mM, □ propranolol 0.5 mM and protamine 0.5 mM, ○ protamine 0.5 mM, △ neither drug.

The rapid initial uptake of ^{42}K tracer ions produced by 0.5 mM propranolol was greatly reduced when 0.5 mM protamine was added simultaneously (Fig 26). In propranolol treated cells the inward and outward rate constants after 2.5 min were 17 hr^{-1} and 2.3 hr^{-1} while those in cells treated with propranolol and protamine were 2.1 hr^{-1} and 0.45 hr^{-1} respectively Maximal inhibition of the initial rate of ^{42}K uptake was observed when the molar concentrations of protamine and propranolol were equal, but some retardation of the ^{42}K uptake was still achieved when the protamine concentration was 10 μM.

The cell/medium concentration ratios of the ^{22}Na tracer ions were slightly lowered after protamine administration (Fig 26). However when the smaller shrinkage of the cells treated with propranolol and protamine is taken into account, approximately equal amounts of the ^{22}Na tracer ions were accumulated in both cases.

After adding protamine 15 min beforehand the flows of bulk potassium and sodium ions and of ^{42}K and ^{22}Na tracer ions were similar to those when propranolol and protamine were added simultaneously

Protamine alone in a concentration of 0.5 mM did not change the behaviour of bulk potassium or sodium ions, packed red cell volumes or ^{42}K and ^{22}Na tracer ions during the 2.5 hr experiments as compared to similar controls without protamine.

Reversibility of normal cation permeability after propranolol treatment

The results of a typical experiment (three were performed) show that the rapid uptake of ^{86}Rb added to intact cell suspensions with propranolol, was reduced in cells previously treated with propranolol and then washed 3 times in a tenfold volume of propranolol free saline (Fig. 27 A) This treatment reduced the outflow of bulk potassium during the 2 hr incubation from 48 mmole/litre cells to 19 mmole/litre cells. The cells still contained about 30—35 % of their initial propranolol content as calculated from experiments with ^{14}C-propranolol (Fig. 7).

When propranolol treated cells were washed for long enough to allow all the initially accumulated propranolol to flow out, the ^{86}Rb tracer accumulated at a similar rate in the control cells and the cells previously treated with propranolol (Fig. 27 B) The outflow of bulk potassium was negligible The rate of ^{86}Rb accumulation was the same as that found by Ekman *et al.* (1969)

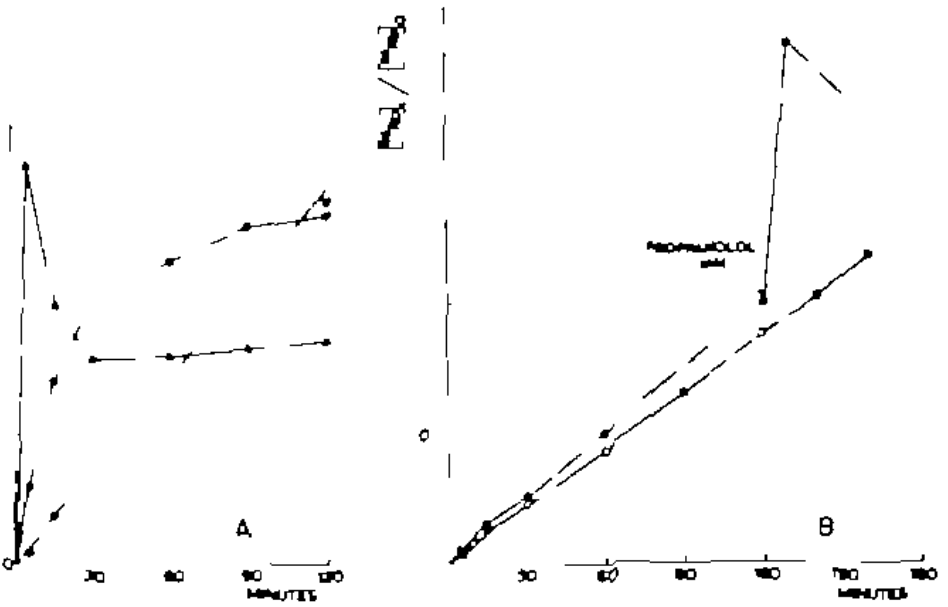

Fig. 27 Reversibility of normal uptake of ^{86}Rb tracer ions in red cells treated with 0.5 mM propranolol, then washed free of propranolol. Cell (i)/medium (o) *concentration ratios f ^{86}Rb added to the medium at 0 min. A)* ▲ *propranolol* and ^{86}Rb added to intact red cell suspension, ○ intact cells without propranolol, ● propranolol-treated cells washed 3 times in tenfold volume of saline. B) ● cells treated with propranolol and washed free of propranolol. After 120 min 0.5 mM propranolol was added, ○ washed as before but not treated with propranolol.

for fresh control cells, which shows that the cells had not suffered during the procedure. Readdition of propranolol after 120 min induced the characteristic rapid uptake of ^{86}Rb tracer ions. Simultaneously bulk potassium ions began to leak out and the packed red cell volumes began to decrease.

Sucrose permeability

After 3 hr the cell to medium concentration ratios of ^{14}C-sucrose, added to the medium, remained as low as 0 014 and 0.022 in cells treated with 0.5 *mM and 1 mM propranolol, while that of the controls was 0 011 (n = 3)* Thus, the low permeability of the red cell membrane to sucrose was not destroyed by propranolol.

Adenosine triphosphate concentration

The ATP concentration of control cells without propranolol was 0 64 ± S E 0.072 mmole/litre cells at the beginning of the experiments and 0.52 ± S. E 0.065 mmole/litre cells after 60 min incubation at 38 C (n = 6) In the first sample after addition of 0.5 mM propranolol (about 5 min) the ATP concentration was 1.06 ± S. E. 0.083 mmole/litre cells. After 60 min incubation it was 0.98 + S. E. 0 071 mmole/litre cells (n = 6)

Adenosine triphosphatase activity

In whole red cells the ATPase activity as inorganic phosphate (Pi) liberated in 60 min was increased by treatment with propranolol (Table VII). In control experiments the mean Pi production rate was 1.04 ± S. E. 0.039 mmole/litre cells/hr (n = 9). With 0.5 mM of propranolol the amount of Pi liberated during the 60 min incubation was 1 61 times that of the controls. Higher concentrations of ouabain, as used in experiments with isolated red cell membrane stroma, were not used with the whole cell suspension since they caused a considerable haemolysis.

With 0.5 mM propranolol plus 10 μM ouabain the Pi production rate was 1.33 times that of the controls, so that in this case the amount of Pi liberated was less than that with propranolol alone. During the 60 min incubation the decrease was 0.28 mmole/litre cells, which was the same as that produced by ouabain without propranolol.

When calcium was withdrawn the mean Pi production rate was 0 98 ± S. E. 0.050 mmole/litre cells/hr (n = 9) without propranolol, with 0.5 mM

TABLE VII. Relati e ATPase activity as inorgani phosphate liberated in 60 min, in propranolol and/or ouabain-treated whole red cells and isolated red cell membrane stroma. Activity in similar controls without drugs taken as unity. Mean values ± S.E. Numbers of determinations in parentheses.

	Propranolol (mM)					Ouabain (mM)		Propranolol + Ouabain (mM) (P) (O)	
	1	0.5	0.1	0.01	0.001	0.1	0.01	0.5(P) + 0.1(O)	0.5(P) + 0.01(O)
Whole cells		1.61					0.68		1.33
± S.E.		0.084					0.035		0.057
		(10)					(10)		(6)
Red cell membrane stroma	0.62	0.75	0.89	0.98	1.04	0.56		0.54	
± S.E.	0.058	0.035	0.037	—	—	0.028		0.030	
	(5)	(8)	(4)	(3)	(3)	(7)		(6)	

propranolol it was 1.20 ± S. E. 0.033 mmole/litre cells/hr and 0.72 ± S. E. 0.039 mmole/litre cells/hr with 10 μM ouabain.

In contrast to the results with whole red cells, higher concentrations of propranolol decreased Pi production in red cell membrane stroma (Table VII). In controls without propranolol the mean Pi production rate during the 60 min incubation was 0.65 ± S. E. 0.027 μmole/mg protein (n = 8). That with 0.5 mM propranolol was 0.49 = S. E. 0.030 μmole/mg protein (n = 8). When 0.1 mM ouabain was added the Pi production rate was 0.56 times that of the controls. With 0.5 mM propranolol plus 0.1 mM ouabain the Pi production rate was 0.54 times the control value, indicating that propranolol could not counteract the decrease caused by ouabain.

In the above experiments conditions were arranged so as to measure the $(Na^+ + K^+)$-activated, Mg^{++}-dependent, ATPase activity.

In additional experiments with 5 mM calcium inhibition of the Pi production rate by 0.1 mM ouabain was low, about 8 %. In 3 series of experiments with propranolol in a concentration range from 1 μM to 1 mM the Pi production rate was not detectably different from that of controls.

Experiments with isolated rat diaphragm

Cation and water contents

The potassium and sodium concentrations were 98.9 ± S. E. 2.8 and 31.6 ± S. E. 0.50 mmole/kg wet muscle in fresh diaphragms (n = 12). It is however difficult to keep isolated diaphragm muscles in this state. The muscle potassium content decreases, and the sodium content increases rather rapidly until a new stationary state is reached after a few minutes. After 15 min soaking the potassium concentration of the control muscles was reduced to 84.6 ± S. E. 1.9 mmole/kg (n = 6). Thereafter their potassium content remained rather constant throughout the 2.5 hr experiments, but with high concentrations of propranolol potassium ions continued to flow out (Fig. 28).

The sodium concentration in the control muscles was 53.4 ± S. E. 3.2 mmole/kg (n = 8) after 15 min soaking. There was a tendency for the sodium ion content to increase further during the course of the experiment, and after 2.5 hr the sodium concentration was 70.5 ± S. E. 2.9 mmole/kg (n = 8). Propranolol increased this process, so that muscle sodium ion concentrations were 88.4 ± S. E. 2.7 mmole/kg (n = 5) and 123.6 ± S. E. 3.6 mmole/kg (n = 5) after 2.5 hr with 0.1 mM and 1 mM propranolol.

The water concentration of the fresh muscle was 765 ± S. E. 4.9 g/kg (n = 7). After soaking for 2.5 hr the water concentration was 780 ± S. E. 4.6 g/kg (n = 8) in control muscles without propranolol and 834 ± S. E. 5.2 g/kg

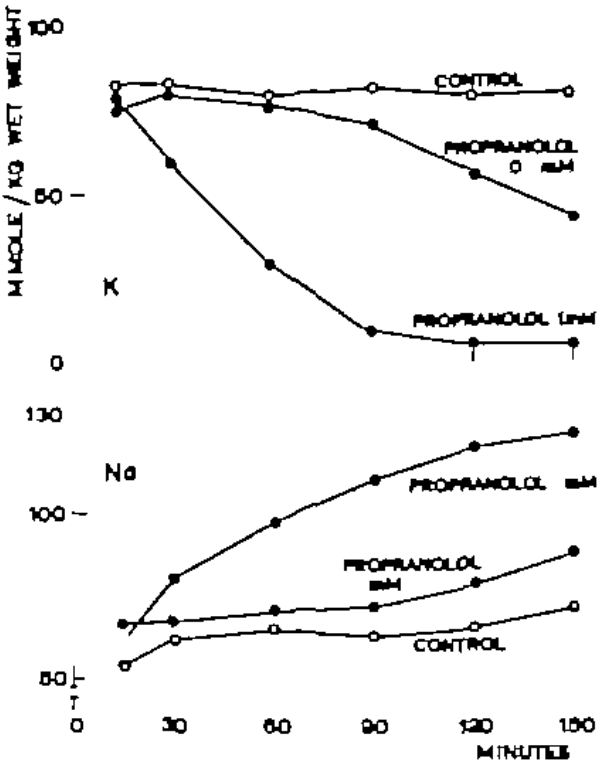

Fig. 28. Potassium and sodium ion concentrations of the rat diaphragm muscle as mmole/kg wet weight in propranolol treated and control muscles during incubation.

(n = 8) in muscles treated with 1 mM propranolol. The increase of in water content of the propranolol treated muscles is significant ($P < 0.001$)

Extracellular space

The extracellular space was determined with ^{14}C-sucrose. Fig 29 shows the uptake of ^{14}C-sucrose when the diaphragm muscles were immersed in enough ^{14}C-sucrose-containing saline to maintain a practically constant composition. The ^{14}C-sucrose that has entered the tissue is expressed as sucrose space, as defined by the ratio ^{14}C-sucrose per 100 g tissue/^{14}C-sucrose per ml of extracellular fluid. When a steady state was reached after 3 hr the

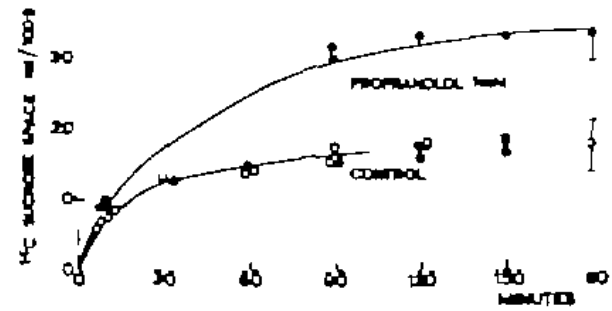

Fig. 29 Sucrose space in the diaphragm muscle. Means ±S D f 6 determinations after 180 min, other marks are individual values of 3 different experiments.

sucrose space, as means ± S E. of 6 determinations, was 18.6 ± 0.41 ml/100 g tissue and 34.8 ± 0.63 ml/100 g tissue with no and 1 mM propranolol respectively

Intracellular cation and water concentrations

The intracellular cation and water concentrations were calculated from the tissue analyses together with the values of the extracellular space (Table VIII). In fresh diaphragm muscle intracellular sodium ions represented 14.9 % of the total muscle sodium content. During the 2.5 hr incubation their amount increased to 62 %. The corresponding increment in the cellular sodium concentration as mmole/kg fibre water was from 8.1 to 73. There was also a slight loss in the intracellular potassium ion concentration.

With 1 mM propranolol the increase in the internal sodium concentration was even more prominent than in the controls. After 2.5 hr the intracellular sodium ion concentration was 147 mmole/kg fibre water in propranolol treated muscles, a value equal to the sodium concentration in the medium. The internal potassium concentration was concomitantly decreased, the ratio internal/external concentration remaining however above unity

Inflow of ^{22}Na and ^{42}K tracer ions

Fig. 30 shows the uptake of tracer ions as muscle/medium concentration ratios against time when the muscle strips were soaked in a large volume

TABLE VIII. Effect of propranolol on cation and water concentrations in diaphragm muscle.

		Initial	2.5 hr soaked	
			Control	Propranolol 1 mM
Internal concentration (mmole/kg fibre water)	N^+	8.1	73	147
	K^+	169	145	12
Ratio internal/ external concentration	N^+	0.06	0.50	1.0

of buffered saline containing ^{42}K and ^{22}Na tracer ions. The accumulation of ^{42}K in the control muscles was mono-exponential towards a constant stationary state having an inward rate constant, k_{in}, of 10.2 hr^{-1}. Treatment with high concentrations of propranolol lowered the muscle/medium concentration ratios of ^{42}K. As with red cells, the tracer transiently attained concentrations in the muscles that were higher than those in the final propranolol induced stationary state. With the highest propranolol concentration used (1 mM) the muscle/medium concentration ratio of ^{42}K was 1.1 after 2.5 hr. When the ^{42}K concentrations were calculated per volume of water the cell/medium concentration ratio was 2.2, which is near the 2.4 obtained from the bulk potassium ion concentrations.

Propranolol increased the muscle/medium concentration ratios of ^{22}Na tracer ions (Fig. 30). The rate constant for ^{22}Na inflow was 1.4 hr^{-1} in the control muscles, and 1.8 hr^{-1} and 2.4 hr^{-1} in mucles treated with 0.1 mM and 1 mM propranolol.

Outflow of ^{22}Na, ^{42}K, and ^{86}Rb tracer ions

The diaphragms were loaded with tracers by intraperitoneal injections given 12—36 hr beforehand. Fig. 31 shows the ^{22}Na and ^{86}Rb activities in the diaphragms plotted semi logarithmically against time after soaking in a succession of samples of inactive saline. The rate of outflow of ^{86}Rb from the control muscles was rather constant with a half life of 59 min, the corresponding outflow rate constant, k_{out}, was 0.70 hr^{-1}. After a few minutes

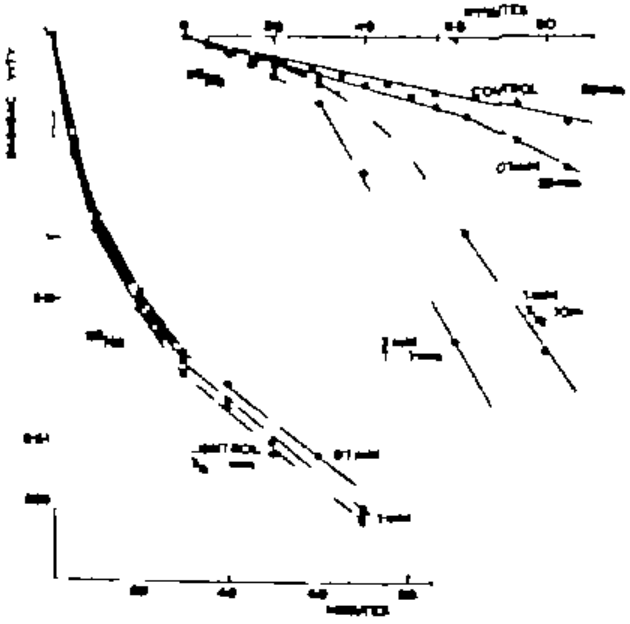

Fig. 31. Effect of propranolol on the outflow of ^{22}Na and ^{86}Rb tracer ions from isolated hemidiaphragms. Fraction of the initial radioactivity remaining in the diaphragms when soaked in a succession of samples of non radioactive saline is plotted semilog. against time.

propranolol increased the rate of ^{86}Rb efflux. When the new constant values were reached, the rate constants were 1.4 hr^{-1} 4.1 hr^{-1} and 5.9 hr^{-1} with 0.1 mM, 1 mM, and 3 mM propranolol respectively With 0 01 mM propranolol the efflux rate was similar to that in controls.

The outflow of ^{42}K in two series of experiments with various concentrations of propranolol from 0.01 mM to 3 mM was qualitatively similar to that of ^{86}Rb. The rate constant for the ^{42}K outflow in control muscles without propranolol was 0 65 hr^{-1} The ^{86}Rb tracer was used in most experiments instead of ^{42}K, because its half life is more suitable for these prolonged experiments.

The outflow of ^{22}Na tracer ions can be divided into two parts, one rapid, the other slow representing the flow from the extracellular and from the cellular space. After 20 min the outflow from the rapidly exchanging portion

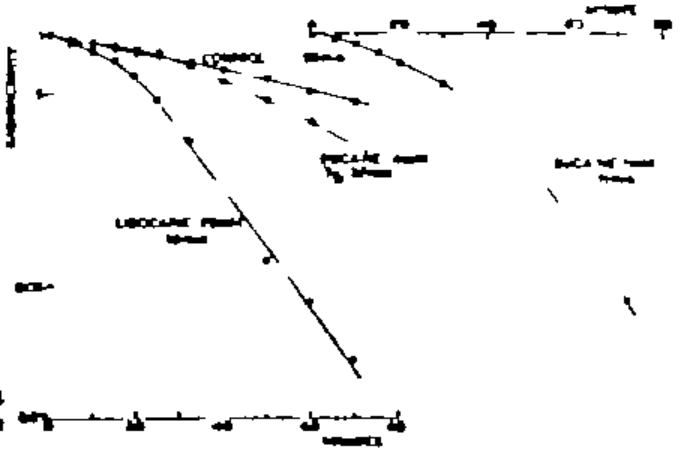

Fig. 32. Outflow of ^{86}Rb tracer ions from diaphragms exposed to lidocaine or dibucaine.

was practically finished. After that the semi logarithmic plot of the remaining radioactivity in the muscles against time gave a straight line. At this time the outflow rate constant for ^{22}Na tracer in the control muscles was 3.2 hr^{-1} No apparent differences could be discerned between the controls and the propranolol-treated muscles. The zero time intercept of the slowly exchanging part of the ^{22}Na indicated that about 10—15 % of the total ^{22}Na content in the muscles was composed of the slowly exchanging, i.e. intracellular ^{22}Na ions. This is the same as that found by the bulk sodium ions.

Effect of lidocaine and dibucaine on ^{86}Rb tracer outflow

Like propranolol, lidocaine and dibucaine increased the rate of ^{86}Rb outflow though higher concentrations were needed (Fig 32) After a few minutes the outflow reached a new constant rate the rate constants were then 1.5 hr^{-1} and 4.1 hr^{-1} with 4 mM and 20 mM lidocaine, and 3 8 hr^{-1} with 1 mM dibucaine.

DISCUSSION

Accumulation and exchange of propranolol

When ^{14}C-propranolol was added to the medium the radioactivity in the cells after 5 min was 7—10 times higher than that in the medium. When the total propranolol concentration was so low that no shifts of bulk alkali ions were produced, the final stationary distribution of propranolol between the cells and the medium was reached at 5 min. With high concentrations of propranolol and in the presence of calcium ions propranolol continued to accumulate in the cells. Approximate stationary distribution was reached after 30 min, the cell/medium concentration ratios of propranolol being 20—30. Potter (1967) previously showed that cells accumulate propranolol. He found 30 times higher propranolol concentrations in the cells of isolated rabbit atria than in the medium.

The great accumulation of propranolol was accompanied by outflow of bulk potassium ions, and increased exchange as judged by experiments with radioactive tracer ions. Experiments in which the inflow and outflow of ^{14}C propranolol was studied with total concentrations of propranolol that brought the system into a non-stationary state showed that propranolol itself, as well as alkali ions, was exchanging at bi-directionally accelerated rates across the membrane. During the non-stationary state the inflow of propranolol, suprisingly increased more than in linear proportion to the increase in the propranolol concentration.

Addition of protamine or lowering of the pH decreased both the uptake of propranolol and the accelerated cation exchange. The free base form of local anaesthetics can diffuse freely across lipid barriers normally impermeable to charged molecules (Ritchie and Greengard 1966). Lowering the pH decreases the amount of the uncharged form of propranolol, which could be one reason for the lowered uptake of propranolol at low pH. However reduction in the amount of uncharged propranolol due to a pH drop from 7.4 to 7.0 can hardly be the sole explanation since even at pH 7.4 only a small fraction of propranolol, having pKa 9.45 is in the uncharged form. Changes in charged groups of the membrane seem to be important factors in these events.

Binding of propranolol by membrane stroma was less than the uptake into whole cells, the stroma/medium concentration ratios were about 2. In contrast to the results with whole cells, increasing the propranolol concentration lowered the stroma/medium concentration ratio, indicating an ordinary saturable process. Binding to the membrane was not influenced by ATP or calcium ions.

A simple possibility for the high uptake of propranolol by whole cells is that propranolol might be bound to haemoglobin. The lowered uptake of propranolol at pH 7.0 in whole cells could be due to the fact that the negative charge of haemoglobin is near zero at pH 7.0 (Harris 1960). Uptake of lidocaine and procaine in frog nerves is also lower at pH 7.2 than at pH 8.2 (Strobel and Bianchi 1970). The phenomenon is, however further complicated by the finding that calcium ions did not increase propranolol uptake by isolated membranes while they did increase uptake by whole cells.

Effect of calcium, magnesium potassium, and sodium bulk ions on propranolol induced cation shifts

In the absence of calcium ions the propranolol induced outflow of potassium ions was low and was accompanied by a similar inflow of sodium ions. The rate of exchange of potassium ions, determined with tracers, was not greatly increased without calcium ions. Magnesium ions alone had no influence, but when added with calcium they opposed the effects of calcium. In this respect propranolol differs from fluoride, which can accelerate potassium movements in the presence of either calcium or magnesium ions (Gardos 1959, Lepke and Passow 1960).

The role of calcium and magnesium ions in propranolol induced accelerated exchange of cations is difficult to elucidate. Without calcium ions in the incubation medium the epithelial cells of toad bladder became separated and wide aqueous channels are opened. The bladder becomes permeable to inulin (Hays, Singer and Malamed 1965). It has been shown that calcium ions decrease the movements of water and sodium in epithelial cells (Curran, Herrera and Flanigan 1963), and also decrease the permeability of the red cell membrane to cations (Maizels 1959, Bolingbroke and Maizels 1959, Solomon 1960). If red cells were rendered very permeable to alkali ions by treatment with lactose, calcium ions could restore the low permeability. Extracellular calcium ions could thus bind cells to one another and bind the membrane components of individual cells together more tightly in other words narrow the membrane pores, leading to decreased membrane permeability.

On the other hand Hoffman (1962) found that calcium ions produce a considerable increase in the permeability of red blood cell ghosts to potassium ions, while magnesium ions stabilized the membrane and were needed for

the retention of potassium in the ghosts. Similarly in the present work, cells treated with calcium and propranolol released haemoglobin as well as increased amounts of potassium ions. Magnesium ions decreased lysis of cells. The increased cellular fragility in the presence of calcium ions might have some relevance to the finding of Ponder (1953) that cells that have gained calcium ions in exchange for potassium ions are easily broken by mechanical disturbance. This suggests that intracellular calcium ions favour cellular breakdown.

Various cations may compete for the same sites in the membranes. The amount of each cation retained should then depend on the relative affinity of the membrane sites for the particular cation. Thus the access of a given cation to the membrane could be restricted by other cations (Mazia 1940 Gent, Trounce and Walser 1964, Sanui and Pace 1963 and 1965 Carvalho 1968 Magnuson, Shelton and Magnuson 1970). This is probably the reason for the lowered exchange of potassium ions in the high sodium medium Direct competition between sodium and calcium ions has also been suggested (Lüttgau and Niedergerke 1958, Gent et al. 1964, Whittam 1964) Similarly magnesium ions, when added in large amounts, are known to occupy most of the membrane binding sites for cations (Ginzburg, Friedlander and Pouchovsky 1967), which could explain inhibition in the propranolol induced accelerated uptake of potassium tracer ions in the high magnesium medium. Interestingly increasing the magnesium concentration did not alter the exchange of sodium ions.

In a medium of low ionic strength, in which sodium is replaced by the non-penetrating non-electrolyte sucrose, human red cells lose potassium (Parsow 1964, Donlon 1968) In the present experiments, without propranolol but with 115 mM sodium chloride and 0.35 M sucrose, there was a marked outflow of cellular potassium matched by an equimolar entry of sodium. Thus sucrose treatment renders the cell membrane permeable to both potassium and sodium ions. This probably contributes to the decrease in the selective acceleration of potassium exchange by propranolol, the high potassium — potassium exchange being partly changed to potassium — sodium exchange.

Different optical isomers of propranolol

Dextro (+)-propranolol induced a greater outflow and exchange of potassium ions than the laevo (—)-form. The inward rate constant for potassium tracer 2.5 min after addition of propranolol was increased 50-fold by (+)-propranolol and 10-fold by (—)-propranolol. The corresponding outward rate constants were increased 200 and 40-fold. At this time the inward unidirectional fluxes of potassium were 150 mmole/litre cells/hr with (+)-propranolol

and 25 mmole/litre cells/hr with (—)-propranolol. The corresponding outward unidirectional fluxes were 300 mmole/litre cells/hr and 80 mmole/litre cells/hr.

The potassium tracer rate constants were not increased by (—)-propranolol to the same extent as by (+)-propranolol, even when the (—)-propranolol concentration was increased to give a similar outflow of bulk potassium to that with (+)-propranolol.

The inflow of sodium ions was almost equal with (+)- and with (—)-propranolol. Together with the above results this shows that the selectivity between sodium and potassium ions was lower in cells treated with (—)-propranolol than with (+)-propranolol.

The various optical forms of propranolol differ in many other properties. As an adrenergic beta-blocking agent (+)-propranolol is 100 times weaker than (—)-propranolol (Vaughan Williams 1970). Dextro-propranolol, however possesses the non-specific actions of propranolol, for instance local anaesthetic activity, quinidine-like actions on cardiac muscle action potentials, and has the anti-digitalis properties (Howe and Shanks 1966; Dohadwalla et al. 1969; Vaughan Williams 1970). In these cases the doses of (+)- and (—)-propranolol are near one another but the doses are 100 times higher than the doses of (—)-propranolol needed to induce adrenergic beta-blockade. One distinct difference between the optical isomers of propranolol is that in skeletal muscle sarcoplasmic reticulum the total ATPase activity is increased by (+)-propranolol and decreased by (—)-propranolol. In cardiac muscle sarcoplasmic reticulum both isomers of propranolol decrease ATPase activity (Scales and McIntosh 1968).

Propranolol and ouabain

Both cardiac glycosides and propranolol decreased the non-equilibrium distribution of sodium and potassium ions between the cell and the medium. The mechanism of this decrement seems to be different in the two cases. Thurber and Thompson (1967) showed that logarithm of $[Na]_o/[Na] \times [K]_i/[K]_o$, which shows the deviation of the distribution of sodium and potassium ions from the equilibrium is directly related to the flow of lactic acid produced by metabolic reactions. The rate of lactic acid flow per unit of effective membrane area may considered to be the decisive factor in this non-equilibrium. However only the rate of lactic acid flow per volume of cells is known. Decrement of the non-equilibrium may be due to either decreased production of lactic acid or increased effective membrane area. Propranolol did not decrease the rate of lactic acid production when expressed per unit volume of cells (Ekman et al. 1969). The greatly accelerated rate constants of cationic tracers suggest that propranolol would have increased the effective area of the membrane.

In contrast, cardiac glycosides decrease the rate of cation exchange (Glynn 1957). The area accessible for cardiac glycosides in red cell membranes is extremely low about 100—200 molecules are bound per cell (Hoffman and Ingram 1968, Baker and Willis 1969 Ellory and Keynes 1969) Thus it is tempting to suggest that the decreased exchange and non-equilibrium distribution of sodium and potassium ions in red cells treated by cardiac glycosides are related to decreased flow of lactic acid and not to decreased effective area of the membrane. The rate of lactic acid production, as expressed per unit volume of cells, is indeed found to be decreased by 15—50 /s by ouabain (Murphy 1963 Minakami et al. 1964, Whittam and Ager 1965)

The mechanism by which propranolol suppresses cardiac arrhythmias induced by cardiac glycosides is not wholy elucidated. Since depressed sympathetic drive after surgical intervention or after catecholamine depletion by reserpine pretreatment (Méndez, Aceves and Méndez 1961 a and b, Roberts et al. 1963) was found to reduce cardiac glycoside-induced ventricular tachycardias, the protection against these arrhythmias offered by beta-adrenergic blocking drugs was first ascribed to the decreased sympethetic drive on the heart (Stock and Dale 1963 Erlij and Méndez 1964) It was, however found that also (+)-propranolol, a weak adrenergic beta-blocking drug, readily antagonized cardiac arrhythmias caused by toxic doses of ouabain (Howe and Shanks 1966) On the other hand, INPEA (N isopropyl p-nitrophenyl-ethanolamine) and MJ 1999 (isopropylamino-hydroxyethyl-methanesulphonanilide) did not provide protection against cardiac glycoside-induced arrhythmias, even though both were effective against adrenaline-induced arrhythmias (Somani and Lum 1965 1966, Somani and Watson 1968) It was concluded that beta receptor inhibition by propranolol, or other beta-adrenergic blocking drugs, was not the mechanism through which they prevented cardiac arrhythmias induced by cardiac glycosides.

Addition of ouabain together with propranolol did not prevent the propranolol-induced accelerated cation exchange. This, combined with the opposite effects of propranol and ouabain on the rates of cation exchanges, favours an idea that the propranolol reduction of the digitalis-induced cardiac arrhythmias might somehow be coupled to the different movements of cations induced by these agents. It is known that decreased potassium permeability in cardiac muscle contributes to the changes in electrical behaviour and thus also to the arrhythmias, caused by cardiac glycosides (Lyon and DeGraff 1966 Weatherall 1966). There is a close relationship between the decreased potassium permeability of red cells and the lethal doses of various cardiac glycosides (Solomon et al. 1956, Machová 1960) In addition to propranolol, pronethalol (Ekman et al. 1969), butydrine and alprenolol (Manninen 1969) all of which are adrenergic beta receptor-blocking drugs possessing anti-digitalis properties

(Botti, Visioli and Ambanelli 1966 Turner 1966 Duce, Garberg and Johansson 1967), could increase the rate of cation exchange in red cells. However INPEA and MJ 1999 which do not posses the anti-digitalis properties (Somani and Lum 1965 1966 Somani and Watson 1968) did not accelerate the rate of cation exchange in red cells (Ekman *et al.* 1969 Manninen 1969)

ATP and ATPase activity

Since many theories concerning ion transport in red cells involve splitting ATP to ADP and inorganic phosphate, ATP content and ATPase activities seemed worth studying

In whole red cells the ATP concentration was almost immediately doubled by propranolol. In isolated rat liver mitochondria the ATP content is also increased by propranolol (Wickström 1970) ATP turnover and probably also net synthesis of ATP are increased in red cells in which alkali ions are flowing down their concentration gradients (Garrahan and Glynn 1967 Glynn 1968, Lant and Whittam 1968 Glynn and Lew 1970). Thus is is tempting to associate the observed increase in ATP concentration by propranolol with the outflow of bulk potassium salts along their concentration gradient. Chlorpromazine, which also leads to a leak of cations, increases the ATP concentration of rabbit red cells (Ahtee 1966) However lead salts, which have similar effect upon the outflow and exchange of potassium in red cells to propranolol, decrease the ATP content of red cells due to ATP outflow (Lindemann and Passow 1960).

Simultaneously with the ATP increase, propranolol increased the ATPase activity of whole red cells by a factor of 1 6 ATPase activity can also be increased by freezing the cells (Scharff and Vestergaard Bogind 1966) which is also supposed to lead to an altered state of the red cell membrane. Propranolol could not inhibit the ouabain induced diminution in the rate of the ATP breakdown, which suggests that propranolol and ouabain affect red cell ATPase activity independently

The opposite results, that is, propranolol decreased ATPase activity were obtained with isolated red cell membrane stroma, through which no net salt flow occurred. This decrease was similar to that caused by ouabain. The experimental conditions were arranged so as to measure $(Na^+ + K^+)$-activated, Mg^{++}-dependent, ATPase activity which is inhibited by ouabain, and is commonly ascribed to the cation pump ATPase (Post *et al.* 1960 Dunham and Glynn 1961 Jarnefelt 1962, Post 1968). Similar inhibition by propranolol and ouabain, regardless of their opposite effects on the cation exchange rates in whole cells, deserves consideration in regard to suggestions that this ATPase is related to the cation pump.

In isolated red cell membrane stroma there were no gradients of potassium and sodium ions across the membrane, and then increased cation shifts down

ther gradients would not stimulate the adenosine nucleotide metabolism. This might be one reason for the different behaviour of whole cells and the membrane stroma.

Usually higher concentrations of ouabain are needed to decrease ATPase activity than to decrease the uphill fluxes of sodium and potassium ions. In experiments with isolated red cell membrane stroma the doses of ouabain used to suppress ATPase activity are usually 0.1 mM. Similar concentrations were used, for instance, by Whittam (1958, 1964) with whole red cells. In the present experiments this concentration of ouabain induced a considerable outflow of haemoglobin, showing that cell constituents other than the cation pump were affected. The packed red cell volumes, however remained unchanged after ouabain treatment. The lysis was of the non-colloidosmotic type, which may be accompanied by the appearance of rather large holes or pores in the membrane (Jandl 1965).

Low concentrations of ouabain, that are still enough to decrease the rate of cation exchange, have sometimes been found to increase the ATPase activity (Repke 1963, Repke 1965, Palmer Lasseter and Melvin 1966).

ATPase activity is decreased by N-ethylmaleimide (Skou 1965 b, lead salts (Hasan, Vihko and Hernberg 1967 Hernberg 1967), and oxidized glutathione (Dick, Dick and Tosteson 1969) All these agents are known to increase the rate of cation movements in red cells (Passow 1964).

The present results are somehow confusing since propranolol and ouabain both decreased similarly the cation pump ($Na^+ + K^+$)-ATPase activity in isolated red cell membrane stroma, but had opposite effects on cation exchange rate in whole red cells. It is tempting to conclude, at least, that the effect of propranolol on this ATPase activity cannot explain the accelerated exchange of cations in whole red cells after exposure to propranolol.

Isolated rat diaphragm

The present results with isolated rat diaphragms show that propranolol can cause increased cation leakage in cells other than red cells. In the diaphragms the propranolol selectivity for potassium ions as against sodium ions was not so great as in red cells. This may be because, even in control muscles without propranolol, the potassium and sodium ions did not deviate from the non-equilibrium state as much as in the red cells.

Recently van Zwieten (1969) has observed that propranolol may decrease the rate of efflux of ^{86}Rb ions from electrically driven guinea-pig atrial muscle slices. This is quite opposite to the present findings with diaphragm muscle slices. In rabbit atrial muscle fibres the only effect of propranolol in electrical potential measurements is to decrease the rate of the rise of the action potential (Vaughan Williams 1966) According to the customary

principles of electrical potential analysis (Hodgkin 1958, Noble 1966) this means that the sodium conductivity is decreased, and suggests that the potassium permeability is not altered. In the present work with diaphragm muscle propranolol did not change the rate of ^{22}Na tracer outflow but the rate of ^{22}Na tracer uptake and hence the stationary distribution ratio of sodium between the cells and the medium was increased.

Two local anaesthetics, lidocaine and dibucaine, increased the outflow rate of ^{86}Rb tracer ions from the diaphragms as did propranolol. It is tempting to believe that the local anaesthetic property of propranolol is based on the same mechanism as the increased leakage of cations.

Possible effect of propranolol on the membrane structure

The dried red cell membrane is composed of 55 / protein, 35 /o lipids, and 10 % carbohydrate. Various models for the organisation of the membrane components have been put forward (Gorter and Grendel 19..5 Danielli and Davson 1935 Lenard and Singer 1966, Robertson 1967 Zahler 1969) Knowledge of the intimate membrane architecture, especially with respect to the interrelations between various chemical components and their functions, still remains vague. Therefore attempts to explain alterations in cell function in terms of changes in membrane conformation should be regarded as over simplifications.

Since the time-honoured work of Overton and Collander and their co-workers (reviewed by Wartiovaara and Collander 1960) there is reason to believe that membrane lipids participate in transport across cell membranes. The total lipid content of human red cells is about 5 mg/ml cells, made up of cholesterol, phospholipids, and neutral lipids in molar ratios of 1 0.8 0 1 (for review see e.g van Deenen and De Gier 1964, Panow 1969).

Some results suggest that membrane lipids could participate in propranolol induced accelerated exchange of cations. Propranolol has a high chloroform/ water partition ratio (Almirante *et al.* 1966) It also has a high affinity for cell constituents, as revealed by the high uptake of propranolol, not only by whole red cells, but also by isolated red cell membrane stroma. Propranolol inhibits the swelling of mitochondria (i.e. lysis) induced by phospholipase A (Saris and Seppälä 1970) Propranolol also inhibits the lipid facilitated transport of calcium ions from the aqueous phase to chloroform (Nayler 1966)

Recently artificial bimolecular lipid leaflets have proved to be useful models to study the membrane transport phenomena, although their properties differ in some respect from the cell membranes from which the lipids used in their formation were extracted. For example the electrical resistance and the cation and anion selectivities are altered from the original cell membranes

(Passow 1969). In natural membranes interactions between lipids and proteins also contribute to the permeability properties (Wallach and Gordon 1968)

Valinomycin and certain other natural and synthetic polypeptides and polyethers, that increase the potassium permeability of red cells, also selectively decrease the resistance of artificial bimolecular lipid leaflets to potassium and rubidium ions more than to sodium ions (Andreoli *et al.* 1967 Lev and Buzhinsky 1967 Mueller and Rudin 1967 Lardy 1968 Tosteson 1968 Henderson *et al.* 1969) In bimolecular leaflets made of calf brain lipids propranolol does not decrease the membrane resistance for cations, but the valinomycin induced potassium over sodium selectivity is decreased by propranolol (Lev and Grinfeldt, unpublished results). In the case of erythrocyte lipid leaflets they found that concentration asymmetry of propranolol leads to a potential difference positive potential arising on the side of higher concentration of propranolol.

The effect of valinomycin on red cells and thin lipid membranes is explained by the formation of pores of low resistance (Chappell and Crofts 1965), or the formation of selective ring channels in which the valinomycin molecule is the main part of the ring through which the cations would pass selectively (Tosteson *et al.* 1967) Valinomycin might also act as a mobile carrier (Eisenman 1968, Haynes, Kowalsky and Pressman 1969) The first suggestion is general enough to include many kinds of mechanisms. It does not seem likely that such small and structurally simple chemicals as propranolol, fluoride, or lead ion alone could produce increased selective cation leakage by the two other suggested means.

Some detergents dissolve the membrane lipids making the red cell membrane leaky to one or several species of ions (Ponder 1948, Passow 1964, Jacob 1967 1968) In hereditary spherocytosis cellular cholesterol is more loosely bound than in normal cells. This may be related to the increased permeability of spherocytes to sodium ions (Jacob 1967 1968 Cooper and Jandl 1968). Propranolol does not, however elute cholesterol or phospholipids from isolated red cell membrane stroma (Manninen, unpublished results) Further if propranolol eluted some essential membrane component, the damage would be irreversible. However normal behaviour towards potassium bulk ions and rubidium tracer ions could be restored to red cells that were previously treated with propranolol. Readdition of propranolol again initiated accelerated cation exchange. These results show that the presence of propranolol in the membrane is needed to lower the resistance of the red cell membrane to cation passage.

Decreasing the negative charge of the cell by adding protamine, a strong polycation, or lowering the pH from 7.5 to 7.0 reduced the propranolol-induced uptake of ^{14}C-propranolol and ^{42}K tracer ions. The effects differed in that reducing pH also decreased the inflow of sodium ions. The out

SUMMARY

Propranolol was found to induce a massive outflow of bulk potassium ions from human red cells. Tracer potassium was rapidly taken up into the cells against this flow The potassium inward and outward rate constants just after addition of dextro (+)-propranolol were as high as 20 hr^{-1} and 3.2 hr^{-1} The corresponding rate constants for intact control cells were 0.37 hr^{-1} and 0 019 hr^{-1} The potassium shift produced by laevo (—)-propranolol was far less than that with the (+)-isomer

The concomitant net uptake of bulk sodium ions was low The red cell volumes were decreased.

Propranolol in all instances was readily taken up into the red cells. Exposing cells to concentrations of propranolol that induced an outflow of potassium, still increased the uptake of propranolol more than in a linear proportion to the increase in propranolol concentration. Uptake of propranolol by isolated red cell membrane stroma was less than that by the whole red cells.

Calcium ions were needed for the accelerated potassium potassium exchange and for the increased uptake of propranolol. Magnesium ions alone had no influence, but opposed the effect of calcium. In a high sodium medium potassium exchange was reduced.

Cation shifts and the uptake of propranolol were reduced by addition of protamine or lowering the pH from 7.5 to 7.0

Ouabain did not abolish propranolol induced accelerated exchange of potassium ions.

Normal cation permeability could be restored after propranolol treatment by washing out propranolol. Readdition of propranolol again induced accel erated exchange of cations.

Sucrose permeability was not increased by propranolol.

ATP concentration and ATPase activity in whole red cells were increased by propranolol, while in isolated red cell membrane stroma ($Na^+ + K^+$)-ATPase activity was decreased. Ouabain decreased ($Na^+ + K^+$)-ATPase activity in red cell membrane stroma as did propranolol.

Propranolol induced cation shifts, similar to those in red cells, also occurred in isolated rat diaphragm muscle.

It is suggested that an accelerated carrier-mediated exchange of cations across the membrane, driven by the flow of bulk ions down their gradients, would explain the observed bi-directionally accelerated movements of tracer ions. Based on models systems, described in the literature, it is supposed that circulation of water across the membrane would act as the carrier A non-homogeneous membrane is a prerequisite for such a theory

Introduction

Vitamin C was apparently the first individual nutrient to be widely associated with disease. Primitive people in many parts of the world knew of the necessity for fresh food, particularly from plant sources to prevent and cure the disease now recognized as scurvy Among all the animals studied so far only man and other primates, guinea-pigs and a few other species are dependent on food sources for the vitamin (Roy and Guha 1958 a, b)

In 1928 Szent-Györgyi isolated a substance with the chemical formula $C_6H_8O_6$ from the adrenal cortex of the guinea-pig. This substance was called hexuronic acid and was found to cure scurvy Later it was given the name of ascorbic acid[1] (Szent-Gyorgyi and Haworth 1933) Since its identification

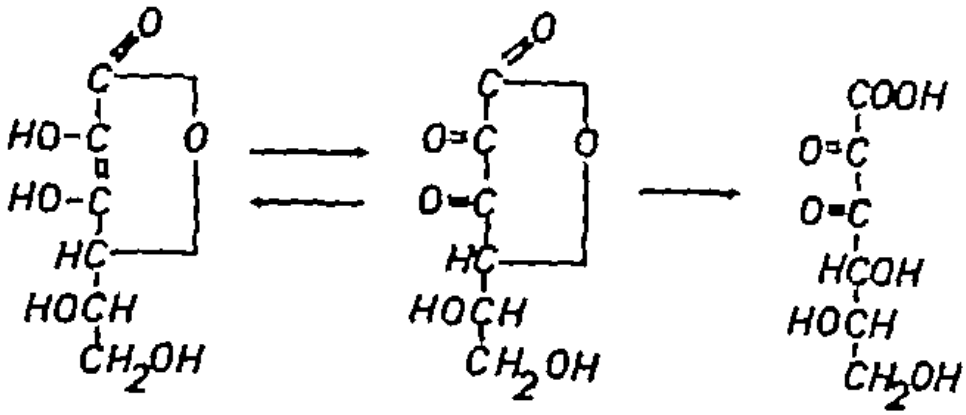

Fig. 1 Structural formulae of ascorbic acid, dehydroascorbic acid and 2,3-diketogulonic acid.

numerous, mainly chemical, investigations have been performed on ascorbic acid. However the biochemical role of this substance in the organism is not yet clear and a variety of functions have been suggested (see Baker 1967) During the biochemical reactions ascorbic acid is oxidized to dehydroascorbic acid which easily reduces back to ascorbic acid in the tissues both *in vivo* and *in vitro* (Fig. 1) (Johnson and Zilva 1934 Fox and Levy 1936,

[1] Ascorbic acid refers throughout this study to the biologically active levo-ascorbic acid.

Roe and Barnum 1936 Borsook *et al.* 1937 Schulze *et al* 1938 Penney and Zilva 1943 Todhunter *et al.* 1950, Dayton *et al.* 1959 1966 Patterson and Mastin 1951 Martin 1961 Martin and Mecka 1961)

Dehydroascorbic acid[1] is considered to be a normal constituent in the organism. It has been reported that human plasma contains dehydroascorbic acid in variable amounts comprising on average about 20 % of the ascorbic acid content (Stewart *et al.* 1952)

Little work has been done on the physiological relationship between ascorbic acid — dehydroascorbic acid and the central nervous system. Both decreased and increased concentrations of ascorbic acid appear to affect normal functions of the brain. Crandon *et al.* (1940) reported that in experimental ascorbic acid deficiency in man, extreme fatigue develops at an early stage. Mental and emotional changes have also been observed. Hodges *et al.* (1969) reported symptoms of depression in man. In scorbutic guinea pigs an impaired nervous activity has been noticed (Follis 1958) On the other hand, if large amounts of ascorbic acid are given to man, insomnia, irritability and anxiety develop (see Glatzel 1966) If the concentration of ascorbic acid in the brain of guinea pigs is increased by injection of dehydroascorbic acid, a rise in the higher nervous activity (producing general neuromotor excitement) lasting for several days has been observed (Lyhs and Tegeler 1963)

Administration of dehydroascorbic acid to rats is followed by some pronounced acute pharmacological responses, e. g. a rise in the blood pressure, increased salivation lacrimation and motor activity (Patterson and Mastin 1951) Hypertension following injection of dehydroascorbic acid has also been observed in cats and guinea pigs (Wegman 1958) Both adrenergic and cholinergic mechanisms seem to be activated by injected dehydroascorbic acid. It has been suggested that most of the pharmacological responses are evoked in the central nervous system.

As dehydroascorbic acid is rapidly reduced to ascorbic acid in the tissues, it was suggested by Patterson and Mastin (1951) that the responses recorded after injection of dehydroascorbic acid were triggered by metabolically formed ascorbic acid. However no definite conclusion can be drawn.

Defects in the circulatory system have been observed in scorbutic humans and animals Investigations have shown that ascorbic acid is probably involved in the maintenance of the tone of the blood vessels (Lee 1961) When tested on the blood pressure different responses have been noticed. Kreitmair (1934) and Wegman (1958) observed that injection of ascorbic acid into cats resulted in a transient decrease in the blood pressure due to its acidic properties (Weg

[1] Dehydroascorbic acid refers throughout this study to levo-dehydroascorbic acid.

man 1958) Reiser (1938) on the other hand noticed a slight hypertensive action of injected ascorbic acid in spinalized cats. It has also been reported that ascorbic acid induces increased pressor reflexes and decreased depressor reflexes in dogs (Ungar and Ungar 1938)

Ascorbic acid has been shown to act as a co-factor in hydroxylation reactions (see review by Schneider and Staudinger 1964) Model systems for aromatic hydroxylation where ascorbic acid functions as an electron donor have been described (Udenfriend *et al* 1954 Breslow and Lukens 1960) Ascorbic acid has also been shown to act as a co-factor in dopamine β-hydroxylation *in vitro* (see review by Kaufman and Friedman 1965) Furthermore, it has been suggested that ascorbic acid participates in dopamine β-hydroxylation *in vivo* Izquierdo *et al* (1968) reported that ascorbic acid injected intraperitoneally into rats caused an increase of the endogenous noradrenaline level and a decrease of the dopamine level in various parts of the brain. These observations were associated with an increase of the dopamine β-hydroxylase activity caused by ascorbic acid.

Autoradiographic studies have revealed that injected ascorbic acid and dehydroascorbic acid are distributed fairly equally in the body (Hammarström 1966) A specific accumulation of both substances to sites of catecholamine synthesis was noticed.

In the present study the pharmacological properties of dehydroascorbic acid and ascorbic acid on the central and peripheral nervous systems have been extensively investigated. Special attention has been drawn to the effects of injected dehydroascorbic acid.

The aim of the present study was to ascertain

1 whether injected dehydroascorbic acid and ascorbic acid cause pharmacological responses in mice, cats and rabbits (conscious and anaesthetized) as earlier observed in rats (Patterson and Mastin 1951) The following parameters were studied motor activity salivation, lacrimation tone of the nictitating membrane, sympathetic ganglionic transmission, neuromuscular transmission and blood pressure.

2 whether the pharmacological responses to injected dehydroascorbic acid were influenced by prior decerebration, spinal cord section or bilateral adrenalectomy.

3 whether the pressor response to injected dehydroascorbic acid could be affected by compounds known to interfere with adrenergic mechanisms, and if dehydroascorbic acid could interfere with the blood pressure response to acetylcholine.

4 whether the so called "membrane pump blocking agents and reserpine influenced the tissue uptake of ^{14}C-labelled dehydroascorbic acid and ascorbic

acid in brain and heart tissues *in vivo*

5 whether injected dehydroascorbic acid and/or ascorbic acid influenced the levels of some endogenous catecholamines in brain and heart tissues *in vivo*

6 whether dehydroascorbic acid and/or ascorbic acid was/were able to inhibit cholinesterases *in vitro*

CHAPTER I

Pharmacological Effects of Dehydroascorbic Acid and Ascorbic Acid in Conscious and Anaesthetized Animals

In the following experiments dehydroascorbic acid or ascorbic acid was injected into cats, rabbits and mice. Some of the previously observed effects were confirmed (Patterson and Martin 1931 Wegman 1958) Effects of the two substances on other parameters, e. g. the tone of the nictitating membrane the sympathetic ganglionic transmission and the neuromuscular transmission were also studied.

The pharmacodynamic actions of dehydroascorbic acid were studied more extensively than previously and some new pharmacological properties of this compound ha ve been observed.

Part 1 General materials and methods

Preparation of substances

Ascorbic acid obtained commercially in crystalline form (Pharmacopoea Nordica) was dissolved in redistilled water at a concentration of 50 mg/mL The pH of this solution was 2.2.

Dehydroascorbic acid was prepared in two different ways by oxidation of ascorbic acid as described by Patterson (1950) and by preparation from a dehydroascorbic acid — methanol complex.

One gram of ascorbic acid dissolved in 20 ml redistilled water was shaken with an equal volume of diethylether containing 0.61 g benzoquinone. This amount of benzoquinone is equivalent to the amount of ascorbic acid. After shaking for 15 minutes the ether phase was removed and the water solution was washed 5 times w ith an equal olume of ether The final concentration was estimated to be 50 mg dehydroascorbic acid per ml[1] Since there was some residual ether after this procedure the sample was placed under vacuum for about 30 seconds. After this a little ether still remained but gradually evaporated in the open air during the experiment. thus cooling the sample

[1] According to the hromatographic investigations (page 10) minute amounts of impurities were detected However throughout the present study the doses of dehydroascorbic acid given were alculated as if the oxidation exchange from ascorbic acid or release from the methanol complex was 100 %

Dehydroascorbic acid is very easily decomposed at high temperatures but this can be prevented by keeping the solution cool.

By adding redistilled water at +60°C to crystalline dehydroascorbic acid — methanol complex, dehydroascorbic acid was released from the complex. The complex was obtained from Mann Research Laboratories, New York, USA and its preparation and properties are described by Pecherer (1951) The dehydroascorbic acid released from the complex is reported to give all the normal chemical reactions of dehydroascorbic acid. Within two minutes the crystals had completely dissolved and the solution was immediately cooled to about +4°C. Before injection this solution was warmed to room temperature. No adverse effects have been reported from the small amount of methanol present in the solution (Clayton *et al.* 1954 see also Chapter I Part 5 Fig 10)

The solutions of dehydroascorbic acid were freshly prepared before each experiment and were used within 4 hours. The pH of freshly prepared and 4 hours old solutions of dehydroascorbic acid prepared in either way varied between 2.2 and 2.5

2,3-diketogulonic acid[1] was prepared by oxidation of dehydroascorbic acid obtained from ascorbic acid oxidation. Ascorbic acid (3.5 g) was dissolved in 35 ml redistilled water and shaken with 2.1 g benzoquinone dissolved in ether After being shaken for 15 minutes the ether phase was removed. The water phase was washed 5 times with ether After the final washing the ether was evaporated under vacuum. Ten ml 2 N NaOH was added to the water phase and shaken for 10 minutes to adjust the pH for an optimal oxidation reaction. Five ml 4 N HCl was then added and the solution was shaken again for 5 minutes. The final concentration of the 2,3-diketogulonic acid solution was estimated to be 50 mg/ml. This preparation has previously been described in detail by von Euler and Hasselquist (1952) The pH of the prepared solution was 1.1

Chromatographic investigations

Dehydroascorbic acid decomposes easily at neutral or alkaline pH. According to Prochazka (1958) and Heimann and Heimann (1965) however it is fairly stable at pH —3

Ascorbic acid is also easily decomposed, especially when heavy metal ions, i.e. copper and iron, are present.

In order to check the purity of the ascorbic acid solution and that of dehydroascorbic acid obtained by ascorbic acid oxidation and from the methanol complex, thin layer chromatography was performed (see Chapter

[1] The levo-form.

III and Hammarström 1966) The chromatograms showed that negligible amounts of impurities were present in fresh as well as 4 hours old solutions of dehydroascorbic acid. A very small spot with the same R_f value as ascorbic acid could be detected. According to Patterson (1950) ascorbic acid is oxidized to 95—98 % with benzoquinone.

Animals and diet

Cats (1.5—4.0 kg body weight) and rabbits (2.0—3.0 kg) of both sexes and female mice (NMRI strain with an average body weight of 20 g) were used in the investigations.

The cats were fed with "Mjau" (purchased from Tre Kök AB, Sweden) This is a commercial canned cat food made from fresh fish and primary products of beef and pork. Vitamins added per kilo are vitamin A 5,000 I. U., vitamin D 500 I. U vitamin E 5 mg, vitamin B_1 1 mg and vitamin B_2 1 mg The cats were also given water or milk *ad lib*

The rabbits were kept on a diet consisting of carrots, Swedish turnips and cabbage *ad lib*

The mice were fed a complete pelleted mouse diet and water *ad lib* The pellets were supplied by AB Ewos, Södertälje, Sweden and were composed of whey powder steamed cereals, soybean powder Prot Animal (defatted fish protein concentrate) dry yeast, soybean oil lime stone bentonite, vitamin concentrate, and trace elements. Average analysis of dry matter crude protein 22.5 % crude fat 5.0 % fiber 3.0 % NaCl 0.5 % Ca 0.8 % P 0.6 % water 8.0 % Vitamins added (per kilo) vitamin A 7,200 I U vitamin D_3 720 I. U vitamin E 84 mg, vitamin B 3 mg, vitamin B_2 6 mg, Ca-pantothenic acid 10 mg Trace elements added (per cent) Fe 0.0017 Cu 0.00017 Co 0.000017 I 0.00006, Mn 0.0017 Zn 0.0125

Anaesthesia

The *cats* were anaesthetized either by intraperitoneal injection of pentobarbitone, (Mebumalnatrium® ACO) (35 mg/kg) or by intramuscular injection of a solution containing chloralose and urethane. The doses were 64 mg chloralose/kg and 214 mg urethane/kg.

The *rabbits* were anaesthetized by intravenously administered 20 % urethane solution. The dose was 1.4 g urethane/kg

6 % pentobarbitone in propyleneglycol solution.

in the conscious and anaesthetized animals are probably expressions of the same mechanism(s)

Following dehydroascorbic acid injection, certain atropine-sensitive effects have been observed i.e. increased salivation and lacrimation which corresponds with observations on rats by Patterson and Mastin (1951) In the present study also ear twitching was observed and this is interpreted as the result of a central cholinergic activation (cf Armitage *et al.* 1966) by dehydroascorbic acid (see General Discussion)

Injected ascorbic acid, on the other hand, did not seem to produce any behavioural changes or to affect the salivation and lacrimation in cats and rabbits.

Part 3 Effects of dehydroascorbic acid and ascorbic acid on the nictitating membrane in cats

Materials and methods

In this investigation 8 chloralose-urethane and 14 pentobarbitone anaesthetized cats were used.

The nictitating membrane was connected by a silk thread to a force-displacement transducer (Grass FT 03) and the tension was adjusted to 2 grams.

In 4 chloralose urethane and 10 pentobarbitone anaesthetized cats the tone of the non-stimulated nictitating membrane was studied before and after injection of dehydroascorbic acid or ascorbic acid. In 4 cats (2 chloralose-urethane and 2 pentobarbitone anaesthetized) the sympathetic trunk was first severed above the cervical sympathetic ganglion and later on during the experiment the ganglion was removed.

In 4 of the pentobarbitone and 4 of the chloralose-urethane anaesthetized cats the cervical sympathetic trunk was cut and a bipolar platinum electrode was applied to the peripheral end (preganglionic) Stimulus currents were supplied by a Grass model S 4 stimulator The stimulation consisted of square wave pulses of ?0 msec duration and an intensity of 1.5 V Stimulation was given in the form of trains of such pulses. The duration of the individual trains was 5 sec and the frequency within the trains was varied between 1 and 20 imp sec The train repetition rate was 95 sec. After obtaining reproducible contractile responses the substances to be tested were injected.

Recordings were made on a Grass ink writing oscillograph model 5 (Grass Instrument Co. Quincy Mass. USA) The paper speed was 0.25 mm/sec.

A polythene tubing (Portex PP 90 Portland Plastics Ltd., Hythe, Kent England) was inserted in one of the femoral veins. The tubing was provided with a cannula. All injections were made through this.

The doses of dehydroascorbic acid (obtained by ascorbic acid oxidation) used were 5 10 25 50 100 and 150 mg/kg (8 chloralose urethane and 11 pentobarbitone anaesthetized cats)

Ascorbic acid was tested on the non-stimulated nictitating membrane in 6 of the cats (3 pentobarbitone and 3 chloralose urethane anaesthetized) and on the stimulated nictitating membrane in 3 of the cats (pentobarbitone anaesthesia) Doses of ascorbic acid tested were 25 50 100 and 200 mg/kg

Atropine (1—2 mg/kg) was given intravenously to 3 cats (non-stimulated nictitating membrane) prior to injection of dehydroascorbic acid. In 2 cats 2 mg/kg of propranolol (Inderal® ICI) and 1 mg/kg of dihydroergotamine (Orstanorm® Sandoz) were injected intravenously prior to administration of dehydroascorbic acid.

Results

Non stimulated nictitating membran

The effect of dehydroascorbic acid on the non-stimulated nictitating membrane was different in pentobarbitone and chloralose-urethane anaesthetized cats. When the former anaesthetic was used the responses were faint and not uniform. Injection of 5 mg/kg caused a small contraction whereas injection of 10 mg/kg always caused a small, fairly long lasting relaxation (Fig. 2) The relaxation increased with a higher dose (Fig 3) Preganglionic sympathectomy or removal of the cervical ganglion did not alter the response. Atropine treatment, however reversed the relaxation to a small contraction when the nerve supply was intact.

In the chloralose-urethane anaesthetized cats injection of dehydroascorbic acid caused a dose dependent contraction of the nictitating membrane (Fig.4) After premedication with propranolol and dihydroergotamine the response to injected dehydroascorbic acid was markedly reduced. After preganglionic sympathectomy no effect at all was observed (Fig. 4)

In some of the cats injection of ascorbic acid resulted in a small contraction of the nictitating membrane. In others no effect at all could be seen. The response appeared to be independent of the type of anaesthetic used.

Stimulated nictitating memb ane

Administration of dehydroascorbic acid influenced electrically stimulated contractions of the nictitating membrane. The effects were not uniform, how-

Note the increase in amplitude of the response to stimulation of the nictitating membrane immediately after the injection.

ever Injection of ascorbic acid had no effect whatever on the response to stimulation at any of the doses tested

When *low frequency stimulation* (up to 10 imp/sec) was applied, injection of 5 mg/kg dehydroascorbic acid did not change the response to stimulation. If the dose was increased to 10 and 25 mg/kg the amplitude of the response from the electrically induced contractions increased by about 50 % (Fig. 5) This augmented response was, however only observed in 3 of the tested cats (chloralose urethane anaesthesia) The other 5 animals either did not respond at all or demonstrated a small reduction in amplitude. When higher doses (50 and 100 mg/kg) of dehydroascorbic acid were given a decrease in amplitude lasting for about 5—10 minutes was always observed (Fig 6) After injection of 100 mg/kg the response to stimulation immediately after injection was reduced to about 75 % of the normal response.

When *high frequency stimulation* (10—50 imp/sec) was applied any of the doses of dehydroascorbic acid tested caused an inhibition of the response to stimulation.

Discussion

Since dehydroascorbic acid activates central sympathetic centres causing blood pressure rise (Part 6 Chapter II) it was thought that, analogous to sympathomimetic agents with direct or indirect adrenergic effects, administration of dehydroascorbic acid would result in a constriction of the smooth muscle

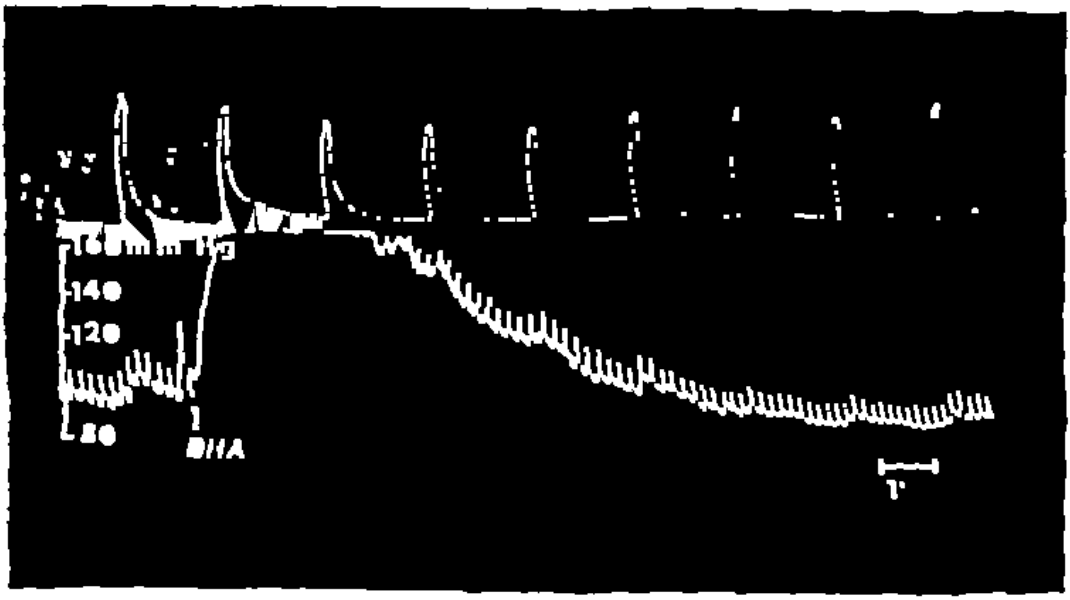

Fig. 6. Cat, chloralose-urethane anaesthesia. The effect of intravenous injection of 100 mg/kg dehydroascorbic acid (DHA) on the stimulated nictitating membrane (see text)

of the non-stimulated nictitating membrane. However two different types of response were observed. In the pentobarbitone anaesthetized cats injection of dehydroascorbic acid was followed by relaxation of the nictitating membrane. This effect still remained after cutting the sympathetic nervous supply above or below the superior cervical ganglion. Furthermore it was shown that the relaxation was inhibited by premedication with atropine. This suggests that the relaxation was due to activation of cholinergic mechanisms.

In the chloralose urethane anaesthetized cats the nictitating membrane constricted after administration of dehydroascorbic acid, demonstrating a sympathomimetic effect. It was observed that the constrictor response was reduced by premedication with propranolol and dihydroergotamine, indicating an effect via adrenergic receptors. Following sympathetic denervation no constriction at all was observed after injection of dehydroascorbic acid, indicating a central site of action.

After injection of ascorbic acid a small constrictor response was occasionally observed. However further experimental work is required to clarify whether injected ascorbic acid really affects the nictitating membrane or not.

The effects of injected dehydroascorbic acid on the stimulated nictitating membrane are thought to be due to activation of adrenergic mechanisms at ganglionic level and/or at postganglionic sites (see General Discussion). The response appears to be dependent on the anaesthetic used (cf. above).

Part 4 Effects of dehydroascorbic acid and ascorbic acid on neuromuscular transmission

Materials and methods

In this investigation 10 pentobarbitone or chloralose-urethane anaesthetized cats were used.

Induced contractions of the gastrocnemius muscle were recorded. The tendon of the muscle was connected via a thread to a force-displacement transducer (Grass FT 10). The muscle was excited by stimulation of the sciatic nerve. A bipolar platinum electrode was applied to the peripheral end of the free-dissected and cut nerve. Stimulus currents were supplied by a Grass model S 4 stimulator. Single pulses were given every 5th second. The duration of each pulse was 50 msec and the intensity 1 V.

Recordings were made on a Grass ink writing oscillograph model 5. The paper speed was 0.5 mm/sec.

In one of the femoral veins a polythene tubing (Portex PP 90) was in-

troduced. The tubing was provided with a cannula. Intravenous injections were made through this catheter in 6 cats. In 4 cats injections were made through a cannula inserted in the femoral artery close to the branch supplying the gastrocnemius muscle.

The doses of dehydroascorbic acid given intravenously were 5, 10, 25, 50, 100 and 150 mg/kg (4 cats). Two doses, 10 and 25 mg/kg of dehydroascorbic acid were injected intraarterially (? cats).

Ascorbic acid (50, 100 and 150 mg/kg) was given intravenously to ? cats and intraarterially to another ? cats.

Results

Intravenous injection

Low doses (5—25 mg/kg) of intravenously injected dehydroascorbic acid did not influence the muscular response elicited by sciatic stimulation. From 50 mg/kg an enhanced excitability was observed. The amplitude of the contraction recordings increased gradually with the dose. At 100 and 150 mg/kg the response to stimulation was increased by almost 100 % and 200 % respectively (Fig. 7). The effect lasted for about 10 minutes.

Ascorbic acid given intravenously in equivalent doses to dehydroascorbic acid did not produce any changes of the electrically induced contractions (Fig. 8).

Close intraarterial injection

Intraarterial injection of 10 and 25 mg/kg of dehydroascorbic acid caused an increased amplitude of the response to stimulation (25 % and 100 % respectively). This effect lasted for 5—10 minutes.

After an intraarterial injection of ascorbic acid a slight dose-dependent inhibition of the response to stimulation was observed.

Discussion

The facilitatory effect of dehydroascorbic acid on neuromuscular transmission in the gastrocnemius muscle seems to be due to a local action in the muscle since the response was produced equally well by intravenous injection and by close intraarterial injection of low doses. This augmented response might probably be attributed to the slight cholinesterase-inhibiting action of dehydroascorbic acid (Chapter V). This is supported by the fact that injection of ascorbic acid, which seems to be devoid of cholinesterase inhibiting action

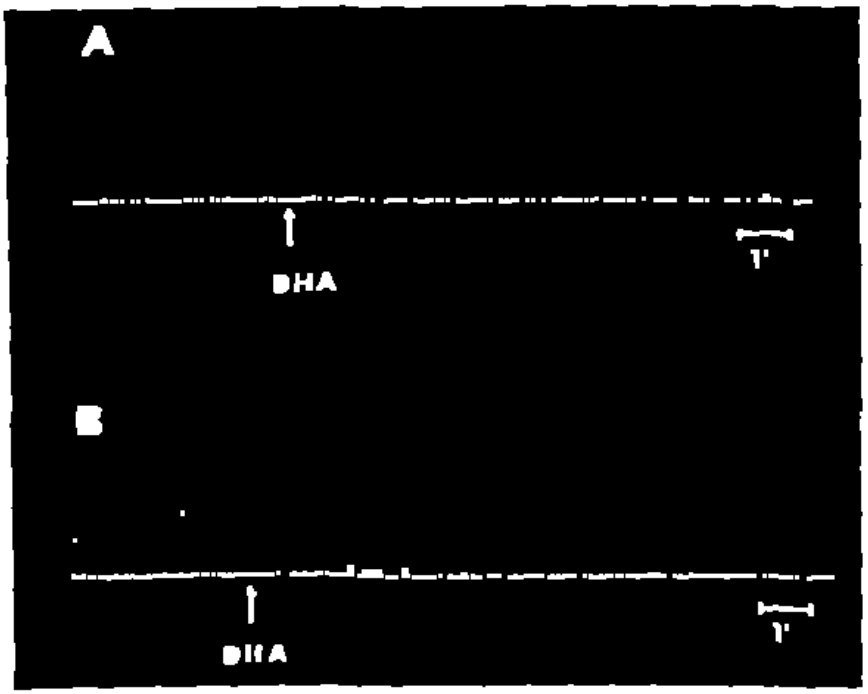

Fig. 7 Cat, pentobarbitone anaesthesia. The effect of intravenous injection of 100 mg/kg (A) and 150 mg/kg (B) dehydroascorbic acid (DHA) on the stimulated gastrocnemius muscle. Note the increase of the amplitude immediately after the injection.

(Chapter V) does not cause facilitation of the neuromuscular transmission. The cause of the slight inhibitory effect observed after intraarterial injection of ascorbic acid is not known.

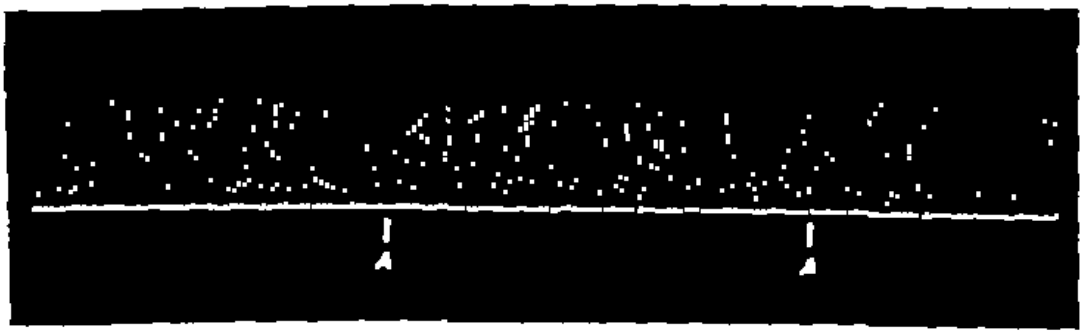

Fig. 8. Cat, pentobarbitone anaesthesia. The effect of intravenously injected ascorbic acid (↓) on the stimulated gastrocnemius muscle. The first arrow indicates injection of 100 mg/kg and the second arrow injection of 150 mg/kg ascorbic acid.

Part 5 Effects of dehydroascorbic acid and ascorbic acid on the blood pressure in cats and rabbits

Materials and methods

The experiments were carried out on 24 chloralose-urethane and 28 pentobarbitone anaesthetized cats and on 70 urethane anaesthetized rabbits.

One of the common carotid arteries was cannulated with a polythene tubing (Portex PP 90) which was connected to a Stratham P 23 Ac transducer for measuring the systemic blood pressure.

In 3 of the pentobarbitone anaesthetized cats the cervical vagi and sinus nerves were cut.

Recordings were made on a Grass ink writing oscillograph model 5. The paper speed was 0.25 mm/sec.

In one of the femoral veins a polythene tubing (Portex PP 90) was inserted. The tubing was provided with a cannula. In 2 of the rabbits one of the common carotid arteries was cannulated with a cranially orientated polythene tubing for intraarterial injections. In these animals the blood pressure recordings were registered from one of the femoral arteries.

Dehydroascorbic acid, obtained by ascorbic acid oxidation, was injected intravenously. The doses employed were 5, 10, 25, 50 and 100 mg/kg. Dehydroascorbic acid prepared from the methanol complex (10—100 mg/kg) was given to 2 cats (1 pentobarbitone and 1 chloralose-urethane anaesthetized cat) and 1 rabbit.

Ascorbic acid (5—150 mg/kg) was injected intravenously to 5 pentobarbitone and 3 chloralose-urethane anaesthetized cats and to 1 rabbit.

In one chloralose-urethane anaesthetized cat 2,3-diketogulonic acid (see Part 1) was injected intravenously (50 and 100 mg/kg).

Lactic acid (Pharmacopoea Nordica) solution was prepared by diluting the concentrated lactic acid with redistilled water to a final concentration of 3 N (*pH* 1.6). This solution was injected intravenously into 3 rabbits in volumes equivalent to those used for dehydroascorbic acid. In 2 rabbits lactic acid was also injected into the common carotid artery.

A solution was made in the same manner as that employed for preparing dehydroascorbic acid omitting the ascorbic acid. To the solution was added a small quantity of hydroquinone (approximately 30 mg) which is the product formed from benzoquinone during ascorbic acid oxidation. This solution (reagent blank) was injected intravenously into 2 pentobarbitone and 2 chloralose-urethane anaesthetized cats and into 2 rabbits. The administered volumes were equivalent to those used for dehydroascorbic acid.

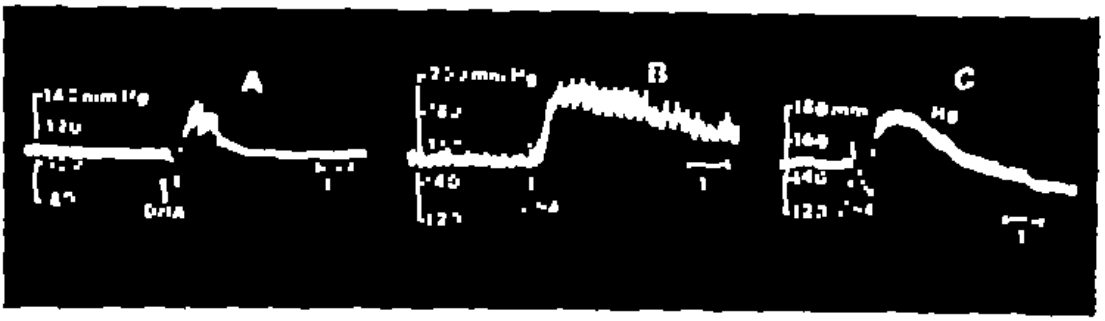

Fig. 9 The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) in a pentobarbitone anaesthetized cat (A) a chloralose-urethane anaesthetized cat (B) and a urethane anaesthetized rabbit (C)

Redistilled water was also injected intravenously in volumes up to 3 ml/kg into 2 pentobarbitone and 2 chloralose-urethane anaesthetized cats and into 2 rabbits.

Results

Injection of dehydroascorbic acid often resulted in two different effects, an initial transient depressor response immediately followed by an increase of the blood pressure. The depressor response was more pronounced in the rabbits and the pentobarbitone anaesthetized cats than in the chloralose-urethane anaesthetized cats. It was observed that this decrease in blood pressure (about 20—30 mm Hg) did not change appreciably with the amounts injected. The depressor response rapidly decreased with the number of subsequent injections. In most experiments no depression was visible at the 3rd or 4th injection.

100	51±5	4

Chloralose-urethane anaesthetized cats

Dose mg/kg	B.P increase mm Hg	No. of animals
5	13±3	4
10	20±18	3
25	27±3	4
50	60±4	5

Urethane anaesthetized rabbits

Dose mg/kg	B.P increase mm Hg	No. of animals
5	22±14	4
10	32±9	6
25	36±8	16
50	40±8	38

Pressor responses were always obtained after injection of dehydroascorbic acid into the rabbits as well as into the cats (independent of the type of anaesthetic used) (Fig. 9). This pressor effect increased with the dose. Table 2 shows the dose-dependent increase of the pressor response following a single injection of dehydroascorbic acid to anaesthetized cats and rabbits. The values refer to the first injection of dehydroascorbic acid to each animal.

After injection of dehydroascorbic acid prepared from the methanol complex no differences in blood pressure responses were seen from those obtained after injection of dehydroascorbic acid prepared by ascorbic acid oxidation (Fig. 10).

When dehydroascorbic acid was given in repetitive doses (50 mg/kg) to cats or rabbits there was a difference in response between the first and subsequent injections. If several injections with 10—15 minutes intervals were made, the pressor response gradually increased and reached a maximum after

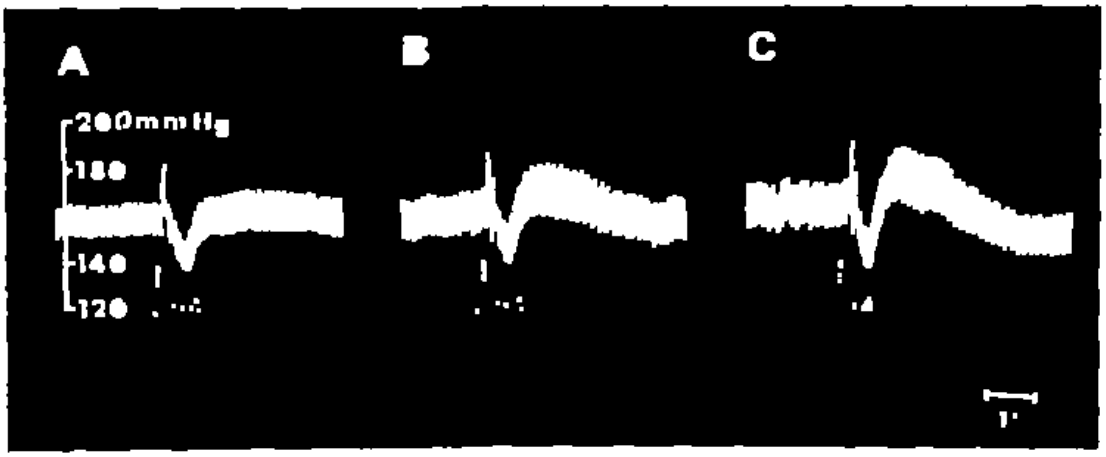

Fig. 11 Cat, chloralose-urethane anaesthesia. The blood pressure response to repeated intravenous injections of 50 mg/kg dehydroascorbic acid (DHA) with 10—15 minutes intervals. Note the successiv increase of the pressor response.

2—3 injections (Fig. 11) After 5—6 injections or more the blood pressure never completely returned to the initial level but remained slightly elevated. This level rose gradually following each subsequent injection.

When 50 mg/kg dehydroascorbic acid was given repeatedly to rabbits at 2 minute intervals the depressor and pressor effects gradually diminished, while after 3—6 injections the depressor response was abolished and after 15—20 injections no pressor response was obtained.

The dehydroascorbic acid solution obtained by ascorbic acid oxidation contains apart from oxidized ascorbic acid also redistilled water minute amounts of ether and possibly benzoquinone and hydroquinone. In order to check if the vehicle contributed to the observed effects a reagent blank was prepared. When injected intravenously in volumes equivalent to those used for dehydroascorbic acid only transient depressor responses were obtained (Fig. 12)

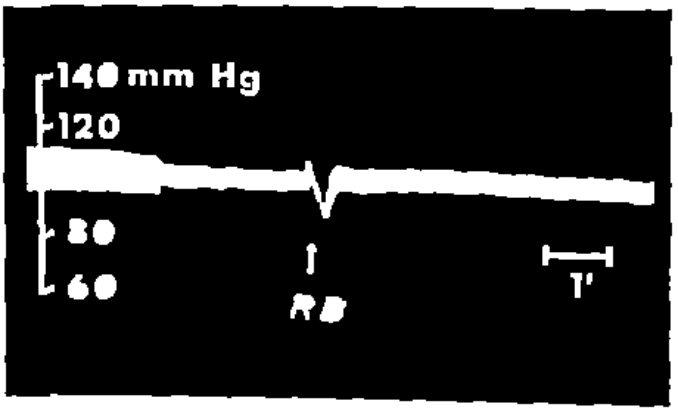

Fig. 12 Cat, pentobarbitone anaesthesia. The blood pressure response to intravenous injection of a reagent blank (RB ml/kg) For details see text.

Fig. 13. Cat, pentobarbitone anaesthesia. The blood pressure response to intravenous injection of 1.0 ml/kg redistilled water.

As the injected volumes were rather large (up to 3 ml/kg) the influence of corresponding volumes of redistilled water on the blood pressure was tested. When the redistilled water was injected at the same speed as the dehydroascorbic acid solution a transient fall in blood pressure was observed (Fig. 13) which was very similar to the initial depressor response observed after dehydroascorbic acid administration.

Dehydroascorbic acid is easily oxidized at neutral pH and it was thought that oxidative products might be formed in the blood. The first oxidative step from dehydroascorbic acid, 2,3-diketogulonic acid, could perhaps be responsible for or contribute to the observed pressor effects. This oxidation product

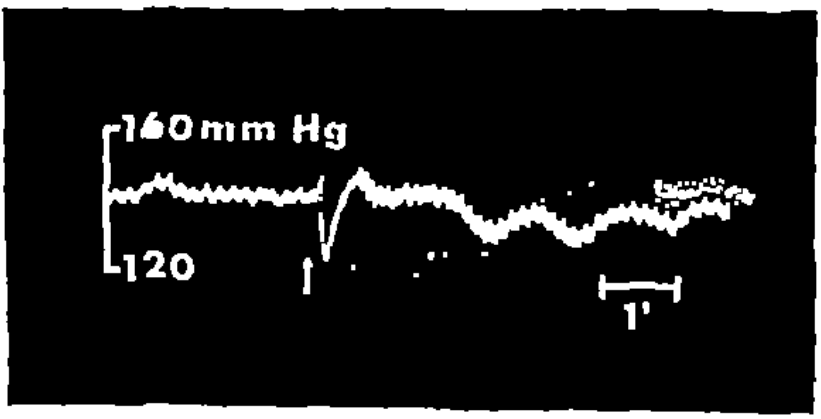

Fig. 14. Cat, chloralose-urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg 2,3-diketogulonic acid.

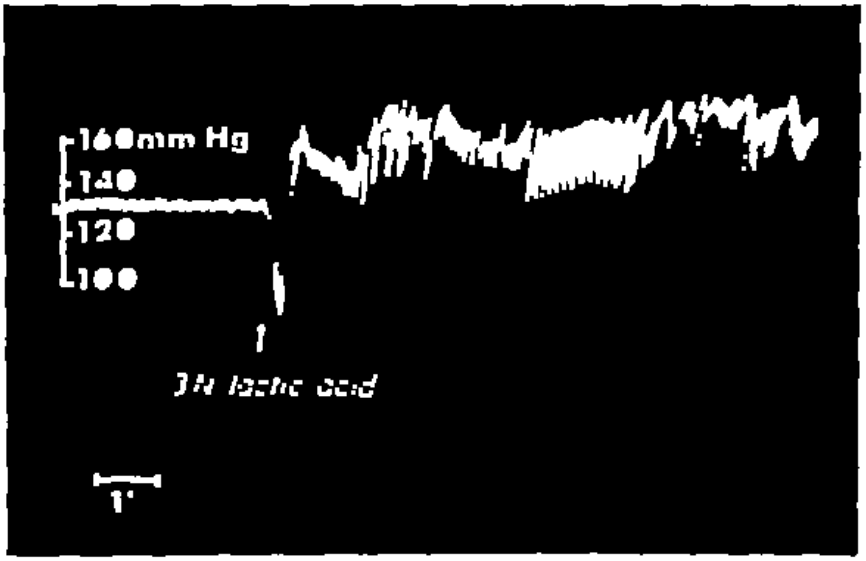

Fig. 15. Rabbit, urethane anaesthesia. The blood pressure response to intraarterial injection (carotid artery) of 3 N lactic acid (2 ml)

was synthetized (Part 1) and when injected intravenously into a chloralose-urethane anaesthetized cat only a transient depressor response was observed (Fig. 14)

Although the blood is known to possess a strong buffer capacity it was believed that when large amounts of the acidic dehydroascorbic acid solution (Part 1) were injected intravenously this buffer effect might be exceeded. To compare the effects of an acidic compound and those of dehydroascorbic acid on the blood pressure, lactic acid was chosen to induce acidosis. The strongest concentration it was possible to inject intraarterially into the carotid of the rabbit without immediately killing the animal was found to be 3 N (2 ml). The blood pressure response then recorded was a transient, fairly marked depressor effect followed by a long lasting increase in the blood pressure to a level slightly above normal (Fig. 15). When given intravenously the same concentration of lactic acid caused a fall in the blood pressure.

Following injections of different doses of ascorbic acid, only transient depressor responses were observed (Fig. 16). In 3 cats the cervical vagi and the sinus nerves were cut. When dehydroascorbic acid was injected into these cats (5 and 10 mg/kg) a pronounced hypertensive response was recorded in contrast to the small rise in the blood pressure often preceded by a transient depressor response obtained with the same doses prior to the nerve section. Fig. 17 illustrates the blood pressure response to 10 mg/kg dehydroascorbic acid before and after nerve section in one of the experiments.

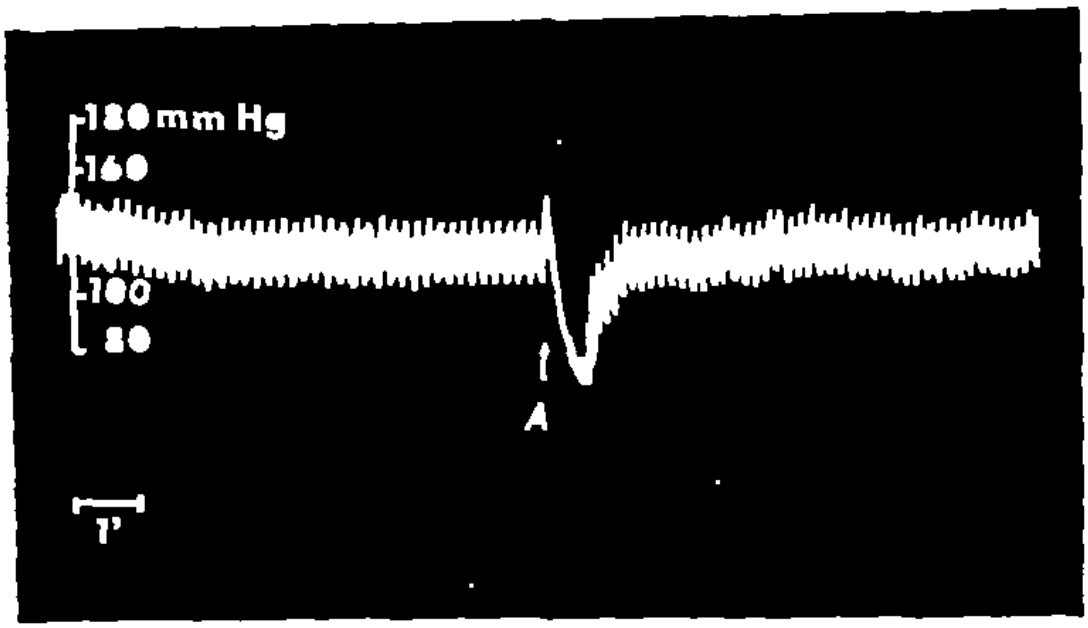

Fig. 16. Cat, chloralose-urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg of ascorbic acid (A)

Discussion

In the present investigation it was shown that intravenous injection of dehydroascorbic acid, prepared by ascorbic acid oxidation or from a dehydroascorbic acid—methanol complex, into anaesthetized cats and rabbits caused changes in the blood pressure. Very often this response presented a biphasic character depressor response followed by pressor response. These results are in agreement with observations by Wegman (1958) who found that injection

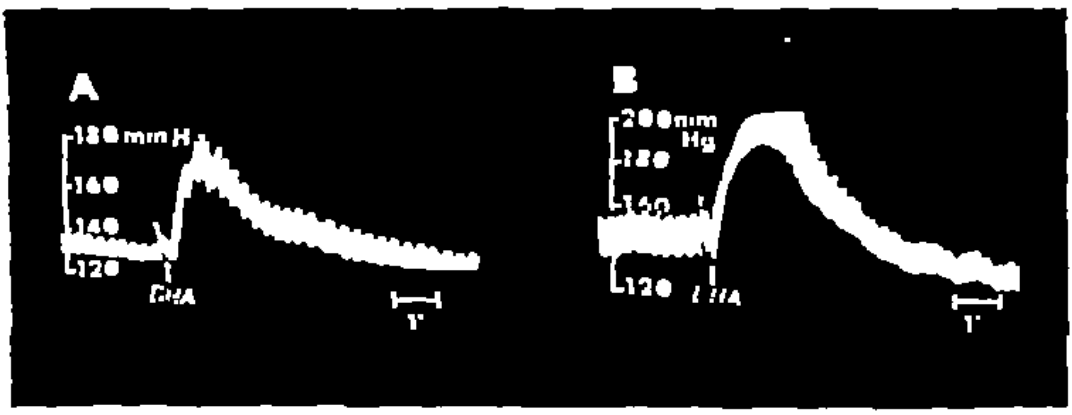

Fig. 17 Cat, pentobarbitone anaesthesia. The blood pressure response to intravenous injection of 10 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) the cervical *ag* and *sinus nerves were cut*. Note the pronounced increase of the pressor response after the nerve section.

of dehydroascorbic acid into nembutal anaesthetized cats resulted in a similar biphasic response. It has previously also been shown that injection of dehydroascorbic acid causes pressor response in the rat (Patterson and Martin 1951) and the guinea pig (Wegman 1958)

The hypotensive response observed after dehydroascorbic acid administration in the present study is interpreted as mainly being due to an activation of baroreceptors caused by the large amount of liquid injected. Similar depressor responses were observed after injection of equivalent volumes of either redistilled water or reagent blank. The acidity of the injection solution (pH 2.2—2.5) may be a contributory factor

Section of the vagi and the sinus nerves altered the blood pressure response to injected dehydroascorbic acid. In normal cats a low dose caused an initial depressor response followed by a small rise in blood pressure. In animals where the nerves were sectioned the same dose of dehydroascorbic acid caused pronounced pressor responses. No hypotensive response was observed. This shows that when the baroreceptor mechanism is inactivated by nerve sectioning the depressor response disappears.

Injection of ascorbic acid always caused depressor responses, which is in agreement with observations by Kreitmair (1934) and Wegman (1958). Reiser (1958) however observed that injection of ascorbic acid into spinalized cats resulted in a small increase of the blood pressure. In anaesthetized dogs injection of ascorbic acid enhances the baroreceptor reflex causing an increase of the pressor reflex (Ungar and Ungar 1938) In the same investigation it was observed that the blood pressure response to electrical stimulation of the sinus nerve was depressed following injection of ascorbic acid.

The depressor effect of ascorbic acid in the present investigation is probably the result of an activation of baroreceptors and/or the acidic properties of ascorbic acid as shown by Wegman (1958)

The pressor effect of dehydroascorbic acid in cats and rabbits was shown to be increased with the dose. This pressor action is reported to be independent of the pH of the injected solution (Wegman 1958)

After repeated injections of the acidic dehydroascorbic acid solution the buffer capacity of the blood is most probably exceeded. This would result in a gradually increasing acidemia as well as a corresponding increase in stimulation of chemoreceptors hence a rise in blood pressure with successive injections. A similar rise in blood pressure was observed after intraarterial injection of lactic acid.

It was observed that the first 3 injections of dehydroascorbic acid, administered with long time intervals between the injections, resulted in gradually increasing pressor responses in the cats as well as in the rabbits. This phe-

nomenon has earlier been observed in rats by Patterson and Mastin (1951) and in cats by Wegman (1958)

It is known that dehydroascorbic acid is readily taken up by blood corpuscles and reduced to ascorbic acid (Hendry *et al* 1964 Hughes and Kilpatrick 1964 Hughes and Maton 1968) Injected dehydroascorbic acid is also widely distributed in the organism and easily taken up and reduced by various tissues (Hughes 1964 Hammarström 1966) These factors might contribute to a decrease in the amounts of dehydroascorbic acid in the blood thus reducing the amount of the substance reaching the brain. These depots will presumably become saturated with increasing amounts of injected dehydroascorbic acid, thus resulting in an increased amount of the active substance in the blood so that a larger amount would reach central effector sites (see Chapter I, Part 6)

Repeated injections of dehydroascorbic acid into rabbits at short time intervals caused a gradually decreasing pressor response thus demonstrating tachyphylaxis. This is consistent with observations in rats by Patterson and Mastin (1951) The direct mechanism of tachyphylaxis is not completely understood. It is possible that dehydroascorbic acid tachyphylaxis is due to a gradual saturation of the effector sites with metabolically formed ascorbic acid thus gradually reducing further uptake of dehydroascorbic acid. Further work is required before more definite conclusions can be drawn.

Part 6 Effects of dehydroascorbic acid following decerebration spinal cord section and bilateral adrenalectomy

Materials and methods

The experiments were carried out on anaesthetized cats (pentobarbitone or chloralose urethane anaesthesia) and rabbits.

Blood pressure recordings were performed as described in Part 5 The gross behaviour of the animals during anaesthesia was also observed.

Dehydroascorbic acid (obtained by ascorbic acid oxidation) was injected intravenously (see Part 5) in doses varying between 5 and 150 mg/kg.

Other drugs used were adrenaline (10 μg base) and noradrenaline (10 μg base) These substances were given by rapid intravenous injection.

Decerebration

Four cats and 9 rabbits were decerebrated. The cranium was exposed and the whole roof above the cerebrum removed. After incision of the brain membranes

Fig. 18. Cat, pentobarbitone anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) in (A) a normal animal, (B) after decerebration of the same animal and (C) after spinal cord section in the same animal.

the brain stem was cut directly in front of the tentorium in the cats and immediately in front of the cerebellum in the rabbits. All parts of the brain (including the pituitary gland) in front of cerebellum and pons were removed. A cotton cloth was pressed into the hole in the skull in order to prevent excess bleeding and the skin was closed. Twenty minutes were allowed to pass before recordings were made.

Spinal cord section

Seven cats (pentobarbitone or chloralose-urethane anaesthesia) and 2 rabbits were spinalized by cutting the spinal cord between C 1 and C 2. At the same time artificial respiration (Starling pump) was started.

Bilateral adrenalectomy

The adrenals were removed in 4 cats.

Results

At the beginning of each experiment (i.e. prior to operation) dehydroascorbic acid was injected 3—4 times with 10—15 minutes intervals in order to achieve uniform pressor responses. In some animals the pressor response was preceded by a transient fall of the blood pressure. Lacrimation, mucous salivation and an arousal effect were observed after each injection in both cats and rabbits.

Decerebrated cats

Immediately after the decerebration the blood pressure dropped from 140—160 mm Hg to about 60—100 mm Hg and became stabilized at this level.

After injection of dehydroascorbic acid (50 mg/kg) a rise in the blood pressure was obtained. The intensity and duration of this pressor response were

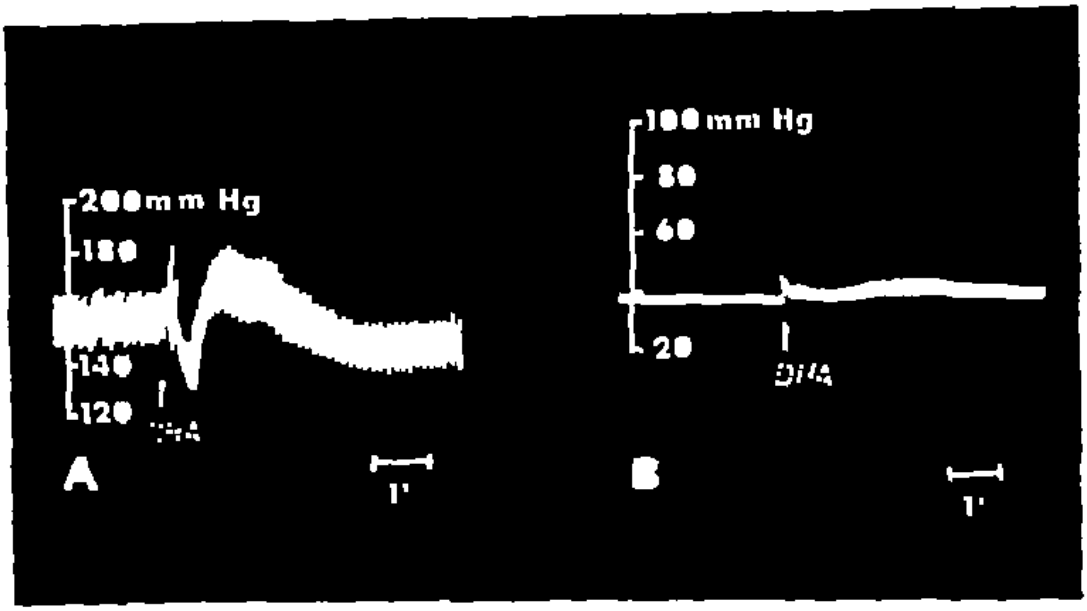

Fig. 19 Cat, chloralose-u ethane anaesthesia. The blood pressure response to intra venous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) spinal cord section.

the same as before decerebration. In one cat the pressor response was even larger than before the operation (Fig. 18)

In most experiments the blood pressure never returned to the original level (80—100 mm Hg) but remained slightly elevated until the next injection of dehydroascorbic acid.

Neither increased salivation and lacrimation nor arousal effect were observed in the decerebrated cats.

Spinal cord section in cats and rabbits

After sectioning of the spinal cord in the cats and rabbits the blood pressure dropped to about 40—60 mm Hg and remained constant at this level. Intravenous injection of dehydroascorbic acid (50—150 mg/kg) into either of the species resulted exclusively in a slight pressor effect independent of the dose injected. This pressor effect consisted mainly of an increase in the systolic pressure (Figs 18 and 19). This effect lasted for about 10 minutes.

Neither increased salivation and lacrimation nor arousal effect were observed in the spinalized cats and rabbits.

Adrenaline and noradrenaline were given in order to check the variation ability of the blood pressure following decerebration and spinal cord section. These injections resulted in pronounced pressor effects, thus indicating a normal function at the peripheral adrenergic α-receptor sites.

Fig 20. Cat, chloralose-urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) bilateral adrenalectomy

Bilateral adrenalectomy in cats

Following this operation, injection of dehydroascorbic acid (50 mg/kg) resulted in a pressor response which was somewhat smaller than before the operation (Fig. 20)

Removal of the adrenals did not change the effect of dehydroascorbic acid on salivation and lacrimation. The arousal effect was also observed as prior to the operation.

Discussion

In the present investigation it was shown that the pressor effect of dehydro ascorbic acid remained unchanged after decerebration in cats. Injection of dehydroascorbic acid into decerebrated rabbits also caused a pressor response although it was somewhat reduced compared to that obtained prior to the operation. This suppressed response is probably due to partial damage to the vasomotor areas in the reticular formation caused by the operation.

Following spinal cord section the pressor effect of dehydroascorbic acid was markedly reduced in cats as well as in rabbits, presenting another character These results are in agreement with earlier observations in spinalized rats (Patterson and Mastin 1951) and cats (Wegman 1958)

Based on the present observations in decerebrated and spinalized cats and rabbits it is suggested that th pressor effect of dehydroascorbic acid is mainly evoked from caudal parts of the brain stem, most probably from the so called vasomotor centre in the medulla oblongata.

In the present experiments it was noticed that following bilateral adrenalectomy in cats, injection of dehydroascorbic acid caused a somewhat smaller

pressor response than prior to the operation. This may be an indication of a release of catecholamines from the adrenals by dehydroascorbic acid or metabolically formed ascorbic acid (McLean and Cohen 1963)

Adrenalectomy in rats, however does not appear to affect the pressor response of dehydroascorbic acid (Patterson and Martin 1951)

The increased salivation and lacrimation and the arousal effect observed after administration of dehydroascorbic acid into normal anaesthetized cats and rabbits were not seen after decerebration and spinal cord section. These results indicate that the effects mentioned are evoked in the central nervous system.

CHAPTER II

Effects of Various Compounds on the Pharmacological Response to Dehydroascorbic Acid of the Blood Pressure in Cats and Rabbits

Injections of dehydroascorbic acid into cats and rabbits result in both pressor and depressor responses. The depressor response is considered to be caused by the large volume injected and/or due to the acidity of the injection solution (Chapter I Part 5) and the pressor response is attributed to an effect of dehydroascorbic acid. This pressor response is similar to that obtained after injection of adrenergic nerve stimulants, e.g. tyramine or amphetamine.

It has also been observed that dehydroascorbic acid facilitates neuromuscular transmission (Chapter I Part 4)

The aim of the present experiments was to determine whether the pressor effect of dehydroascorbic acid could be affected by compounds known to interfere with adrenergic mechanisms and whether dehydroascorbic acid would interfere with the response to acetylcholine on the blood pressure.

Materials and methods

In these experiments anaesthetized cats (pentobarbitone or chloralose-urethane anaesthesia) and rabbits were used. For details of animals and anaesthesia see Chapter I Part 1

The animals were prepared for blood pressure recording as described in Chapter I Part 5. The number of animals, species, substances and doses tested in the various experiments are listed in Table 3.

Dehydroascorbic acid (obtained by ascorbic acid oxidation see Chapter I Part 1) was given intravenously in the following doses: 10, 25, 50, 100 and 150 mg/kg. In most experiments dehydroascorbic acid was injected 3—4 times initially at 10—15 minutes intervals in order to obtain uniform pressor effects.

All the drugs were administered intravenously (see Chapter I Part 5) unless otherwise stated.

In some experiments adrenaline, noradrenaline and tyramine were administered as control substances in order to ascertain normal response and to check the capacity for variation of the blood pressure

pressor response than prior to the operation. This may be an indication of a release of catecholamines from the adrenals by dehydroascorbic acid or metabolically formed ascorbic acid (McLean and Cohen 1963)

Adrenalectomy in rats, however does not appear to affect the pressor response of dehydroascorbic acid (Patterson and Mastin 1951)

The increased salivation and lacrimation and the arousal effect observed after administration of dehydroascorbic acid into normal anaesthetized cats and rabbits were not seen after decerebration and spinal cord section. These results indicate that the effects mentioned are evoked in the central nervous system.

Noradrenaline Free base	0.01[2]
Tyramine Tyramine hydrochloride	2—5

[1] Administered intraperitoneally daily for 4 consecutive days.
[2] Amount injected independent of body weight.

Results

Before treatment with any of the drugs used injection of dehydroascorbic acid always caused a pressor response sometimes preceded by a transient lowering of the blood pressure (compare Chapter I Part 5)

Ganglion blocking agents

Two different ganglion blocking agents were used, hexamethonium and tetra ethylammonium (TEA) In animals intravenously premedicated with either of these compounds the pressor response after dehydroascorbic acid injection was changed. When treated with hexamethonium (1—5 mg/kg) a reduction of the pressor effect was observed, but it was never completely eliminated (Fig. 21)

In experiments where TEA was used instead of hexamethonium a more pronounced action on the pressor response of dehydroascorbic acid was observed. After administration of a low dose of TEA (1 mg/kg) intravenously

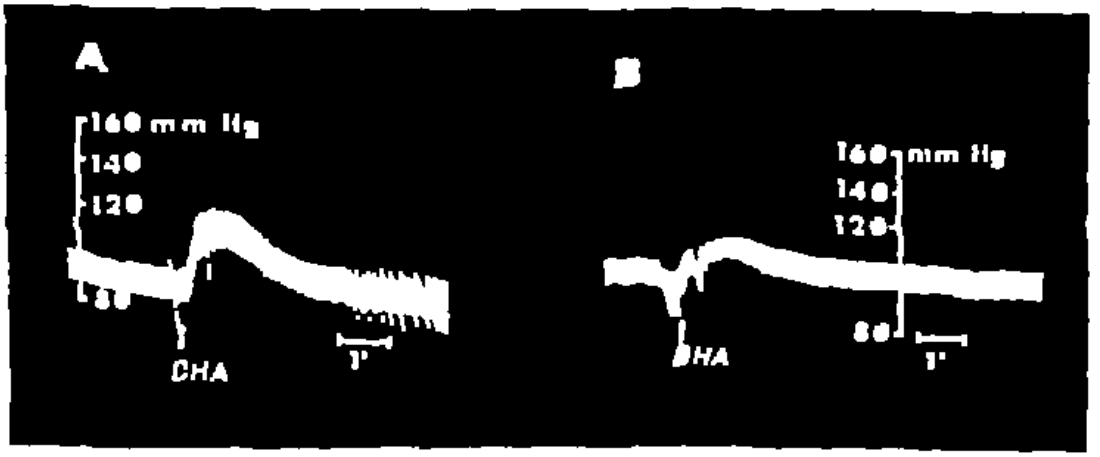

Fig. 21 Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) treatment with hexamethonium (2 mg/kg intravenously)

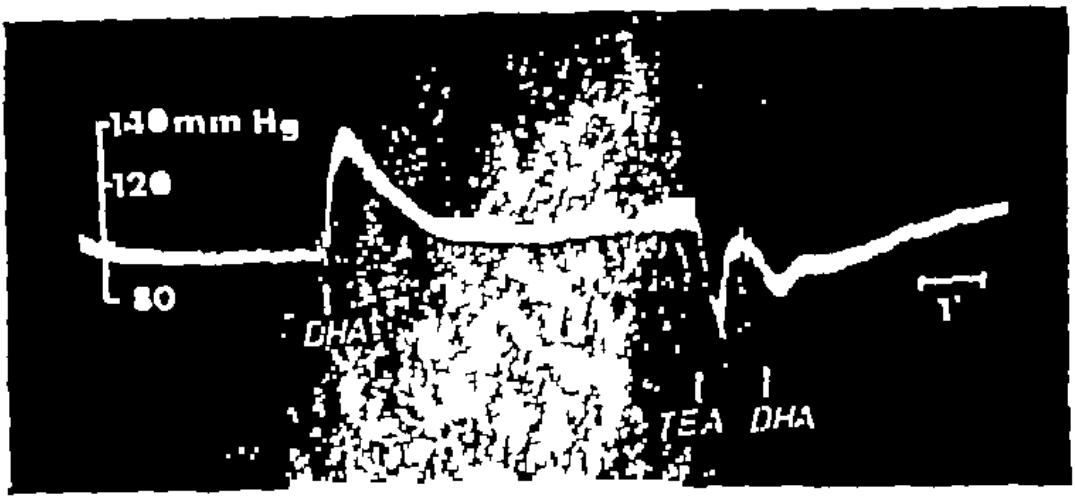

Fig. 22. Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before and after treatment with tetraethylammonium (TEA 1 mg/kg i.v.)

the pressor effect of dehydroascorbic acid was completely eliminated (Fig. 22).

Guanethidine and bretylium

The blood pressure response following dehydroascorbic acid was markedly changed after guanethidine and bretylium treatment. The pressor response to dehydroascorbic acid was strongly reduced, and in some experiments completely abolished following treatment with either of the two compounds (Figs. 23 and 24).

Vasodepressor agents

These experiments were carried out on chloralose-urethane anaesthetized cats as this type of anaesthesia and animal are most suitable for such experiments.

Fig. 23. Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before and after treatment with bretylium (Br 5 mg/kg i.v.)

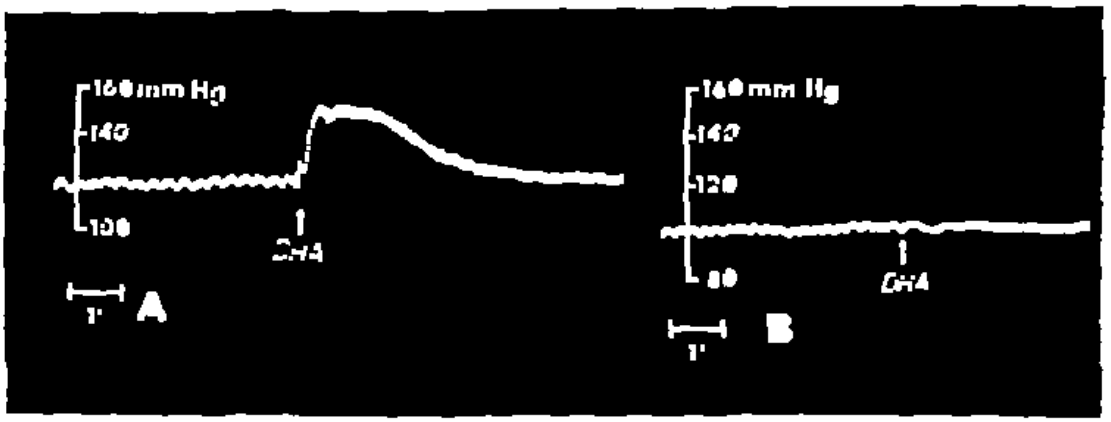

Fig. 24. Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) treatment with guanethidine (1 mg/kg I.V.).

Dihydroergotamine and phenoxybenzamine were used in different experiments in order to block the sympathetic α-receptors. Propranolol was used for blocking the adrenergic β-receptors.

After treatment with the α-receptor blocking agents the blood pressure response of injected dehydroascorbic acid changed. Instead of the usual pressor response a prominent depression was recorded (Fig. 25). In some experiments, however the pressor effect of dehydroascorbic acid was blocked but no depressor response occurred.

In experiments where injection of dehydroascorbic acid resulted in a fall of the blood pressure after α-receptor blocking (3 out of 7 tested cats) propranolol was given intravenously. When dehydroascorbic acid was given after the propranolol treatment faint pressor and depressor responses were observed (Fig. 26). When both adrenergic α- and β-receptors were blocked the response

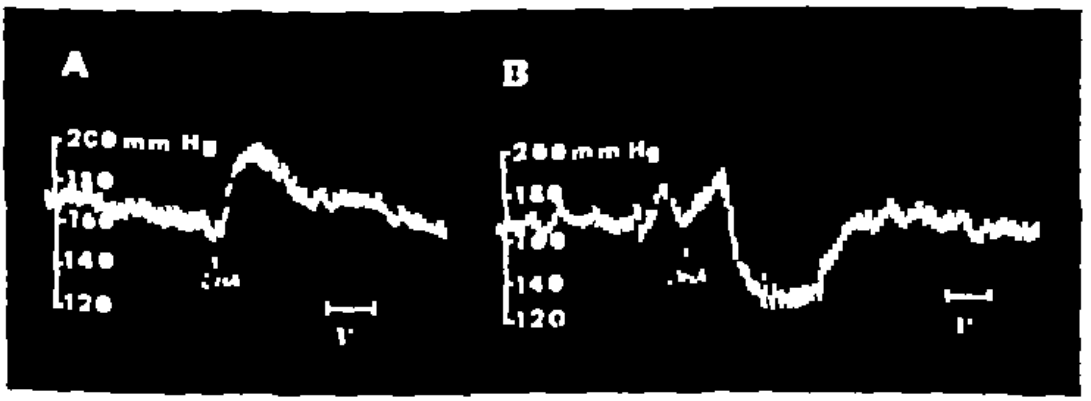

Fig. 25. Cat, chloralose-urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) treatment with dihydroergotamine (1 mg/kg I.V.). Note the reversal of the blood pressure response.

the pressor effect of dehydroascorbic acid was completely eliminated (Fig. 22).

Guanethidine and bretylium

The blood pressure response following dehydroascorbic acid was markedly changed after guanethidine and bretylium treatment. The pressor response to dehydroascorbic acid was strongly reduced, and in some experiments completely abolished following treatment with either of the two compounds (Figs. 23 and

Acute experiments following ganglion blocking agents

These experiments were carried out on chloralose-urethane anaesthetized cats and rabbits. Deep anaesthesia and animal are most suitable for such experiments.

Fig. 23. Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before and after treatment with bretylium (Br 5 mg/kg i.v.).

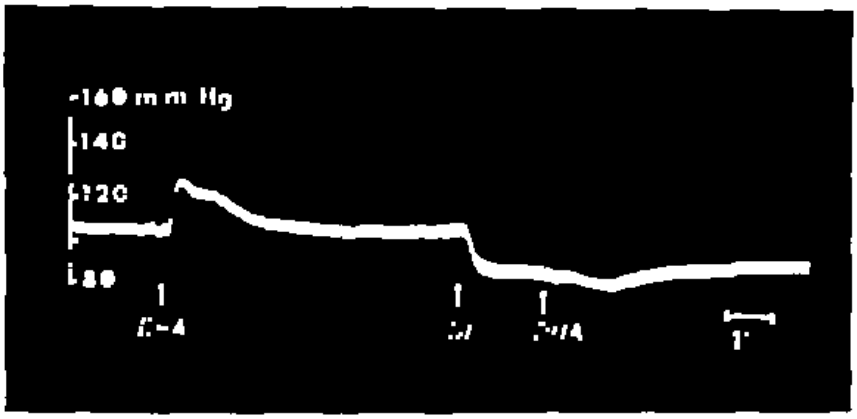

Fig. 28. Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before and after treatment with desmethylimipramine (DI 2 mg/kg I.v.)

To demonstrate the established effect of reserpine, tyramine (2—5 mg/kg) was also given to the reserpine treated animals. A slight rise in the blood pressure could be detected when the larger dose was given. The tyramine response was, however much smaller than that obtained in non reserpinized rabbits.

Imipramine desmethylimipramine and cocaine

Imipramine desmethylimipramine and cocaine affected the pressor response elicited by dehydroascorbic acid injection in rabbits. Pretreatment with low doses of imipramine and desmethylimipramine (0.5 mg/kg) and cocaine (1 mg/kg) reduced the pressor response to injected dehydroascorbic acid. When repeated low doses or single high doses (2 mg/kg) of either Imipramine or desmethylimipramine were given, the pressor response to dehydroascorbic acid was completely abolished (Figs 28 and 29). This was also observed after

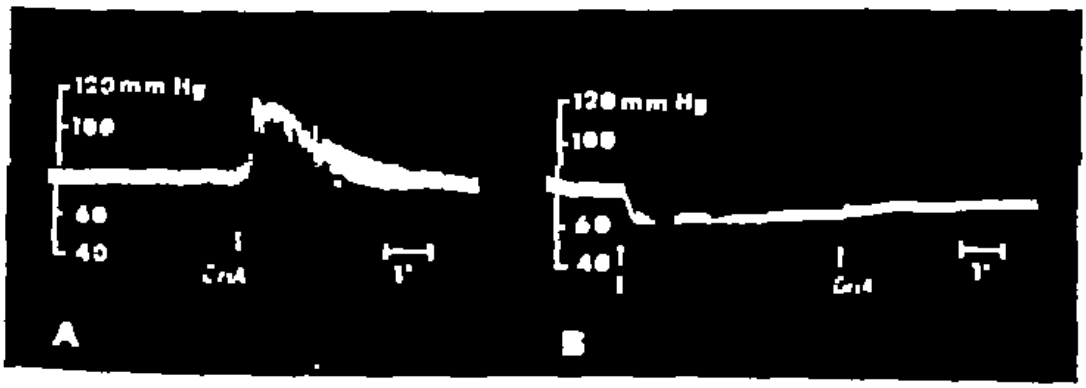

Fig. 29. Rabbit, urethane anaesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) treatment with imipramine (I 2 mg/kg I.v.)

Fig. 30. Rabbit, urethane anesthesia. The blood pressure response to intravenous injection of 50 mg/kg dehydroascorbic acid (DHA) before (A) and after (B) treatment with cocaine (20 mg/kg i.

premedication with high doses (40 mg/kg) of intravenously administered cocaine (Fig. 30). The cocaine effect, however, was of rather short duration compared to that of the other 3 substances tested. In 1 cat dehydroascorbic acid was given after intravenous premedication with desmethylimipramine. In this experiment it was shown that the pressor response to dehydroascorbic acid was strongly reduced.

Acetylcholine

In the cat experiment it was observed that administration of dehydroascorbic acid in doses up to 50 mg/kg did not noticeably affect the depressor response caused by acetylcholine injection. However, when the dose was increased to 100 or 150 mg/kg the depressor response of acetylcholine was significantly enhanced. The level of the depression was increased and the duration was prolonged (Fig. 31). When 5 minutes had passed after dehydroascorbic acid administration the acetylcholine response was identical with that obtained before the dehydroascorbic acid injection.

In the rabbit injection of 50 mg/kg or more of dehydroascorbic acid changed the response of the blood pressure to acetylcholine. Prior to dehydroascorbic acid injection, administration of acetylcholine caused a fall in blood pressure which rapidly returned to normal. However, after the dehydroascorbic acid injection, when the pressor response had returned to the normal level, injection of acetylcholine caused a hypotensive response of the same magnitude as before but the blood pressure returned more slowly to the normal level. The duration of this depressor response of acetylcholine increased with the dose of dehydroascorbic acid injected. Acetylcholine injected during the pressor phase

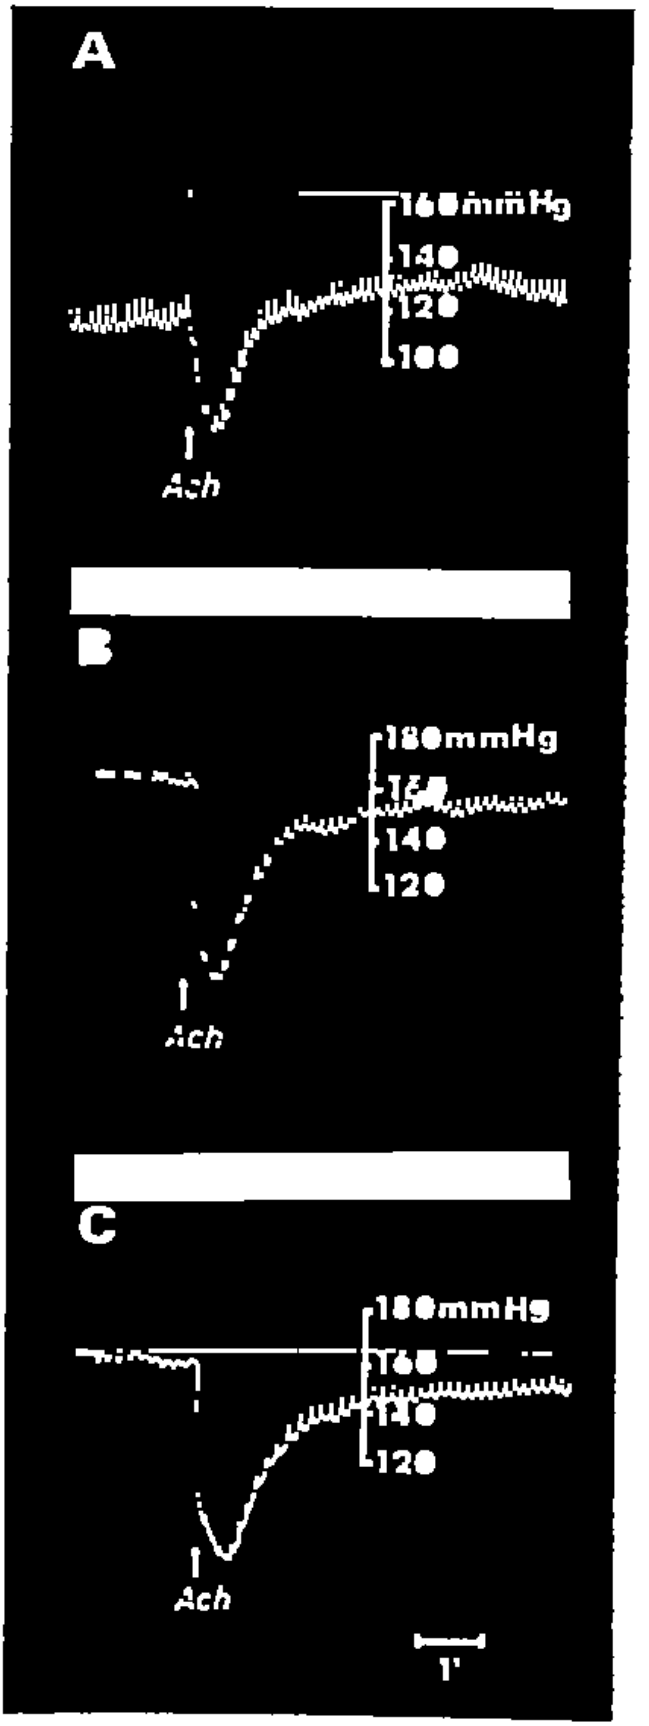

Fig. 31 Cat, chloralose-urethane anaesthesia. The effect of dehydroascorbic acid on the depressor response to acetylcholine. A the response to intravenous injection of 1 µg acetylcholine (Ach.) B the response to the same dose of acetylcholine after intravenous injection of 100 mg/kg dehydroascorbic acid. C the response to the same dose of acetylcholine after intravenous injection of 150 mg/kg dehydroascorbic acid.

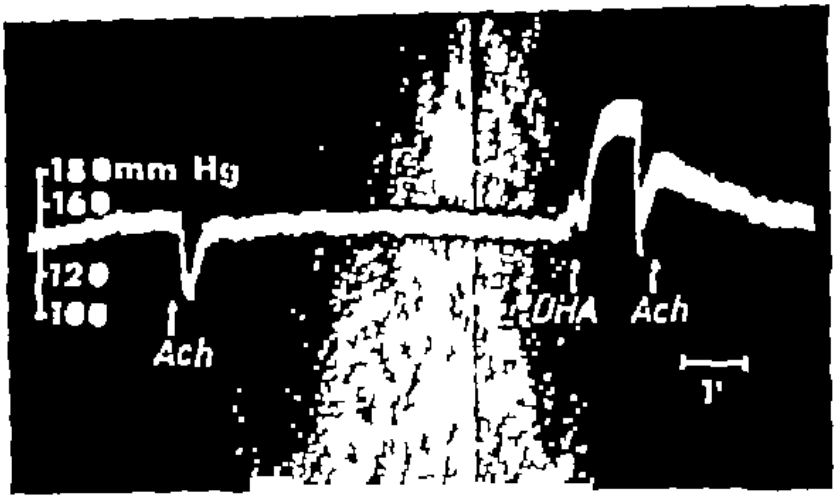

Fig. 32. Rabbit, urethane anaesthesia. The effect of dehydroascorbic acid (DHA 50 mg/kg i. v.) on the depressor response to acetylcholine (Ach 1 µg i.v.) the latter injected during the pressor phase of dehydroascorbic acid

of dehydroascorbic acid (150 mg/kg) caused a significantly larger fall than both before the administration of dehydroascorbic acid and after the pressor response had returned to the normal level (Fig. 32).

The response to dehydroascorbic acid on the blood pressure was not changed when given immediately after a single injection or after repeated administrations of acetylcholine.

Discussion

In the present investigation it was found that several compounds interfering with adrenergic mechanisms at different sites and by different actions changed the pressor response to injected dehydroascorbic acid.

After ganglion blocking with hexamethonium the pressor response following dehydroascorbic acid was partly reduced. Total blocking never occurred and this corresponds with observations by Patterson and Mastin (1951). In order to ascertain whether the failure of hexamethonium to abolish the pressor response to dehydroascorbic acid was due to an incomplete ganglion block, tetraethylammonium which has a potent ability to interrupt transmission in sympathetic ganglia (Moe and Freyburger 1950) was also used. After treatment with this drug a complete inhibition of the blood pressure response of dehydroascorbic acid was observed. These results show that the pressor effect of dehydroascorbic acid is not evoked from sites below ganglionic level (compare Chapter I Part b).

The pressor effect of dehydroascorbic acid was blocked by premedication with guanethidine and bretylium. Both substances are known to block adrener-

gic transmission (for references see Cass and Spriggs 1961 Chang *et al.* 1967) It is thought that they exert their adrenergic neuron blocking activity by means of different mechanisms of action and perhaps at different sites (Boura and Green 1962 Brodie *et al.* 1965) It is presumed that they prevent the liberation of adrenergic transmitter from nerve endings (Maxwell *et al.* 1959 1960 a, b Boura and Green 1959) As the pressor response to injected dehydroascorbic acid was blocked by guanethidine and bretylium it may be suggested that dehydroascorbic acid causes activation of adrenergic nerves, similar to electrical nerve stimulation (Kurpekar *et al.* 1969)

It is evident that the pressor response observed after dehydroascorbic acid injection is the result of an activation of adrenergic α-receptors since the hypertensive response is abolished by the blocking of these receptors. This is *in agreement with observations by Patterson and Martin (1951) and* Wegman (1958) After an α-receptor blockade dehydroascorbic acid injection resulted in a hypotensive response in some of the tested animals. Similar response of dehydroascorbic acid injection was observed in rats by Patterson and Martin (1951) In the present investigation it was found that this depressor response was strongly reduced by premedication with propranolol, a β-receptor blocking agent. This suggests that the adrenergic β-receptors also are activated following dehydroascorbic acid administration.

In the reserpine treated rabbits the pressor effect of dehydroascorbic acid was abolished. Reserpine treatment leads to a strongly impaired adrenergic transmission (Carlsson *et al.* 1957) At the same time there is a marked depletion of noradrenaline. Reserpine causes a blockade of the uptake and storage mechanism in the amine storage granules (Hillarp and Malmfors 1964 Lindmar and Muscholl 1964 Malmfors 1965 Carlsson and Waldeck 1965) The membrane pump mechanism is not affected by reserpine (Malmfors 1965)

The abolished pressor response to dehydroascorbic acid in the reserpinized animals is interpreted as being a consequence of decreased amounts of adrenergic transmitter available for release. In this respect the blood pressure response to dehydroascorbic acid injection is very similar to electrical or chemical stimulation of sympathetic nerves, this response to stimulation being blocked by prior reserpine treatment (Bertler *et al* 1956 Muscholl and Vogt 1958)

A complete inhibition of the pressor response to injected dehydroascorbic acid was observed after treatment with some so called membrane pump blocking agents, Imipramine, desmethylimipramine and cocaine. These substances are supposed to block the cellular uptake of noradrenaline (Whitby *et al* 1960 Dengler *et al.* 1961 Muscholl 1961 Titus *et al.* 1966) It is believed that certain drugs which release intraneuronal noradrenaline are

transported by the membrane pump to reach their site of action e.g. tyramine (for references see Ross 1967). The results from the present experiments suggest that the pressor effect of dehydroascorbic acid is brought about by its being taken up into the adrenergic nerve cells by means of the imipramine-desmethylimipramine- and cocaine-sensitive transport mechanism, and that dehydroascorbic acid thus behaves like an indirectly acting sympathomimetic compound. The probable site and mechanism of action of dehydroascorbic acid will be further discussed and put in relation to other experimental data obtained (see General Discussion).

Earlier it was shown that intravenous injection of high doses of dehydroascorbic acid facilitated neuromuscular transmission in the cat (Chapter I Part 4). In the present experiments it was found that the depressor response to acetylcholine was enhanced after treatment with dehydroascorbic acid in cats and rabbits. It is supposed that there is a common mechanism of action of dehydroascorbic acid in the two different investigations mentioned. In both cases the effect of dehydroascorbic acid is plausibly related to its cholinesterase-inhibiting action (Chapter V). As early as 5 minutes after the injection, dehydroascorbic acid had obviously lost its capacity to potentiate the depressor response caused by acetylcholine. This may be explained by the fact that dehydroascorbic acid is rapidly reduced in the organism forming ascorbic acid (Patterson and Mastin 1951, Hammarström 1966) which is devoid of cholinesterase-inhibiting action (Chapter V). It may also be pointed out that the cholinesterase-inhibiting action of dehydroascorbic acid is weak and consequently fairly high doses are required to produce a demonstrable effect in the organism.

CHAPTER III

Effects of Various Compounds on the Accumulation of ^{14}C-Dehydroascorbic Acid and ^{14}C-Ascorbic Acid in Brain and Heart Tissues of Mice *in vivo*

The pressor effect observed after injection of dehydroascorbic acid was shown to be inhibited by prior treatment with so called membrane pump blocking agents (Chapter II) This inhibition was interpreted as being due to the blocking of dehydroascorbic acid uptake at the intraneuronal transmitter sites. The pressor effect was also found to be inhibited by prior reserpine treatment (Chapter II) It was thus suggested that dehydroascorbic acid (or metabolically formed ascorbic acid) releases noradrenaline from reserpine-sensitive amine storage granules. In order to affect the noradrenaline content of these granules dehydroascorbic acid (or metabolically formed ascorbic acid) has to pass the adrenergic cell membrane and reach the storage sites at the granular membrane.

The aim of the present experiments was to study the influence of certain membrane pump blocking agents and reserpine on the tissue uptake of labelled dehydroascorbic acid and ascorbic acid. The uptake was studied in brain and heart tissues of mice. The brain was chosen because the pressor effect of dehydroascorbic acid is mainly of central origin (Chapter I Part 6) and the effect is probably due to an interference with the intraneuronal transmitter in this tissue. The heart was chosen for studying the uptake in a peripheral tissue with known adrenergic activity

Materials and methods

Radioactive compounds

Ascorbic acid-1 ^{14}C with a specific activity of 3.36 millicuries per millimole was obtained from New England Nuclear Corporation, Boston, Mass., USA. The radiochemical purity was tested by chromatography (N.E.N.) and was found to be 99 % (see below) The radioactive ascorbic acid was dissolved in redistilled water to give a concentration of 0.26 mg/ml (corresponding to 5 μCi/ml)

For preparation of labelled dehydroascorbic acid 2.6 mg (50 μCi) of C-ascorbic acid was dissolved in 10 ml redistilled water Benzoquinone (1.6 mg) dissolved in 10 ml ether was added and the mixture was shaken for 15

minutes. The ether phase was removed and the water phase was washed 3 times with ether. The final dehydroascorbic acid concentration was estimated to be 0.26 mg/ml (corresponding to 5 μci/ml).

Chromatography

The purity of the prepared solutions of ^{14}C-dehydroascorbic acid and ^{14}C-ascorbic acid was checked by thin-layer chromatography and by subsequent autoradiography (Hammarström 1966).

One to 5 μl of each solution was spotted under a stream of nitrogen on 250 μ thick silica gel thin-layer plates for chromatography. The plates were prepared as described by Stahl (1967). Silica gel H and 3 % metaphosphoric acid were used for the preparation. The plates were activated by heating at 120° C for 1 hour.

The solvent system for thin-layer chromatography used was benzene-methanol-acetone-acetic acid (70 : 20 : 5 : 5). The development of the chromatogram was performed under nitrogen. The front was allowed to run approximately 14 cm.

Non-radioactive ascorbic acid and dehydroascorbic acid were always run on each plate as reference substances. After development of the chromatograms these were located by spraying the plates with 2,6-dichlorophenol indophenol in 96 % ethanol (w/v) and 0.1 % 2,4-dinitrophenylhydrazine in 96 % ethanol (w/v) to which had been added 1 ml concentrated HCl.

The radioactive compounds were located by autoradiography. The plates were pressed against Kodirex (Kodak) or Structurix (Gevaert) X-ray film. The exposure time was 1—2 weeks. Then the radioactive spots were scraped off with a razor blade into liquid scintillation vials and counted in a Packard Tri-Carb liquid scintillation spectrometer as a suspension in 15 ml of 0.5 % 2,5-diphenyloxazole + 0.03 % 1,4-bis-2(4-methyl-5-phenyloxazolyl)benzene + 4 % silica gel (Aerosil®) in toluene (Snyder and Stephens 1962). Correction for quenching was made by the external radiation source of the spectrometer.

When the ^{14}C-ascorbic acid solution was run 3 radioactive spots were detected. The major spot had the same R_f value as non-radioactive ascorbic acid, one spot corresponded to dehydroascorbic acid (about 10 % of the total radioactivity) and one spot remained at the starting point (5—10 %). Moreover when ^{14}C-dehydroascorbic acid solution was chromatographed 3 spots were observed. The major spot had the same R_f value as non-radioactive dehydroascorbic acid, one spot corresponded to ascorbic acid (5—10 %) and one spot remained at the starting point (5—10 %).

Animals

Seventy-two female mice of NMRI strain with an average body weight of 20 g were used. The mice were fed a complete pelleted diet and water *ad lib* (see Chapter I Part 1)

Experimental procedure

The mice were divided into 12 groups with 6 animals in each group. In some groups the animals were premedicated with various compounds (see Premedication) C-ascorbic acid (1 μci/animal) was given intravenously into a tail vein to each animal in 6 of the groups and ^{14}C-dehydroascorbic acid (1 μci/animal) to the other 6 groups. The mice were sacrificed by stretching the spine 30 minutes after injection of the labelled substance.

The brain stem and the heart were used for analyses. The two tissues from each animal were weighed and placed separately in vials containing 1 ml sample solubilizer (Soluene™ 100 Packard Instrument Company Ill., USA) The samples were heated to +40 C and within 3 hours the tissues were dissolved. To each sample 15 ml toluene-PPO (5 g diphenyloxazole in 1 l toluene) was added. Radioactivity assay was then performed by liquid scintillation of the whole sample in a Packard Tri-Carb liquid scintillation spectrometer

The body weights of the animals varied between 18 and 22 g and no dose correction was made.

No attempts were made to separate C-dehydroascorbic acid and C-ascorbic acid or labelled metabolites of these substances in the tissues.

Premedication

The animals in the 12 experimental groups were premedicated with 4 different compounds, desmethylimipramine (Pertofrin® Geigy 10 mg/kg) cocaine (cocaine chloride 10 mg/kg) protriptyline (protriptyline hydrochloride 10 mg/kg) and reserpine (Serpasil® Ciba 5 mg/kg) These substances were given intraperitoneally 30 minutes prior to intravenous injection of either of the labelled substances. The animals in the 2 control groups were given physiological saline solution intraperitoneally in equivalent volume to the substances mentioned above (0.1 ml/10 g body weight)

Statistical evaluation

Tests of significance were conducted using Student's t test. The level of significance used was $P < 0.05$

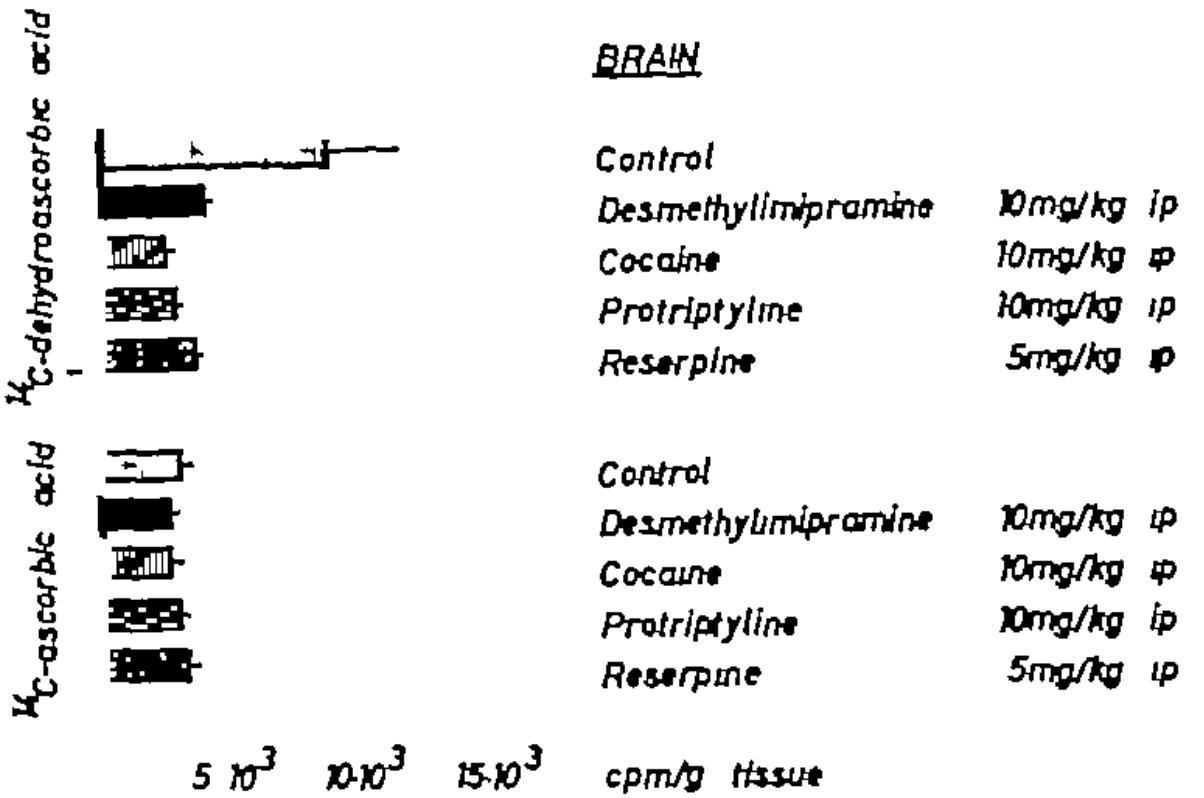

Fig. 33 The total amount of radioactivity per gram tissue in brains of mice 30 minutes after intravenous injection of 1 μci ^{1} C-dehydroascorbic or ^{14}C-ascorbic acid. Each value represents the mean of 6 determinations (standard error of the mean horizontal bars) Some groups of animals were premedicated with various compounds (see text) 30 minutes prior to injection of the labelled substance.

Results

Figs 33 and 34 show the total amount of radioactivity per gram tissue (wet weight) in brains and hearts of mice injected with labelled dehydroascorbic acid or ascorbic acid. The recovered amounts of radioactivity 30 minutes after injection in these 2 tissues were considerably larger after administration of ^{14}C-dehydroascorbic acid than after injection of ^{1} C-ascorbic acid.

After premedication with desmethylimipramme, cocaine protriptyline and reserpine, significantly smaller amounts ($P < 0.05$) of radioactivity were recovered in both tissues following injection of labelled dehydroascorbic acid. In brains and hearts of animals injected with labelled ascorbic acid, on the other hand, no significant differences were observed.

The concentration of radioacti ity in both tissues of premedicated animals injected with labelled dehydroascorbic acid was almost equal to that noted in the tissues of the control animals injected with ^{1}C-ascorbic acid.

The differences in recovered amounts of radioactivity between the premedicated groups given ^{14}C-dehydroascorbic acid were not statistically significant.

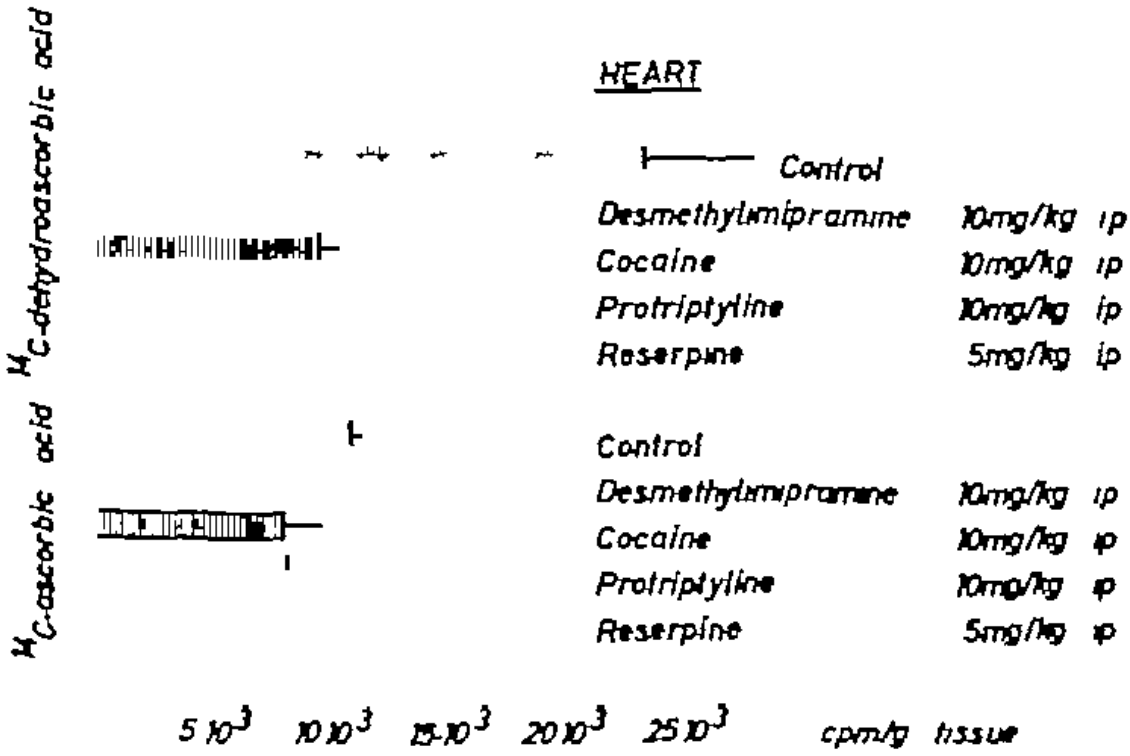

Fig. 34 The total amount of radioactivity per gram tissue in hearts of mice 30 minutes after injection of ^{14}C-dehydroascorbic acid or ^{14}C-ascorbic acid. For further details see Fig. 33 and text.

Discussion

The decreased amount of radioactivity after injection of ^{14}C-dehydroascorbic acid recovered from brain and heart tissues of animals pretreated with desmethylimipramine, cocaine and protriptyline compared to that found in corresponding tissues of control animals is interpreted as a decreased uptake of radioactivity. Desmethylimipramine, cocaine and protriptyline are potent inhibitors of amine uptake through the adrenergic nerve cell membrane, the so called membrane pump (Hillarp and Malmfors 1964 Lindmar and Muscholl 1964 Carlsson and Waldeck 1965 Carlsson *et al.* 1966). In the present experiments it was noticed that all 3 blocking compounds inhibited the uptake of ^{14}C-dehydroascorbic acid to the same extent.

From the present results it may be suggested that the membrane pump blocking agents inhibit the transfer of C-dehydroascorbic acid across the adrenergic cell membrane. This is compatible with the observation that the pressor response of injected non-labelled dehydroascorbic acid is inhibited by prior treatment with membrane pump blocking agents (Chapter II). The uptake is equally inhibited in both brain and heart tissues which suggests that ^{1} C-dehydroascorbic acid is taken up by the same mechanism in both tissues.

Presumably the inhibition was complete, since the amount of radioactivity recovered after premedication was almost identical with that found in animals injected with ^{14}C-ascorbic acid. The latter compound is not supposed to be taken up by the same mechanism (see below)

After premedication with reserpine a smaller amount of radioactivity was recovered from both tissues than from those of the controls following injection of ^{14}C-dehydroascorbic acid. It is well established that reserpine blocks the transmitter uptake and storage mechanisms in amine granules (Hillarp and Malmfors 1964 Lindmar and Muscholl 1964 Malmfors 1965 Carlsson and Waldeck 1965) From the present results it is assumed that these mechanisms must be intact in order to fully concentrate radioactivity in brain and heart tissues of animals injected with ^{1} C-dehydroascorbic acid.

Heath and Fiddich (1966) studied the uptake of labelled dehydroascorbic acid in the rat retina *in vitro* and found that 75 % of the dehydroascorbic acid which entered the cells was reduced to ascorbic acid intracellularly Autoradiographic investigations with labelled dehydroascorbic acid have shown that the injected substance is rapidly reduced to ascorbic acid in the tissues and then retained for several days in the nervous tissue (Hammarström 1966) Nichelmann *et al.* (1966) showed that ascorbic acid is bound to a protein in the nervous tissue. It has been suggested that ascorbic acid is required for dopamine β-hydroxylation (Kaufman and Friedman 1965) The hydroxylating enzyme has been shown to be attached to the amine storing granules *in vitro* (Stjärne and Lishajko 1967) and it is possible that the injected ^{14}C-dehydroascorbic acid may be bound to the granular membrane most probably in the form of ascorbic acid. In the present experiments this binding mechanism may be inactivated by the reserpine treatment which might explain the differences in recovered radioactivity in the tissues between reserpine premedicated and control animals after injection of ^{14}C-dehydroascorbic acid.

The amount of radioactivity recovered from brain and heart tissues of animals *pretreated with any of the compounds after injection of* ^{14}C-*ascorbic* acid was almost the same as that found in the control animals. Based on this observation it is concluded that ^{14}C-ascorbic acid is not taken up in the cells by *the same mechanism as* ^{14}C-*dehydroascorbic acid. The amount of radio*activity observed in these tissues is most probably derived from extracellularly located radioactivity or from ^{14}C-ascorbic acid taken up by some other mechanism.

CHAPTER IV

Effects of Dehydroascorbic Acid and Ascorbic Acid on Levels of Endogenous Noradrenaline and Dopamine in the Brain and of Noradrenaline in the Heart of Mice

It has been shown that injection of dehydroascorbic acid to various species is followed by responses indicating that adrenergic mechanisms are involved, preferentially in the brain (Patterson and Martin 1951 Wegman 1958, Chapters I and II) The rise in the blood pressure caused by injected dehydroascorbic acid has been shown to be blocked by drugs interfering with the uptake of dehydroascorbic acid into brain and heart tissues (Chapters II and III)

The aim of the present experiments was to determine whether dehydroascorbic acid and/or ascorbic acid were able to release noradrenaline from brain and heart tissues and if they caused any changes of the normal levels of noradrenaline and dopamine. The dopamine content in the heart was too small to be detected by the method used and therefore only the amount of dopamine in the brain has been estimated.

Materials and methods

Animals

Female mice of NMRI strain were used. The average body weight was 20 g The mice were fed a complete pelleted diet (AB Ewos) and water *ad lib*

Experimental procedure

The experiments were performed on 87 groups of mice (6 animals in each group) The mice were injected intravenously in a tail vein with dehydroascorbic acid (obtained by ascorbic acid oxidation) or ascorbic acid. These solutions were prepared as described in Chapter I Part 1 and diluted with redistilled water Each animal was given 0.1 ml of either solution. Control animals were injected intravenously with the corresponding volume of redistilled water

The mice were sacrificed by stretching the spine and the heart and brain were rapidly removed from each animal. Six organs (1 group) were pooled in each sample, weighed and homogenized in 0.4 N perchloric acid (10 and 1 ml for the heart and brain samples respectively) by an Ultra-Turrax™ homo-

genizer After centrifugation and neutralization (K_2CO_3) cation exchange chromatography was performed (Dowex 50 W—X 4) Noradrenaline and dopamine were eluted and determined in a spectrophotofluorometer (Aminco —Bowman) One determination per group. The recovery of noradrenaline and dopamine after elution was calculated to be 90 % and 80 % respectively The conversion of noradrenaline and dopamine to fluorescent compounds was calculated to be 100 % for both substances. The methods of analysis are described in detail by Bertler *et al* (1958) (noradrenaline) and Carlsson and Waldeck (1958) *modified by Carlsson and Lindquist* (1967) *(dopamine)*

In a first series of experiments varying doses of dehydroascorbic acid (10 50 100 and 125 mg/kg) or ascorbic acid (50 100 150 and ?00 mg/kg) were injected into 32 groups of mice. The survival time was 60 minutes. Eight groups served as controls.

In a second series of experiments, 100 mg/kg dehydroascorbic acid was injected intravenously into 16 groups of mice which were sacrificed at different time intervals (5 30 60 and 120 minutes) after the administration. Four groups served as controls.

Each value in the results from these two series of experiments is the mean of 4 different determinations ± standard error of the mean.

In a third series of experiments, ?7 groups of mice were premedicated with 500 mg/kg of a methyl ester of α methyltyrosine (H 44/68) given by intra peritoneal injection 3 hours prior to intravenous injection of 100 mg/kg dehydroascorbic acid or ascorbic acid. H 44/68 is a potent inhibitor of cate cholamine synthesis at the tyrosine-dopa step (Corrodi and Malmfors 1966) The survival time was 30 minutes after the last injection. Three of the groups were controls (Table 7)

Statistical evaluation

Tests of significance were conducted using Student s t test. The level of significance used was $P < 0.05$

Results

Table 4 illustrates the recovered amounts of endogenous noradrenaline in the brain and heart 60 minutes after injection of various doses of dehydroascorbic acid and ascorbic acid. It was noticed that injection of ascorbic acid caused no changes at all in the noradrenaline content In either of the tissues. In the hearts of animals gi ven dehydroascorbic acid a slight increase with the dose up to 100 mg/kg was observed. However the differences in the noradrenaline concentration between the treated and control groups were not found to be statistically significant.

TABLE 4 Endogenous levels of noradrenaline (NA) (μg/g tissue) in hearts and brains of mice 60 minutes after intravenous injection of different doses of dehydroascorbic acid or ascorbic acid. The values are means of 4 determinations ± S.E.M.

Dehydroascorbic acid			Ascorbic acid	
Dose mg/kg	Heart NA	Brain NA	Heart NA	Brain NA
Control	0.72 ± 0.06	0.42 ± 0.02	0.85 ± 0.03	0.43 ± 0.01
10	0.74 ± 0.05	0.44 ± 0.02		
50	0.81 ± 0.05	0.48 ± 0.05	0.85 ± 0.07	0.46 ± 0.02

125	0.72 ± 0.09	0.39 ± 0.04		
150			0.88 ± 0.05	0.42 ± 0.02
200			0.89 ± 0.05	0.40 ± 0.01

The noradrenaline level in the heart tended to increase slightly with increase in survival time after administration of dehydroascorbic acid (Table 5) The amount of noradrenaline recovered from the brain, however was not found to be changed.

The dopamine content in the brains of animals given ascorbic acid was found to be almost identical with that of the controls (Table 6) In the dehydroascorbic acid treated animals on the other hand the dopamine content tended to increase slightly with the dose and also with increase in survival time (Tables 5 and 6)

TABLE 5. Endogenous levels of noradrenaline (NA) (μg/g tissue) in brains and hearts of mice and of dopamine (DA) (μg/g tissue) in brains of mice after injection of 100 mg/kg dehydroascorbic acid to mice sacrificed t different survival times after the injection. The values are means of 4 determinations ± S.E.M.

In control animals treated with H 44/68 3 ½ hours before sacrifice, the contents of noradrenaline and dopamine in the brain were noticeably reduced and the noradrenaline level in the heart was slightly decreased compared to non-treated control animals. This indicates a blocking of the catecholamine synthesis in the two organs.

After premedication with H 44/68, injection of 100 mg/kg of dehydroascorbic acid caused a marked decrease of the amount of endogenous noradrenaline in both brain and heart tissues (Table 7). The dopamine level was the same in the treated animals as in the control animals. Administration of the same dose of ascorbic acid did not change the amounts of noradrenaline and dopamine in either of the two tissues.

TABLE 7. Endogenous levels of noradrenaline (NA) (μg/g tissue) in brains and hearts and of dopamine (DA) (μg/g tissue) in brains 30 minutes after an intravenous injection of 100 mg/kg dehydroascorbic acid or ascorbic acid to mice. All the animals were premedicated with H 44/68 (500 mg/kg i.p.) 3 ½ hours before sacrifice. The values are means ± S.E.M. The number of determinations is shown in brackets.

	Brain NA	Heart NA	Brain DA

Discussion

In the present investigation it was observed that the recovered amount of endogenous noradrenaline in the brain of animals injected with either dehydroascorbic acid or ascorbic acid was almost identical with that of the control animals. When the catecholamine synthesis was blocked with H 44/68 injection of dehydroascorbic acid resulted in a pronounced decrease in the level of endogenous noradrenaline. Administration of ascorbic acid on the other hand did not appear to influence the noradrenaline level. These results indicate that injection of dehydroascorbic acid is followed by a release of brain noradrenaline. It is assumed that a similar noradrenaline release occurs in other species and may explain the central adrenergic effects of injected dehydroascorbic acid described earlier (Chapter I, Parts 2, 5 and 6)

The fact that the noradrenaline level was unchanged when the catecholamine synthesis was intact is most certainly due to the circumstance that the release caused by injected dehydroascorbic acid is compensated by new formation of noradrenaline, indicating an increased turnover of noradrenaline. It has been considered that increased activity in adrenergic nerves produced by e.g. electrical stimulation has very little or no effect on their noradrenaline level (Euler and Hellner Björkman 1955) due to effective mechanisms for keeping a constant level of transmitter concentration.

The noradrenaline levels in the hearts of normal and premedicated animals were affected in a similar manner as observed in the brains after injection of dehydroascorbic acid and ascorbic acid. This shows that injection of dehydroascorbic acid is also followed by a release of noradrenaline in the heart. This observation and the fact that the noradrenaline level in the heart was unchanged after injection of dehydroascorbic acid into animals with intact catecholamine synthesis, indicate that dehydroascorbic acid causes an increase in noradrenaline turnover in the heart. Injected ascorbic acid, however did not seem to possess any releasing action on the heart noradrenaline.

In Chapter III it was suggested that dehydroascorbic acid was taken up into adrenergic nerve cells in the brain and heart tissues of the mouse and that the uptake of ascorbic acid on the other hand was more doubtful. The present results support this suggestion, since injected dehydroascorbic acid, by contrast to injected ascorbic acid, clearly interferes with the noradrenaline content in both tissues.

CHAPTER V

Effects of Dehydroascorbic Acid and Ascorbic Acid on Cholinesterases *in vitro*

Some of the effects of injected dehydroascorbic acid, e.g. facilitation of neuromuscular transmission (Chapter I Part 4) were thought to be due to an interaction with cholinergic mechanisms. This facilitatory effect was only seen when high doses of dehydroascorbic acid were given intravenously showing an action similar to cholinesterase inhibitors (see review by Karczmar 1967). Administration of ascorbic acid on the other hand did not appear to cause facilitation of neuromuscular transmission.

It has also been observed that injection of high doses of dehydroascorbic acid potentiates the depressor response to injected acetylcholine in cats and rabbits (Chapter II) suggesting an inhibition of cholinesterases by dehydroascorbic acid (or metabolically formed ascorbic acid).

The aim of the present investigation was to determine whether dehydroascorbic and/or ascorbic acid were able to inhibit cholinesterases. The investigation was performed on blood cholinesterases in man, cat and rabbit by using an *in vitro* method.

Materials and methods

The presumed inhibitory effect of dehydroascorbic acid (obtained by ascorbic acid oxidation) on cholinesterases was determined by an electrometric routine method (Tammelin 1953) using erythrocytes and plasma from man, cat and rabbit. Ascorbic acid was tested only on human cholinesterases in erythrocytes and plasma. For preparation of dehydroascorbic acid and ascorbic acid see Chapter I Part 1.

Erythrocytes and plasma from human, cat and rabbit blood were used as sources of acetylcholinesterase and butyrylcholinesterase respectively and were prepared from heparinized blood by centrifugation. The red blood cells were washed 3 times with physiological saline solution and suspended in distilled water in the proportion 1 + (v/v). The plasma was also diluted with distilled water in the proportion 1 + (v/v). One ml of the erythrocyte or plasma solution was used for each determination. The cat erythrocytes, however had a low normal cholinesterase activity.

The enzyme preparations were incubated at 25 C for about 10 minutes in

test tubes with different concentrations of either dehydroascorbic acid (10^{-3}—10^{-5} M) or ascorbic acid (up to 2×10^{-3} M) To the incubation tubes were also added 3 ml of a veronal buffer (pH 8.2) (Michel 1949) and distilled water to a final volume of 6 ml.

Acetylcholine iodide was used as a substrate for the cholinesterases. Of a standard solution of acetylcholine iodide (2.2 g/100 ml) 0 6 ml was added to the incubation solution after 30 minutes incubation of the enzyme with the inhibitor The acetylcholine concentration was 7.3 mM.

One of the incubation solutions of each run (comprising 6 determinations) served as a control and therefore no inhibitor" was added.

The hydrolysis of acetylcholine by the cholinesterases was recorded as the pH changes in the reaction vessels, caused by the liberated acetic acid. Spontaneous hydrolysis was corrected for The inhibitory effect was expressed as the remaining cholinesterase activity in per cent of the control activity in the presence of different concentrations of inhibitor The inhibitory power was expressed as pI_{50} (the negative logarithm of the inhibitor concentration giving 50 % inhibition)

Each value presented in the results is the mean of 2 determinations.

Results and comments

Determinations of the inhibitory effect of dehydroascorbic acid and ascorbic acid on cholinesterases showed that ascorbic acid had no effect on either acetylcholinesterase (erythrocytes) or butyrylcholinesterase (plasma) from human blood. The highest concentration of ascorbic acid tested was 2×10^{-3} M. Dehydroascorbic acid on the other hand showed slight inhibitory action on both kinds of cholinesterases in human and rabbit blood. The cholinesterase inhibiting effect, expressed as pI_{50} of dehydroascorbic acid in erythrocytes and plasma in the different species are presented in Table 8. Cholinesterase in rabbit erythrocytes was inhibited somewhat more than in the plasma. The lowest inhibitory action was found in plasma from cat blood.

It may be pointed out that the observed anticholinesterase properties of dehydroascorbic acid are very weak compared to conventional cholinesterase inhibitors which should inhibit a cholinesterase in concentrations below 10^{-8} M (for comparison see Augustinsson 1963)

It is known that dehydroascorbic acid easily decomposes at room temperature and at neutral pH values (see Chapter I Part 1) This probably means that the dehydroascorbic acid added to the incubation tubes gradually decomposed and consequently the cholinesterase-inhibiting effect observed was lower than it would have been if the dehydroascorbic acid had been protected

TABLE 8. Cholinesterase-inhibiting effect, expressed as pI_{50} of dehydroascorbic acid in erythrocytes and plasma in different species.

against decomposition. Erythrocytes also contain a factor which reduces dehydroascorbic acid to ascorbic acid (Panteleeva 1952 Christine *et al.* 1956 Hendry *et al* 1964) thus causing at least a partial decomposition of added dehydroascorbic acid in the erythrocyte preparations. However as mentioned at the beginning of this chapter high doses of dehydroascorbic acid had to be injected *in vivo* in order to visualize interference with cholinergic mechanisms. Consequently the amount of circulating dehydroascorbic acid is fairly high and may inhibit cholinesterases not only in the blood but also at cholinergic transmitter sites, e g the neuromuscular junction in skeletal muscles. This may be a possible explanation of the observed *in vivo* effects after injection of dehydroascorbic acid. It may be noted that ascorbic acid, which appears to be devoid of cholinesterase-inhibiting action was found not to interfere with neuromuscular transmission (Chapter I Part 4)

General Discussion

Earlier investigations (Patterson and Mastin 1951 Wegman 1958) and the present study show that injection of dehydroascorbic acid is followed by some marked pharmacological responses which may be referred to as activation of certain mechanisms in the central and peripheral nervous systems. In the present study it has been observed that injected dehydroascorbic acid interferes with both cholinergic and adrenergic mechanisms in cats and rabbits and the results are compatible with those obtained in other species (Patterson and Mastin 1951 Wegman 1958)

Injected ascorbic acid, on the other hand, did not reveal any conspicuous pharmacological activity on the various parameters studied. Earlier investigations have shown that injected ascorbic acid causes hypertension (Reuter 1938) or hypotension (Kreitmair 1934 Wegman 1958) Wegman (1958) showed that intravenous injection of a strongly acidic solution (pH 2.2) of ascorbic acid resulted in a fall of the blood pressure, but if the solution was buffered to pH 4—6.5 it did not cause any alteration at all in the blood pressure when injected. The transient depressor response observed in the present experiments may be ascribed to the low pH of the injected solution (pH 2.2) or possibly the rather large volume injected (1—3 ml/kg)

The most prominent responses observed after injection of dehydroascorbic acid into both conscious (rabbits and mice) and anaesthetized (rabbits and cats) animals were the pronounced increase in salivation and lacrimation. It was observed that these effects were inhibited by premedication with atropine (Chapter I Part 2) decerebration and spinalization (Chapter I Part 6) These results suggest a central site of action and most probably an interaction with cholinergic mechanisms. The present results are compatible with observations in conscious rats by Patterson and Mastin (1951)

Similar site and mechanism of action of injected dehydroascorbic acid may also be assumed when causing an increase in lacrimation.

In the anaesthetized cats, ear twitching was frequently observed following injection of large doses of dehydroascorbic acid. This phenomenon has been noticed after administration of compounds known to interfere with cholinergic mechanisms such as cholinesterase inhibitors (see Karczmar 1967) and nicotine (Armitage *et al.* 1966 Hall and Rent 1966) Since this action of nicotine is referred to as an activation of central cholinergic mechanisms, it is believed that injected dehydroascorbic acid activates these mechanisms, most probably

by means of cholinesterase inhibition, analogous to the interpretation of some peripheral effects of high doses of injected dehydroascorbic acid.

Facilitation of neuromuscular transmission and increased depressor response to injected acetylcholine were observed following intravenous administration of high doses of dehydroascorbic acid. Similar effects on neuromuscular transmission were also obtained following close intraarterial injection of small doses of dehydroascorbic acid. Both these effects are interpreted as being due to a cholinesterase-inhibiting action of dehydroascorbic acid (Chapter V)

Ascorbic acid, on the other hand, did not affect neuromuscular transmission. Neither does ascorbic acid seem to possess cholinesterase-inhibiting properties, judging from experiments on human blood cholinesterases (Chapter V)

Another pronounced response observed following injection of dehydroascorbic acid was increased motor activity (Chapter I Part 2) This effect was noticed in conscious mice and rabbits as well as in anaesthetized rabbits and cats. Similar response of injected dehydroascorbic acid has earlier been reported in other species such as conscious rats (Patterson and Mastin 1951) and guinea-pigs (Lyhs and Tegeler 1963) The arousal effect in the anaesthetized animals was shown to be inhibited after decerebration or spinal cord section (Chapter I Part 6) demonstrating a central site of action. As mentioned in Chapter I Part the effects in both conscious and anaesthetized animals are thought to be expressions of the same mechanism(s) Facilitation of neuromuscular transmission caused by dehydroascorbic acid is presumably a contributory factor to the observed increase in motor activity

The behavioural pattern (rage and arousal symptoms) observed in the conscious and anaesthetized animals after injection of dehydroascorbic acid is very similar to that observed after chemical stimulation of certain areas in the brain e.g after administration of centrally active cholinesterase inhibitors. The behavioural changes caused by these substances are controlled by atropine (Langley and Kato 1915) The increased motor activity caused by injected dehydroascorbic acid, however was found to be unchanged by atropine treatment, suggesting that dehydroascorbic acid influences other central mechanisms than cholinergic when causing this response.

It has been reported that activation of certain sympathetic centres in the brain evokes similar behavioural patterns (reviewed by Gellhorn 1943) to those observed after administration of dehydroascorbic acid. Electrical stimulation of these areas produces so called sham rage which is characterized by peripheral signs of sympathetic hyperactivity and aggressiveness. Thus stimulation of the amygdaloid nucleus results in facial twitching, alertness, mydriasis, mastication salivation and vasoconstriction (Gunne and Reis 1963) These effects were associated with a lowering of the brain noradrenaline content. Central excita

tion is also observed following morphine treatment, which has been associated with the noradrenaline releasing properties of morphine (Vogt 1954) Since dehydroascorbic acid causes similar responses and since it evidently causes an increased release of noradrenaline in the brain (Chapter IV) a stimulatory effect on central sympathetic centres is suggested as the trigger mechanism. Autoradiographic investigations with labelled dehydroascorbic acid have shown that the substance easily passes the blood-brain barrier and that the gray matter of the brain accumulates more of the labelled substance than the white matter but that the distribution is relatively diffuse (Hammarström 1966)

Histochemical and autoradiographical studies have also shown that ascorbic acid and dehydroascorbic acid are accumulated in peripheral nervous tissue (Clara 1954 Hammarström 1966) Furthermore there appears to be a correlation between the localization of these substances and the sites of catechol amine synthesis (Hammarström 1966) It has also been shown that injection of dehydroascorbic acid causes a rise in blood pressure in a similar manner to indirectly acting sympathomimetic amines (Chapter II) Wegman (1958) presented evidence indicating a slight peripheral sympathomimetic effect on the heart of the cat by injected dehydroascorbic acid. In order to check the possible peripheral action of dehydroascorbic acid and ascorbic acid the influence of these substances on the nictitating membrane was investigated.

When tested on the non stimulated nictitating membrane injected dehydroascorbic acid caused two different types of response, relaxation and constriction. The type of response appeared to be dependent on the anaesthetic used.

The relaxing effect of injected dehydroascorbic acid on the nictitating membrane in pentobarbitone anaesthetized cats was inhibited by atropine and even turned into a constriction. These results may suggest an influence on cholinergic mechanisms by dehydroascorbic acid. Whether the activation is evoked from central or peripheral sites is not known.

After injection of ascorbic acid, on the other hand, no convincing pharmacological effect was observed.

In the chloralose-urethane anaesthetized cats, injection of dehydroascorbic acid caused constriction of the nictitating membrane. This response was greatly reduced after treatment with adrenergic α- and β-receptor blocking compounds, indicating an involvement of adrenergic mechanisms. It was further shown that the constrictor response was inhibited by preganglionic sympathectomy thus indicating a central activation of the sympathetic nerves running to the nictitating membrane.

The observed differences between the response in the pentobarbitone and the chloralose-urethane anaesthetized animals are most probably due to different modifying properties of the anaesthetic on the central nervous system.

Ascorbic acid on the other hand, did not produce sympathommetic effects on the blood pressure when injected (Chapter I Part 5) Neither did it influence the levels of endogenous noradrenaline (Chapter IV) It was also observed that very little of this substance was taken up in brain and heart tissues as compared to dehydroascorbic acid (Chapter III) which is in agreement with earlier observations (Hammarström 1966) The differences in uptake between the two substances may be attributed to different physico-chemical properties, dehydroascorbic acid being more lipoid soluble than ascorbic acid (Grab 1965) It has also been suggested that dehydroascorbic acid is the form for transport of ascorbic acid across cellular barriers (Patterson and Martin 1951 Martin 1961 Martin and Mecca 1961)

From the present study it seems as if dehydroascorbic acid but not ascorbic acid is taken up into adrenergic nerve terminals. Autoradiographic studies have revealed that both substances are distributed fairly equally in the body A significan uptake of both substances has been observed in sympathetic ganglia (Hammarstrom 1966) where the cell bodies of the postganglionic fibres are located and here the amine granules are thought to be synthetised (review by Andén *et al.* 1969) If ascorbic acid really acts as a co-factor at dopamine β-hydroxylation *in vivo* (cf Kaufman and Friedman 1965) it would enter its site of action in the cell bodies. Then it should be transported down the axon together with amine granules (see Andén *et al.* 1969) Laduron and Belpaire (1968) showed that dopamine-β-hydroxylase accompanies the amine granules on their way down the axon. After reaching the nerve terminals the enzyme still functions probably without losing any vital co-factor such as ascorbic acid. When ascorbic acid is utilized it is oxidized to semidehydroascorbic acid (an unstable product with only one of the hydroxyl radicals of ascorbic acid oxidized) or dehydroascorbic acid which is rapidly reduced again, regenerating ascorbic acid (review by Schneider and Staudinger 1964) It would appear improbable that ascorbic acid is lost during participation in this reaction. Thus it may be assumed that there is no need for additional extracellular ascorbic acid for dopamine β-hydroxylation. Consequently there would appear to be no need for dehydroascorbic acid to function as a form of transport for ascorbic acid across adrenergic cell membranes at nerve terminals as has previously been suggested.

Injected dehydroascorbic acid has been shown to be fairly rapidly reduced to ascorbic acid in the tissues (Patterson and Martin 1951 Hammarstrom 1966, Heath and Fiddick 1966) Patterson and Martin postulated that central nervous system stimulation following injection of dehydroascorbic acid is produced by metabolically formed ascorbic acid. However their explanation is rather doubtful for several reasons.

As shown by distribution studies, the metabolically formed ascorbic acid from injected dehydroascorbic acid is retained in nervous tissue for several days (Hammarström 1966) and if due to formed ascorbic acid the pharmacological effects of injected dehydroascorbic acid would be more long lasting. The latent period would also be more prolonged. In the present experiments all the pharmacological responses were transient, lasting for about 2—3 minutes.

Ascorbic acid is thought to participate in catecholamine synthesis and has been shown to function as a co-factor in dopamine β-hydroxylation *in vitro* (reviewed by Kaufman and Friedman 1965). Experimental data have been presented suggesting that ascorbic acid is also involved in this enzymatic reaction *in vivo*. Izquierdo *et al.* (1968) reported that ascorbic acid injected intraperitoneally into rats caused an increase in the endogenous noradrenaline level and a decrease in the dopamine level in various parts of the brain which was associated with an increase in dopamine-β-hydroxylase activity. In the present study injection of dehydroascorbic acid was shown to cause an increased release of noradrenaline in the brain (Chapter IV).

There is evidence suggesting that ascorbic acid is implicated in the storage mechanism of noradrenaline. Thoa *et al.* (1966) observed a reduced ability of the heart of scorbutic guinea pigs to take up and bind injected labelled noradrenaline. They also noticed a reduction of the level of endogenous noradrenaline in these hearts. Recently Sears (1969) found that endogenous noradrenaline concentration in the iris of the scorbutic guinea pig is decreased to about 50 % of the amount of noradrenaline present in the iris of normal animals. In the same investigation it was found that the turnover time of noradrenaline was much shorter in the scorbutic iris than in the control and it was suggested that the scorbutic iris has a reduced storage capacity for noradrenaline. The same conclusion was earlier drawn by Bhagat *et al.* (1966) making the same observations in isolated atria from scorbutic guinea pigs. In the present study it was noticed that injection of dehydroascorbic acid was also followed by an increased turnover of noradrenaline.

The relationship between the pharmacological effects of injected dehydroascorbic acid and the suggested mechanisms of action of ascorbic acid therefore appears to be small. It appears more likely that dehydroascorbic acid enters adrenergic cells at nerve terminals, reaches storage sites for noradrenaline and interferes with the storage mechanism in a different manner to ascorbic acid.

In many respects the action of dehydroascorbic acid is very similar to that of sulphydryl inhibitors. Mercury derivatives, e.g. parachloromercuribenzoate, exert a pronounced releasing activity on granular catecholamines *in vitro*

(D Iorio 1957) Keswani *et al.* (1969) presented strong evidence that the uptake of SH inhibitors by storage granules is a reversible exchange process involving protein-sulphydryl groups. They suggested that SH groups arising from the granule protein serve as anchoring sites for catecholamine complexes (involving ATP and Mg^{++}) The SH inhibitors are believed to engage the sulphydryl sites within the granule, thus reducing the possibility of formation of an ATP—Mg^{++}—catecholamine complex.

It has been reported that dehydroascorbic acid and SH compounds (glutathione, cystein) react to form a complex or addition compound *in vitro* (Drake *et al.* 1942) It is also known that sulphydryl compounds are essential for the reduction of dehydroascorbic acid in the tissues (Hughes 1964 Grimble and Hughes 1967) In red blood cells glutathione is involved in the conversion of dehydroascorbic acid into ascorbic acid, the latter being retained within the corpuscles (Borsook *et al.* 1937 Panteleeva 1952, Hughes 1964) Dehydroascorbic acid is also taken up in leucocytes and reduced, this being inhibited by SH inhibitors (Hendry *et al.* 1964)

It may be assumed that dehydroascorbic acid, like genuine SH inhibitors, occupies granular SH groups thus inhibiting the binding mechanism of noradrenaline. This impairment of the amine storage sites would result in an increased amount of non-bound noradrenaline available for release and consequently leading to an increased response when stimulated. This may be an explanation for the observed sympathomimetic effects (increased sympathetic tone) of injected dehydroascorbic acid.

There seems to be a relationship between sites of high rate of noradrenaline turnover and sites where injected dehydroascorbic acid produces sympathomimetic responses.

The turnover of noradrenaline is much faster in the central than in the peripheral neurons (see Andén *et al.* 1969) Injection of dehydroascorbic acid is followed by a pronounced central activation of efferent adrenergic nerves causing a rise in the blood pressure and constriction of the nictitating membrane. Data are presented suggesting that the pressor effect of injected dehydroascorbic acid is evoked from *adrenergic sites in the central nervous system*. Peripheral adrenergic effects were found to be very small.

From these conclusions the following summary may be made regarding a possible mechanism of the sympathomimetic action of dehydroascorbic acid. It is suggested that injected dehydroascorbic acid is taken up into adrenergic cells and reaches amine storage granules. Here it interferes with the binding mechanism of noradrenaline by causing an impairment of the amine storage sites. Dehydroascorbic acid probably occupies binding sites for noradrenaline resulting in an increased amount of free amine in the granules. When these

granules are activated (physiologically) a larger amount of noradrenaline will be released, resulting in an increased response. Dehydroascorbic acid was found to increase the noradrenaline turnover in both brain and heart tissues, indicating an action at both central and peripheral adrenergic sites. However the pharmacological action of injected dehydroascorbic acid was far more pronounced at central sites. This may be explained by the fact that the normal noradrenaline turnover is much faster in the brain than in the peripheral tissues and therefore more sensitive to changes. It may be possible that dehydroascorbic acid and ascorbic acid play a physiological role in the binding (storage) mechanism of noradrenaline in granules.

Summary

In the present study dehydroascorbic acid and ascorbic acid were injected into various species of laboratory animals (conscious and anaesthetized). The pharmacological responses to both substances were observed in normal and premedicated animals. General pharmacological tests were performed and the parameters studied were motor activity, salivation, lacrimation, tone of the nictitating membrane, sympathetic ganglionic transmission, neuromuscular transmission and blood pressure (Chapter I). The response to injected dehydroascorbic acid following decerebration, spinal cord section and bilateral adrenalectomy was observed (Chapter I). From the results it became evident that ascorbic acid did not cause any conspicuous pharmacological responses. On the other hand, when dehydroascorbic acid was injected, marked pharmacological effects were recorded. Some of these were considered as being due to interaction with cholinergic mechanisms and others with adrenergic mechanisms. Most of the responses following injection of dehydroascorbic acid were found to originate from the central nervous system.

In conscious mice and rabbits administration of dehydroascorbic acid was followed by increased motor activity, salivation and lacrimation. In anaesthetized cats and rabbits an arousal effect, increased salivation and lacrimation were observed. These effects were shown to be evoked in the central nervous system. The increased salivation and lacrimation were inhibited by atropine, indicating involvement of cholinergic mechanisms.

When dehydroascorbic acid was tested on the non-stimulated nictitating membrane two kinds of response were obtained depending on the anaesthetic used. In pentobarbitone anaesthetized cats, injected dehydroascorbic acid caused a relaxation which was converted to a constriction after atropine treatment, suggesting an activation of cholinergic mechanisms. In chloralose-urethane anaesthetized cats, dehydroascorbic acid caused a constriction of the nictitating membrane. This response was inhibited by premedication with adrenergic α- and β-receptor blocking compounds indicating an activation of adrenergic mechanisms. The constrictor response was also shown to be evoked in the central nervous system. Injection of ascorbic acid, on the other hand, caused only an occasional, small constriction of the nictitating membrane.

Injected dehydroascorbic acid seemed to affect the response of the stimulated nictitating membrane in a similar manner to catecholamines. Ascorbic acid, however, did not influence the response to stimulation at all.

Facilitation of neuromuscular transmission was observed after administration of dehydroascorbic acid but not ascorbic acid.

In both cats and rabbits injection of dehydroascorbic acid was followed by a transient rise in the blood pressure. This response was abolished after spinal cord section but did not change after decerebration. Premedication with ganglion blocking compounds inhibited the pressor response to injected dehydroascorbic acid (Chapter II). The results indicated that the hypertensive effect was mainly of central origin most probably evoked in the vasomotor centre in the medulla oblongata.

After injection of dehydroascorbic acid into spinalized cats and rabbits, an increase of the systolic blood pressure was observed. This response was believed to be due to a peripheral action of dehydroascorbic acid at adrenergic sites.

The pressor response was strongly inhibited following treatment with various agents interfering with adrenergic mechanisms reserpine guanethidine, bretylium, desmethylimipramine, imipramine, cocaine, propranolol and dihydroergotamine (Chapter II). The results suggested that dehydroascorbic acid interferes with adrenergic mechanisms causing an increase of the tone maintaining the blood pressure.

The accumulation of ^{14}C-labelled dehydroascorbic acid and ascorbic acid in brain and heart tissues of mice was studied (Chapter III). The labelled substances were injected intravenously and the total amount of radioactivity in each tissue 30 minutes after the injection of either substance was estimated.

Some groups of animals were premedicated with compounds known to inhibit the uptake of sympathomimetic amines desmethylimipramine protriptyline cocaine and reserpine. It was observed that the accumulation of labelled dehydroascorbic acid in both tissues was strongly inhibited by premedication with any of the inhibitory compounds. The recovered radioactivity in organs from animals given labelled ascorbic acid did not change after treatment with any of the compounds. Based on these observations and those showing that the pressor response to injected dehydroascorbic acid was inhibited by premedication with the inhibitory compounds. It was suggested that dehydroascorbic acid enters its site of action (most probably adrenergic amine granules) by a mechanism which may be blocked by the compounds known to inhibit cellular uptake of some sympathomimetic amines.

The influence of dehydroascorbic acid and ascorbic acid on the levels of endogenous noradrenaline and dopamine in brain tissue and of noradrenaline in heart tissue of mice has been studied (Chapter IV). Mice were injected intravenously with dehydroascorbic acid or ascorbic acid and the catecholamine content in both tissues was estimated. It was observed that neither dehydroascorbic acid nor ascorbic acid changed the levels of endogenous cate-

cholamines in either tissue. However injection of dehydroascorbic acid after inhibition of catecholamine synthesis was followed by a significantly increased depletion of noradrenaline in both brain and heart tissues. Ascorbic acid, on the other hand, did not change the catecholamine levels after synthesis-blocking

The inhibitory effect of dehydroascorbic acid on cholinesterases was determined *in vitro* by an electrometric method using erythrocytes and plasma from man, cat and rabbit (Chapter V) Ascorbic acid was tested only on human cholinesterases in erythrocytes and plasma. It was observed that ascorbic acid had no effect on the cholinesterases in either erythrocytes or plasma. Dehydroascorbic acid on the other hand showed a slight inhibitory action of both kinds of cholinesterases.

From the various results in the present study it became evident that injected dehydroascorbic acid activates cholinergic mechanisms. It was suggested that the cholinesterase-inhibiting action of dehydroascorbic acid plays a significant role.

Injected ascorbic acid did not seem to interfere with cholinergic mechanisms and was also found to be devoid of cholinesterase-inhibiting activity

The symptomatic action of dehydroascorbic acid was shown to be mainly of central origin and evidences are presented suggesting that dehydroascorbic acid mediated the recorded responses rather than metabolically formed ascorbic acid as suggested by Patterson and Mastin (1951) A probable mechanism of action is discussed.

After injection of ascorbic acid no signs of interference with adrenergic mechanisms were observed

Acknowledgements

The experimental work in the present study was carried out at the Department of Pharmacology Royal Veterinary College, Stockholm (Chapters I—IV) and at the Research Institute of National Defence, Dept 1 (FOA) Sundbyberg, Sweden (Chapter V)

My sincere thanks are due to

Professor Carl G Schmiterlow Head of the Department of Pharmacology who has been my teacher and under whose guidance it has been my privilege to work. His personal interest and stimulating constructive criticism have been of great assistance

Dr Lars Hammarström who directed my interest to these problems

Kabi-Recip drug companies for supporting me in my work

Dr Svante Ross, Astra AB, Södertälje, for fruitful and stimulating discussions

Dr Johan Lundin, for generous help with the experiments reported in Chapter V

Dr Lars-Erik Appelgren for valuable advice and inspiring criticism

Other colleagues in the department for stimulating discussions and encouraging interest

Miss Agneta Janke, Mrs Anita Österbloom, Mrs Marie-Louise Sandberg and Mrs Pia Bergström (FOA) for valuable technical assistance

Mrs Birgitta Hagtorn for skilful preparation of the illustrations

Mrs Ulla Sunnberg for her skill and care in the preparation of the manuscripts

Dr Christopher Hewett for revising the English manuscript.

For generous supplies of drugs I thank the following drug companies AB Astra, Södertälje (H 44/68) through Dr S. Ross S edish Ciba, Vallingby (Ismelin®) Burroughs Wellcome & Co., England (bretylium tosylate) Smith, Kline and French Labs Ltd., England (phenoxybenzamine, Dibenyline®) Merck, Sharp & Dohme the Netherlands (protriptyline hydrochloride)

SUPPLEMENTUM 357

Nordic Society for Cell Biology European Cell Biology Organization

AXOPLASMIC FLOW IN ADRENERGIC NEURONS

Symposium
held at
Institute of Neurobiology
University of Gothenburg
June 5–6 1970

Organized for the Societies by Annica Dahlström

A B S T R A C T S

NSCB The Biological Institute of the Carlsberg Foundation 16 Tagensvej 2200 Copenhagen N Denmark

ECBO Laboratorium voor Celbiologie en Histologie der Rijksuniversiteit te Leiden Rijnsburgerweg 10 Leiden Netherlands

ACKNOWLEDGEMENTS

The generous economical support rendered by Bofors Nobel Pharma AB Hässle AB Lilly Co and FAPI (Representatives of Foreign Pharmaceutical Industries in Sweden) is gratefully acknowledged

A generous supply of beverages during the symposium was obtained from the PRIPP Breweries

PROGRAMME

(Figures refer to abstract numbers)

Axoplasmic transport of neuronal components

Transport and life-span of amine storage granules studied by histochemical and biochemical method A Dahlström & J Häggendal (4)

Electronmicroscopical and biochemical studies on the transport of noradrenaline-containing granules D Mayor & P Banks (18)

Movement of mitochondria within constricted noradrenergic nerve P Banks & D Mayor (2)

The accumulation of DOPA-decarboxylase and MAO activity in rat sciatic nerves after constriction. J Jonsson (10)

Axonal flow of enzymes involved in the biosynthesis of catecholamines P Laduron (16)

Axonal transport in central and peripheral axons J Sjöstrand & J-O Karlsson (22)

A possible role of lysosomal accumulation in constricted in constricted sciatic nerves P Laduron (15)

Transport of Herpes Simplex virus in peripheral nerves K Kristensson E Lycke & J Sjostrand (14)

Axoplasmic transport and nerve function

Immunochemical evidence for the transport of neurophysin in neurosecretory neurons of the dog R Alvarez-Buylla D G Livett L. G Uttenthal B H Milton & D B Hope (1)

Axonal transport of neurohypophyseal proteins in rats under some experimental conditions A Norström & J Sjöstrand (20)

Nerve function after reserpine and axonal flow of amine granules J Häggendal & A Dahlström (8)

Two populations of noradrenaline-particles in the dog spleen W De Potter I W Chubb & A F Schaepdryver (5)

Chromogranins in the catecholamine-storing granules of the adrenal medulla and the splenic nerve trunk. K B Hall (7)

Immunologic l technique for studying the distribution transport and release of chromogranins B G Livett L. B Geffen & R A Rush (17)

Release of chromogranin A and dopamine-β-hydroxylase from adrenergic nerves during nerve stimulation W De Potter A F Schaepdryver & A D Smith (6)

Axoplasmic transport and regeneration

The effect of cut ligation or crush on the synthesis and transport of amine storage granules in rat sciatic nerve L. Karlsson & A Dahlström (12)

Modes of regeneration of adrenergic nerves L. Olson (21)

Mechanisms of axoplasmal transport

Effects of mitosi inhibitors on the transport of amine storage granules in monoaminergi neurons in the rat A Dahlström (3)

Electronmicroscopical observations on the distribution and transport of noradrenaline storage parti l after local treatment with mitosi inhibitors T Hökfelt & A Dahlström (9)

Effect of intravenous vinblastine on intraneuronal transport of noradrenaline in the rat F Kasa & A Livingston (13)

Transport of neurotubular protein and the effect of colchicine on axonal transport J -O Karlsson & J Sjöstrand (11)

Morphology and properties of treatlike lements of the neuron J Matusala (19)

●

1. IMMUNOHISTOCHEMICAL EVIDENCE FOR THE TRANSPORT OF NEUROPHYSI IN NEUROSECRETORY NEURONS OF THE DOG R Alvarez Buylla E G Livett L O Uttenthal E H Milton and D B Hope Departments of Pharmacology Human Anatomy and the Nuffield Department of Experimental Surgery University of Oxford England

The neurosecr tory nerve endings in the posterior pituitary rise from the supra-optic and paraventricular nuclei in the hypothalamu These neurons re chara terized by the presence of Gomori-positive neurosecretory material and, at the ultrastructural lev l by large dense-cored vesicles (1300 Å diam) which store the peptide hormones oxytocin and vasopressin The hormones nd their binding proteins (neurophysins) are probably synthesized in the hypothalamic nucl i and transported down the neuro-hypophyseal tract by oplasmic flow

Two major neurophysin (I and II) have recently been isolated on a large scale from ac tone-dried powder of pig posterior lobes (Uttenthal and Hope Biochem. J. 1970 116 899) and we have prepa ed antibodies to porcine neurophysin-II for use in the indirect or "sandwich method of immunofluorescence histochemistry (Nairn Fluo escent Protein Tracing 1969 Livingstone) to localise this protein in the hypothalamus neuro-hypophyseal tract and posterior lobe of the pig (Livett Uttenthal and Hope Proc int endocrin soc. Bristol, April 1970 in press; Proc roy, soc B in press)

More recently we have made u of an antiserum which cro reacts with dog neurophysin to provide evidence for axoplasmic flow of neurosecretory ve icles in the neurohypophyseal system of the dog The neurohypophyseal stalk of a dog wa exposed at operation by removal of the zygomati arch parietal bone and squamou part of the temporal bone The stalk wa constricted at point with fine forceps and following operation the dog wa allowed to recover consciou ne s After 20 hour the dog wa sacrificed by decapitation under nembutal nd para sagittal nd sagittal sections of the hypothalamo-neurohypophyseal system processed for immunofluorescence Marked ccumulation of fluoresceno ttributabl to neurophysin proximal to the constri tion nd its absence from the portion immedi tely distal to the constriction provides evidence for oplasmic flow of neurophysin from the cell bodi in the hypothalamus to the nerve terminals in the po terior lobe of the pituitary

2. MOVEMENT OF MITOCHONDRIA WITHIN CONSTRICTED MONADRENERGIC AXONS P Banks and D Mayor Depts of Biochemistry and Human Biology & Anatomy University of Sheffi ld England

Following th ligation of cat hypoga tri nerves in vivo mitochondria cha cterized by their electron microscopic morphology and by their cytochrome oxidas otivity ccumulate within the ons on both ids of the constriction and particularly in close proximity to it (Kapeller and Mayor Proc roy soc. B 1969 172 39 and 51; Bank Mangnall and Mayor J. Physiol. 1969 200 745) Thi ccumulation in the 3 mm immediately proximal to a single ligature i always lightly greater than that of th 3 mm immediately di tal to the ligature Within a 1 cm segment of nerve isol ted by two lig tures the total cytochrome oxidase activity does not change significantly with time but is redistributed so that the regions immediately adjacent to the two constrictions contain the highe t enzyme tivities and the greatest number of mitochondrial profiles This ob ervation indicates that the axonal mitochondria are able to redi tribute themselves independently of the cell body by moving in both proximo-di tal and disto-proximal directions This is in trong contrast to the uni-directional movement of dense-cored

vesicles It seems probable therefore that mitochondria and den e-cored ve icles move by different mechanisms

In addition to a redistribution of existing mitochondria it seems probable that the cell bodies contribute to the accumulation of mitochondria on the proximal side of a ingle constriction ince the total cytochrome oxidase of the nerve from ganglion to ligature rises above the control level In contrast it falls below the control level a few mm distal to the constriction

Mitochondria very close to a constriction (within 0 1 mm) tend to be very swollen electron lucent and are probably degenerating Slightly further from the constriction they are still somewhat swollen but not obviously degenerated About 0 5 - 1 mm from the constriction the majority have the elongated and electron dense appearances of normal axonal mitochondria

It has recently been established that mitochondria distribute themselves in constricted axons in vitro in the same manner as in vivo

The factors involved in inducing and sustaining mitochondrial movement in axons are not yet understood

3. EFFECT OF MITOSIS INHIBITORS ON THE TRANSPORT OF AMINE STORAGE GRANULES IN MONOAMINERGIC NEURONS IN THE RAT

A Dahlström, Dept of Histology Inst of Neurobiology University of Göteborg Göteborg Sweden

The proximo-distal transport of amine granules is of the fast type and as such suggested to involve microtubules (cf Schmitt Proc nat Acad Sci 1968 60 1092) Colchicine (COL) and vinbla tine (VIN) both disrupting microtubules were applied locally to adrenergic neurons in the PNS and in the CNS (spinal cord) Effects were obtained with 0 035 and 0 001 M concentrations of COL and VIN respectively

Soaking lumbar sympathetic ganglia with COL (Dahlström, Eur J pharm 1968 5 111) or VIN for 10 min caused a medium increase of noradrenaline (NA) in cell bodies and intraganglionic axons already after 3 h and a marked increase by 24 h Reserpine abolished the NA fluorescence totally indicating that all NA was stored in granules Sciatic nerve ligation 1 h before death 24 h after treatment caused very little or no NA accumulations Controls had normal accumulations The results indicate an arrest of the transport of amine granules from ganglia to axons

Unilateral soaking of cervical superior ganglia with VIN caused in addition to the above mentioned accumulation of NA in cells andintraganglionic axons a disappearance of almost all nerve terminals in the iris of the treated side while the contralateral iris (saline soaked) was normal Unilateral pto is (occuring 18 24 h after operation) wa always observed Administration of α-methyl-NA did not increase the number of nerve terminals observed indicating nerve terminal degeneration Five - 10 d after treatment growth cones were observed in branches of the few remaining nerve terminals Local VIN treatment thu probably cause interruption of not only transport of amine granules but also of substances needed to maintain the nerve terminal membrane

Local application of VIN or COL on the spinal cord caused accumulations of NA and 5-hydroxytryptamine (5 HT) in descending axons of NA and 5-HT containing bulbo-spinal neurons respectively

The results indicate that COL and VIN inhibit the transport of amine storage granules in both central and peripheral monoamine containing neurons Since both substance depolymerize microtubules the results may support the view that microtubules are involved in fast transport of amine storage granules

4. TRANSPORT AND LIFE SPAN OF AMINE STORAGE GRANULES STUDIED BY HISTOCHEMICAL AND BIOCHEMICAL METHODS A Dahlström and Jan Häggendal Institute of Neurobiology and Department of Pharmacology University of Göteborg Göteborg Sweden

A proximo-distal transport of noradrenalin (NA) containing granules has been demonstrated to take place in peripheral and central aminergic neurons (for ref see Dahlström and Häggendal in: Biochemistry of Simple Neuronal Models eds Costa and Giacobini Raven Press 1970 65) Ligation of adrenergic nerves results in an accumulation of NA proximal to the ligation The NA increases approximately linearly up to about 48 h indicating a rate of transport of about 5 mm/h in rat sciatic nerve (Dahlström and Häggendal Acta Physiol. Scand 1966 67, 278) Between simultaneous double ligations a proximo-distal shift of NA was observed but no clear net change in NA in the separated nerve part (Dahlström Acta physiol. scand. 1967 69, 158 Bank Mangnall and Mayor J. Physiol. (Lond.) 1969 200, 745) Based on a) the amount of NA accumulating in the sciatic nerve during 12 h b) the NA amount in the nerve terminals of the adrenergic axons in the sciatic nerve and c) the assumption that amine granules are equally loaded with NA in all parts of the neuron a life-span of about 5 week was earlier calculated for amine granules in adrenergic nerv terminals of the rat

Recent result indicate however that amine granules may be less loaded with NA in the axons than in the nerve terminals Three consecutive 1 cm parts of unligated sciatic nerve were examined for NA content A gr dient wa observed the lowest part of nerve having somewhat higher NA content than the more proximal parts This may indicate either an increa e number of granules in the distal parts of the nerve or an increased loading of NA in the granules occurring during their passage down the axon In support of the last mentioned interpreration delayed double ligations (a low ligation followed 6 h later by a second ligation 1 cm proximal to the first one) resulted in a NA increase of about >0% 9 h after the second ligation Reserpine could depl te the NA in the separated nerve part indicating that the NA increase probably occurred in the amine granules accumulated in thi nerve part during the 6 h after the first low ligation (Dahlström Häggendal Larsson and Magnusson in prep) These results have been u ed for a re-estimation of the rate of transport and life-span of amine torage granules in rat adrenergic neurons The rate of transport is then calculated to about 3-4 mm/h whereas the averag life-span of the granules regarding their capacity to tore endogenou NA ha been calculated to about 3-4 weeks

Supported by S.M F (grants no B70-14X-166-06B and B70-14X 3207-04)

5. TWO POPULATIONS OF NORADRENALINE-PARTICLES IN THE DOG SPLEEN W P De Potter I W Chubb A F De Schaepdryver Heymans Institute of Pharmacology University of Ghent Belgium

The presence of noradrenaline (NA) storage particles in sympathetic nerves a hown by biochemical and morphological tudi s is now well proven and generally accepted The ite of synthe i of these parti les is thought to be in the cell body of the neuron and that they are supplied to the periphery by a process of axoplasmic flow

Recent morphological evidence ha shown that for the cat spleen there ar two ires of vesicles in the terminals only one of which is present in the splenic nerv axons (Geffen and Ostberg J. Physiol., 1969 204, 583) Biochemically evidence ha been presented for a dual di tribution of NA in the rat heart (Roth, Stjärne Bloom and Olarman J Pharmacol exptl Therap 1968 162, 203) and

in the dog spleen (De Potter (1968) Thesis University of Ghent)

More recent work in this laboratory using denervated spleens has shown that both populations are intraneural and that the addition of KCl Mg^{++} or buffers to sucrose does not alter the NA distribution on gradients The densities of the two particles are (means ± S D) 1 128 ± 0 005 (11 spleens) and 1 178 ± 0 011 (12 spleens)

Dopamine-β Hydroxylase activities shown to coincide with NA particles from splenic nerve (Smith De Potter De Schaepdryver Arch, int Pharmacodyn ther, 1969 179 495) was measured on gradients from the spleen The enzyme reflected the NA distribution of the more dense particle but not of the other This finding plus the evidence of a single di tribution of NA from the splenic nerve axons indicates that while one particle may be synthesized and transported from the neuronal cell body the less dense particle must be derived from some other site

6. RELEASE OF CHROMOGRANIN A AND DOPAMINE β-HYDROXYLASE FROM ADRENERGIC NERVES DURING NERVE STIMULATION W P De Potter A F De Schaepdryver nd A D Smith Heymans Institute of Pharmacology University of Ghent Belgium and Department of Pharmacology University of Oxford England

Evidence has accumulated over the pa t few years for an exocyto is type release of catecholamine from the adrenal medulla Experiments were carried out in this laboratory to determine whether such a mechanism was possible for sympathetic nerves One approach to this problem i to determine whether the intravesicular contents are released concomitantly with noradrenaline on nerve timulation

Biochemical evidence has shown that dopamine-β-hydroxylase and chromogranin A the mayor protein constituents of the adrenal chromaffin granule are also present in the noradrenalin-containing vesicles of bovine splenic nerve (Smith De Potter and De Schaepdryver Arch, int Pharmacodyn ther 1969 179 495; Hörtnagl Hörtnagl and Winkler J. Physiol. (Lond) 1969 205 103)

Bovine calf spleens were perfused with Tyrode solution and the splenic nerves were stimulated at 30/sec supramaximally The perfusate from the splenic vein was collected and assayed for noradrenaline dopamine-β-hydroxylase and chromogranin A The results clearly show a imultaneou release of all three The ratio s of both proteins to noradrenaline were much lower than those found in intact plenic nerve vesicles Of the possibilities that could explain these differenc the two most likely are a slow rate of diffusion of the proteins or the presence of a noradrenaline-containing particle lacking either or both proteins The relea s of noradrenalin and proteins from calf pleen was not prevented by the addition of either hexamethonium-bromide (3 mM) or phenoxybenzamine (0 05 mM) to perfusion fluid However omis ion of calcium from the perfusion fluid trongly inhibited the relea e of noradrenaline a well s dopamine-β-hydroxyla e nd chromogranin A

Release of the two vesicle-proteins upon stimulation of the nerve wa not accompanied by release of DOPA-decarboxylase an enzyme present in the soluble xoplasm and so the observ tions are consistent w th the idea that the neurotransmitter is released by exocyto i

7. CHROMOGRANINS IN THE CATECHOLAMINE-STORING GRANULES OF THE ADRENAL MEDULLA AND THE SPLENIC NERVE TRUNK K B Helle Institute of Physiology University of Bergen Norway

Two proteins have so far been found to be characteristic of the catecholamine-storing granule namely chromogranin A and dopamine-β-hydroxylase By immunological techniques both proteins purified from the adrenal medulla have been shown to be identical to proteins present in the noradrenaline-rich particulate fraction of splenic nerve (Bank Helle & Mayor Mol. Pharmacol. 1969 5 210; Geffen Livett & Rush J. Physiol. 1969 204 589)

In the chromaffin granule of the adrenal medulla both chromogranin A (Helle & Serck Hanssen Pharmacol. res. comm. 1969 1 25) and dopamin β-hydroxylase (Laduron & Belpaire Biochem. Pharmacol. 1968 17 1127) occur in a membrane-bound as well as in a soluble form In its bound form chromogranin A has been found to be associated with phospholipids in a complex which can be distinguished from the soluble chromogranin A by its lower mobility in an electric field

In particulate fraction of splenic nerve homogenates chromogranin A has been detected mainly as the water insoluble membrane-bound form and this fraction accounted for about 80% of the total chromogranin detected in the particulate fractions The ratio of CA chromogranin was found to be approximately 1000 nmoles/mg (Bank & Helle Proc roy Soc (Lond) 1970) This value is five-fold less than that obtained for medullary granules and also much less than for granules isolated from nerve terminals (De Potter Proc. roy. Soc. (Lond) 1970) The nerve granules may thus not be fully loaded with transmitter while being transported down the axon

One of the main functional differences between the medullary granules and the nerve granules may well be related to their difference in content and distribution of lipids illustrated by the detection of chromogranin A mainly in the membrane bound form in the nerve granule The water-soluble fraction of the nerve granule apparently accounts for a much smaller proportion of the total granule than is the case for the medullary granule Thus the fraction of protein expected to leave the nerve granule by an exocytotic mechanism of secretion of transmitter must be rather small as indeed experimentally shown (De Potter De Schaepdryver Moerman and Smith J. Physiol. 1969 204 102P)

8. NERVE FUNCTION AFTER RESERPINE AND AXONAL FLOW OF AMINE STORAGE GRANULES J Häggendal and A Dahlström, Depts of Pharmacology and Histology University of Göteborg Göteborg Sweden

The amine storage granules play a central role (e g for the release of transmitter) for functions of the amine containing neurons Several of the functions can be blocked by reserpine Thus after reserpine the granules in e g the sympathetic nerves are emptied of their noradrenaline (NA) content they lose their normal capacity to take up and retain small amounts of labelled NA and no functional response is obtained to stimulation of the nerve fibres

Based on quantitative studies on endogenous NA and ^{3}H-NA retention in tissues with intact or by axotomy interrupted axonal flow the recovery of these functions after reserpine both in the CNS and in the PNS will be discussed mainly being due to axonal transport to the nerve terminals of new granules formed in the cellbody after the reserpine administration The dynamics of transport of newly formed granules and their accumulation in the

terminal appear to be responsible for the recovery of the endogenou NA levels to normal a recovery which requires several weeks to be completed In the nerve terminals the granules appear to have an average life- pan of several weeks with respect to their average capacity to tore endogenou NA

On the other hand the capacity of the nerve terminals to take up and store tracer amounts of labelled NA appears mainly to be dependent on the presance of newly formed granules With respect to this function the amine granules appear to have a much shorter life span in the order of some day( ) The life span of the amine granules may thus differ with respect to different functions (Dahl trön & Häggendal J Pharm, Pharmac 1966 18 Häggendal & Dahlström Subcellular Organization and Function in Endocrine Tissu s Bristol April 1970 in press)

We sugge t that the granules during their life-time may change their morphology (from larger to smaller) their chemical composition (e g content of chromogranin A nd DA β-hydroxylase) and their capacity to take up store and relea e transmitter

The newly formed granules may by suggestion mainly con titute the small pool easily vailable for release whereas the old granule may represent the large stabile pool in which the tr nsmitter appears to be more firmly bound

9. ELECTRON MICROSCOPIC OBSERVATIONS ON THE DISTRIBUTION AND TRANSPORT OF NORADRENALINE STORAGE PARTICLES AFTER LOCAL TREATMENT WITH MITOSIS INHIBITORS Tomas Hökfelt and Annica Dahlström Dept of Histology Karolinska Institut t nd Institute of Neurobiology Univer ity of Göteborg Göteborg Sweden

Colchicine (Sandox) or Vinbla tine (Velbe® Lilly) was applied locally on the lumbar sympathetic ganglia or on the interganglionic connecting nerves of the sympathetic chain Three or 24 h after the treatment these tissu s were fixed for electron microsc py either with 3% potassium permang nate ($KMnO_4$) (Richardson Nature 1966 210 756) or with gluta aldehyde followed by osmium tetroxide (OsO_4)

Principally both mitosi inhibitor produced the same type of effects on the fin tructure of the nervous ti sue tudied Colchicine in higher concentrations than Vinbla tine (0 35 M and 0 01 M respect vely) The effects were con id rably more pronounced after 24 h than fter 3 h A judged from ingle sections the individual neuron seemed to be affected to varying degree

Cell bodies. In number of ell bodies strands of densely packed neurof laments were found running through the cytoplasm Often small clu ter of both small nd larg granular vesicles were found close to these strand The Golg -apparatus seemed to be enlarged often containing rather high numbers of granular vesicles No microtubul were seen Many cell bodi s howed no obvious hange as compared to control In control gangli no strands of neurofilaments were observed but often ingle microtubul could be seen

Axons. The xon profiles could be div ded into several groups to the effect on their fine structure

1 Enlarged xon containing large numbers of electron dens particles probably representing damaged mitochondria

2 Enlarged axons containing abundant tubular and vesicular stru tures some of which contained electron dense cores

3 Enlarged xons containing large amounts of small and large granular ve icl s In these axons the granular vesicles were often lying in the peripher l part of the axon surrounding strand of densely packed neurof laments No neurotubules were visible in these xons

4 Axon w th normal appearance

The present findings re interpreted to indicate that mitosis inhib tors when applied locally arrest the transport of

noradrenaline storage particles from the cell body (Golgi apparatus) to the axon terminals Thi seems to be a sociated with a disappearance of microtubules and n appearance of dense strands of neurofilaments Thi may indicate a fundamental importance of microtubules for intraneuronal transport mechanisms (c f Schmitt Proc nat Acad Sci 1968 60 1092)

10. THE ACCUMULATION OF DOPA-DECARBOXYLASE AND MAO ACTIVITY IN RAT SCIATIC NERVES AFTER CONSTRICTION J Jonason Depart ment of Pharmacology University of Göteborg Sweden

The ctivities of DOPA-decarboxylase and MAO in rat sciatic nerve was determined at different times after constriction of the nerve Both the enzyme activities were found to increase above the ligatur after the con triction However the change in activity of DOPA-decarboxylase differed from those of MAO with respect to time course and magnitude DOPA-decarboxylase tivity in the part proximal to the lesion wa found to increase to about 5 times the normal level during the second day; a reduction from thi high level was observed after 7 day and 14 days fter the operation the values were almost normal An increase in MAO activity in the proximal part of the nerves to a level of bout 2 5 times normal wa observed fter 7 days At three weeks fter the operations the MAO activity was almost in th normal rang

In th parts below the constriction changes in enzyme activities were lso observed DOPA-decarboxylase ctivity wa found to increas to about 2 5 times normal after 4 days wheres MAO activity wa slightly decreased by 2-3 week

Lumbar sympathectomy reduced the activity of DOPA-decarboxy-lase in nonconstri ted nerves to about half of that of normal nerve wheres the MAO ctivity was not significantly changed after thi procedur No increase in DOPA-decarboxylase activity was obtained fter constriction t sympathectomized rats indicating that the increa in DOPA-decarboxyla e ctivity observed in normally inner-vated rats after ligation occured within the sympathetic po tganglioni nerve fibres Furthermo e the real increase in neuronal DOPA decarboxy-las i probably about 10 times that in normal constricted animals ince the a tivity of thi enzyme in unligated nerve of sympathec tomized animals is about half of normal (see above) After lumbar sympathectomy ligation of the sciatic nerve produced an increase of MAO tivity to a level of more than twice the n rmal However this increas reached the maximal level about one week later than in normal constricted rats

It might be concluded that the behaviour of DOPA-decarboxy-lase nd MAO after nerv ligation i quite different from each ther a well from that of nor drenaline (Dahlström & Häggendal Acta physiol scand 1966 67 278) nd dopamine-β hydroxylase (Laduron & Belpair Life sci. 1968 7 1) The pr sent results indicate that n ther DOPA-decarboxylase nor MAO is localized within the amin torag gr nules

11. TRANSPORT OF NEUROTUBULAR PROTEIN AND THE EFFECT OF COLCHICINE ON AXONAL TRANSPORT J -O Karlsson and J Sjöstrand Institute of Neurobiology Univer ity of Göteborg Sweden

The 6 S colchi ine binding protein has been shown to exi t n microtubules (Shelanski nd Taylor J. Cell Biol. 1967 34 549) nd it ha been sugg sted that thi protein is the subunit of neurotubules (Wei enberg et al. Biochemistry 1968 7 4466) In order to study the xonal transport of this protein we injected ^{3}H leu ine into the eye of the rabbit

At various intervals following the injections the retina optic nerves and tracts was dissected out and the colchicine-binding protein was isolated with a batch DEAE Sephadex elution procedure essentially as described by Weisenberg et al. After reduction and alkylation the isolated protein migrated as a single band on 7 5% polyacrylamide gels Incubation of the purified protein with ^{3}H-colchicine showed that it bound 0 24 M colchicine per 120 000 g protein

Determination of the specific radioactivity of the colchicine-binding protein at various interval following injection showed that this protein was synthesized by the retinal ganglion cells and transported along their axons with the slow phase of the axonal transport in this system (1 5 - 2 mm/day)

^{3}H-colchicine (which binds to microtubular protein in vitro) did not seem to be transported in the axons of the retinal ganglion cells in the same manner as the microtubular protein

The role of neurotubules in the different phases of axonal transport will be discussed

12. EFFECT OF CUT LIGATION OR CRUSH ON THE SYNTHESIS AND TRANSPORT OF AMINE STORAGE GRANULES IN RAT SCIATIC NERVE
Lars Karlström and Annica Dahlström Dept of Histology Institute of Neurobiology University of Göteborg Göteborg Sweden

Ligation of peripheral nerves carrying adrenergic axons results in a rapid accumulation of noradrenaline (NA) storing particle The proce appears approximately linear up to about 48 h in rat sciatic nerve Thereafter the amount of NA above the ligation ppeared unchanged up to at least 96 h indicating decrease in accumulating NA Different theories have been put forward to explain this decrease e g cell body reactions resulting in a decreased synthesis and transport of amine storage granules (Dahlström & Häggendal Acta physiol scand. 1966 67 278)

To test this nd to tudy if different kinds of axonal trauma had the same effect the following experiments were done Sprague-Dawley rats (200 g males) were operated upon at a low level of the sciatic nerv which wa cut crushed without ilk ligature or ligated (with remaining ilk-ligature) 1- 23 d before death Controls were shamoperated One or 2 h before death the sciatic nerve was crushed 1 5 - 2 cm above the level of the initial operation Thi high nerve part wa then di sected out and treated for fluorescence microscopy ccording to Falck and Hillarp

The shamoperated r ts always showed strongly green fluo escent fibres with accumulations bove the high crush In the operated rats the amount of accumulated NA was decreased 3 d after operation Between 5 and 13 d no or very little NA accumulated In rats with crushed nerves weakly fluo escent accumulations were again observed at 15 d and around 19 - 21 d the fluorescence intensity nd size of the accumulations appeared normal in the microscope In rats with cut or ligated nerves no recovery of the NA ccumulations above the high crush was seen during the observed period Similar observation have been done in splenic nerve of cat 21 d fter constriction of the nerve (Boyl & Gill spie J. Physiol. 1968 195 27 P) Our results indicate that axotomy cause depre sion in synthe i and transport of amine torage granules in drenerg c nerves A ligation with remaining ligature or a cut appear to cause a more long la ting depression in synthesis and transport of amine tor ge granules than crush or ligation without remaining ligature

13. EFFECT OF INTRAVENOUS VINBLASTINE ON INTRANEURONAL TRANSPORT OF NORADRENALINE IN THE RAT P Keen and A Livingston Department of Pharmacology University of Bristol Bristol England

The transport of noradrenaline storage granules down sympathetic nerves may be interrupted by the local application of colchicine which is known to interact with neurotubules (Dahlström Europ J pharmacol 1968 5 111) Vinblastine also disrupts neurotubular organisation (Wisniewski J cell biol 1968 38 224)

Vinblastine was administered intravenously to rats in an attempt to block intraneuronal transport of noradrenaline Such a chemical ligation might allow a) prolonged inhibition of axonal transport without the peripheral degeneration which follows mechanical ligation and b) study of granular transport in the heart which has no discrete sympathetic nerves which can be ligated

Vinblastine (3 mg/kg iv) reduced the noradrenaline content of the pleen heart and vas deferens to respectively 10% 20% and 50% of that of the controls but had no effect on brain noradrenaline levels Notable features of the effect of vinblastine were a) that noradrenaline levels did not commence to fall until 24 hours after administration of vinblastine b) that the fall was more rapid in the heart and spleen than in the vas deferens possibly a reflection of the lower turnover rate in the latter) that recovery of noradrenaline levels commenced approximately 12 days after the injection of vinblastine; at 21 days heart noradrenaline had risen to 40% of control values Stress increased the rate of depletion of heart noradrenaline following vinblastine suggesting that the decline of noradrenaline levels depends on the normal leaky process Hearts depleted of their noradrenaline by vinblastine were unable to store systemically administered ^{3}H-noradrenaline; experiments with isolated perfused hearts prepared from these animals showed that this was because the neuronal membrane was unable to take up ^{3}H-noradrenaline Electron microscopy of the coeliac ganglion and splenic nerve of vinblastine treated rats did not reveal any abnormality and ligation of the sciatic nerve of these animals showed that noradrenaline transport was proceeding at normal rate suggesting that the effect of intravenously administered vinblastine may be primarily on the nerve endings

14. TRANSPORT OF HERPES SIMPLEX VIRUS IN PERIPHERAL NERVES Kerstin Kristensson Erik Lycke and Johan Sjöstrand Departments of Pathology and Virology and Institute of Neurobiology University of Göteborg Göteborg Sweden

It is well known that herpes simplex virus may reach the CNS along peripheral nerves The problem of in which structural component of the nerve (epi peri or endoneural spaces Schwann cells axons) the infectious agent travels has been discussed in the literature After intradermal inoculation of the virus the lesions were observed to follow the sensory pathways whereas after intramuscular inoculation the motor fibres were primarily affected (Kristensson Acta neuropath (in press)) The findings suggest that there may be a direct transport of the infectious agent within axons To test the existence of a distal-proximal transport in side the axons experiments with different kinds of axonal injuries were carried out

Suckling mice were inoculated with herpes simplex virus intradermally in the sole of the hind foot Signs of paresis developed on the inoculated leg after 4 to 5 days and all animals died one or two days later Titrations for virus were performed from different levels of the sciatic nerve dorsal ganglia and spinal cord Ligatures of the sciatic nerve prevented the spread of the infection if applied within 24 hours after inoculation A similar effect was observed after

freezing of the nerve It ha been reported that colchicine blocks axonal tran port in various nerve (Dahl trön Eur J pharm 1968 5 111 Karlsson and Sjöstrand Brain res. 1969 13 617 Kreutzberg Proc nat Acad Sci 1969 62 722) Soaking of the sciatic nerve with colchicine prevented to a high degree the spread of the infection The ultrastructural changes of the nerve following colchicine treatment were studied and the mechanism for the blocking effect is discu sed It i concluded that in suckling mice a relatively rapid transport in axons from the periphery to the perikaryon most likely responsible for the transmission of herpes simplex viru in the nerve trunks

15 AXONAL FLOW OF ENZYMES INVOLVED IN THE BIOSYNTHESIS OF CATECHOLAMINES P Laduron Department of Biochemical Pharmacology Janssen Pharmaceutica Beerse Belgium

Despite Udenfriend s unitarian theory that the three enzyme of catecholamine biosynthesi (tyrosine hydroxylase DOPA-decarboxylase and dopamine β-hydroxylase) are sociated within the granule containing catecholamines (cf Adrenergic neurotransmission CIBA Foundation 1968) we are now well documented to claim that the two fir t steps of catecholamine biosynthe is occur outside the granules

The rate of accumulation of these three enzymes in the proximal part nd their disappearance in the distal part of constricted nerves provide a suitable tool to study the intracellular localisation of these enzymes

The fact that the rapid accumulation of dopamine-β hydroxy lase above a ligature parallels that of noradrenalin together with some particular aspects of latency and sedimentation indicates its granular belonging On the contrary the low increase or the unchanged activity of DOPA-decarboxylase and tyrosine hydroxylase above a l gature suggests that these enzymes are not linked to a subc llular structure

Ther fore the xonal flow in a way performs a physiolog cal fra tionation of enzymes which can be estimated by the kine tic of accumulation and thus provid s a new pproach to th clas ical methods of ti sue fractionation

However the exact its of synthesi of noradrenaline in the neuron remains questionable If in the neuronal system only the nerve ending re apt to relea e neurotransmitters by exocyto i it eems reasonabl to assume that becau e of the presence of a large amount of noradrenaline along the axon an important part of thi amin is synthe ised in the cell body

16 A POSSIBLE ROLE OF LYSOSOMAL ACCUMULATION IN CONSTRICTED SCIATIC NERVES P Laduron Department of Biochemical Pharmacology Janssen Pharmaceutica Beerse Belgium

In the axoplasmic flow experiments using ligatures of adrenerg c nerves it was generally observed that the gradual cumulation of different components bove the ligature rea hed a maximal level 2 to 4 days after the operation Thereafter a decline period was found especially for the DOPA-decarboxylase

In contra t the ri of lysosomal (cid phosphatase nd acid deoxyribonuclease) and microsomal accumulation (inosine diphosphatase) in the same experimental conditions behaved quite differently in such way that their activities were found to increase gradually on both sides of the constr ction especially from the econd day to reach a maximal level 9 days after the operation A clearcut dissociation between the two kinds of enzymes due to their different intracellular local zation was recently reported (Laduron Arch. int.

Pharmacodyn. 1970 185 200)

A tructure linked latency of acid phosphatase wa demon trated in homogenates in both the proximal and distal egment of nerves which is compatible with previous results showing the presence of variou digestive vacuoles of lysosomal type in cru had sci tic nerves (Holtzman Lysosomes in biology and Pathology 1969)

Furthermore experimental data u ing two ligatures nd various kinetic of coumulation, suggest a possible double origin of these lysosomes During the fir t days after lig ture the accumulation of lysosomal enzymes wa greater in the proximal nd di tal segments than in the segments located between the two ligatures suggesting that at lea t part of the accumulated lysosomes originate from the axons probably by axoplasmic flow However from the second day on a possible extra axonal origin probably in the Schwann cell i suggested by the increase of lysosomal enzymes between two ligatures

Consequently from thes results we put forward working hypothesis according to which the accumulation of granules containing catecholamines nd mitochondria in on tricted nerves disappear within a few days owing to the digestive proces of v rious lysosomal enzymes

This phenomenon mu t be kept n mind to specify the scope of the axoplasmic flow conc pt

17. IMMUNOLOGICAL TECHNIQUES FOR STUDYING THE DISTRIBUTION TRANSPORT AND RELEASE OF CHROMOGRANINS B G Liv tt L B Geffen and R A Rus h Department of Pharmacology University of Oxf rd England, nd Departments of Biochemistry nd Physiology Monash University Clayton Victoria Australia

W have used the opportunity presented by th drenal medulla a relatively homogenous and concentrated source of catecholamin containing vesicles to study by immunological techniques wh ther the soluble vesicl proteins (chromogranin) a also present in sympath ti neurones nd to examine their distribution tran port and participation in the transmi ion proce (Geffen Livett and Rush J. Physiol. 1969 204 58P; J. Physiol. 1969 204 593)

The formaldehyd ind ced fluorescence method for catechol mines by Hillarp and Falck (for methodology see Corrodi nd Jonsson J Histochem Cytochem 1967 15 65) ha been a us ful technique for studying the di tribution torage and transport of the transmitter in drenergic neurones (Dahlström J. Anat. 1965 99 677; Dahlström N S Arch exp Path Pharmak. 1967 257 93) Flu r scence microscopy can also be used to tudy the di tribution of specif c proteins if ntibodie to these proteins a e labelled with fluo escent molecul such a fluorescein isothiocyanate or bodamine B200 The u fulne s of the immunofluorescence hi tochemical technique derives from the fa t that it combine the sensitivity of fluore en e microscopy with the specifi ity of the immune reaction (vide Nairn Fluores ent Protein Tr ing 1969 Livingstone) With thi technique we have shown that chromogr nin-A nd dopamine β-hydroxyla ar cytoplasmic co ti tuents of the cell bodies axons and xon terminal of noradrenergic neurones nd that they ccumulate proximal to a nerve ligation Comps ison of immunofluorescenc hi tology for the two proteins with the f rmaldehyde-indu ed flu r scence method f catecholamines showed that 11 three ha e imilar di tribution

Quantitative microcomplement fixation naly i ha been ed to show that the chromogranin re present in microsomal and soluble fraction of he p vasa deferentia sympathetic ganglia nd plean in the same r lative mounts s noradrenaline nd that chromogranin-A and dopamine β-hydrocylase re relea ed into the pe fusates from isolated sheep pleens pon timulation of th splenic nerves t 10 c p s Th results tog ther with thos of Blank Helle and Mayor (Mol c pharmacol 1969 5 210) and De Potter De

Schaepdryver Moerman and Smith (J. Physiol. 1969 204 102P) suggest that chromogranins are contained within noradrenergic vesicles nd are released together with noradrenaline by exocytosi

18. ELECTRONMICROSCOPICAL AND BIOCHEMICAL STUDIES ON TRANSPORT OF NORADRENALINE-CONTAINING GRANULES D Mayor and P Bank Dept of Human Biology & Anatomy and Biochemi try Sheffield University England

Studies on sympathetic nerves constri ted at one or two points in vivo have shown that noradrenaline and granular vesicles accumulate proximal but not distal to the constriction The amount of noradrenaline above the distal of a pair of constrictions was pproximately equal to the normal noradrenaline content of the piece of nerve isolated between the two lesion Above the proximal constric tion there was a progres ive increase in the number of granular ve- sicles and in the amount of noradrenaline accumulating This reached a peak by 4 days after operation The association between granular ve icles and noradrenalin in these nerves was further confirmed by using reserpin and mono-amin oxidase inhibitors (Banks Mangnall and Mayor J. Physiol. 1969 200 745; Banks Kapeller and Mayor Brit J Pharmac 1969 37 10)

Similar results have recently been obtained using an in vitro preparation of con tricted cat hypoga tric and colonic nerve attached to the inferior mesent ric ganglion Colchicine added to the incubation medium caused a marked reduction in the number of granular vesi l s and in the amount of noradrenaline accumulating above a constriction

The ultrastructural details of cat granular v sicles varied slightly depending on the fixative used However in general most of the granular vesicle accumulating above constriction were lightly smaller than those found in r lation to the Golgi apparatu in the cell body but they were larger than the majority of the granular vesicles in drenergic terminals

Thu granular ve icle containing noradrenalin only move proximo-distally in ligated cat ympathetic nerves both in vivo and in vitro Since this movement occurs in isolated pieces of the nerv it s not entirely dependent on the cell body of the neuron which is however essential for the production of the granular ve icle Furthermor thi movement can take pla e in the absence of preganglionic timulation The precise mechanism by which granular vesicl s mov along sympathetic axon t present uncertain but th inhibition produced by colchicine suggests that the xonal microtubule may be involved

19 MORPHOLOGY AND PROPERTIES OF THREADLIKE ELEMENTS OF THE NEURONE J Matuzals Institut of Neurobiology Faculty of Medicin Univer ity of Göteborg Göteborg Sweden

Since e ghty years there ha been a succession of theorie of cytoplasmic streaming scribing the production of the motive force to gel sol transformations among the different regions of the cyto- plasm In th neuron such transformation can be elated to the conformat onal changes of the filamentous cidic protein isolated from the axoplasm of the squid giant n rve fiber whereby Ca^{++} i a major fa tor in determining the behaviour of the protein (Matuzal J Cell Biol 1969 45 Katchalsky Biophys. J. 1964 4)

Based on differential interference microscopy electron microscopy nd physico-chemical observations of the squid giant nerve fiber and of vertebrate neurones model of the motive force of the neuroplasmic movements i pr sented (Matuzals & I zard, J Cell. Biol 1969 45); Matuzal IIIrd Europ reg conf electr micr ráfu

1964 According to this model gel sol transformations occur either: (1) between the outer or ectoplasmic and inner or endoplasmic portions of the axon and of the cell body of the neurone; (2) along the long xis f the axon causing transverse banding pattern of the axoplasm; in myelinated fibers gel - sol transformations occur between the node (gel) and the paranodal (sol) axoplasm Coiling decoiling and f lding unfolding of the protein molecules caused through inter actions with Ca^{++} would be the primary proce s at the molecular level

20. AXONAL TRANSPORT OF NEUROHYPOPHYSEAL PROTEINS IN RATS AT SOME EXPERIMENTAL CONDITIONS A Norstrőm nd J Sjöstrand Department of Histology Institute of Neurobiology Uni ver ity of Göteborg Göteborg Sweden

Axonal transport of proteins in the hypothalamo-neurohypophyseal system of the male rat was studied after a local injection of (^{35}S) cysteine in the region of the supraoptic nucleus The migration of labelled proteins was followed by measuring the specific radioactivity of the proteins in various parts of the hypothalamo-neurohypophyseal tract Between two and four hours after the isotope injection there was a sharp increase in the protein-bound radioactivity of the posterior pituitary lobe demonstrating that a transport of (^{35}S) labelled proteins had occurred from the supraoptic nucleus to th neurohypophysis The rate of the transport wa 2 to 3 mm/h During the first 24 h after the injection a continuou ccumulation of labelled material occurred in the neural lobe Considerable radioactivity could till be recovered 6 days after the isotope injection

Fractionation of the neurohypophyseal proteins by polyacrylamide gel electrophoresis revealed that pproximately 90% of the radioactivity of the soluble proteins was recovered in a single protein fraction Labelling of thi fraction was not observed until 2 h fter the isotope injection The radioactivity increased markedly up to 4 h It is sugge ted that this protein component is involved in the neurohypophyseal response to osmotic trass ince the protein disappeared from the posterior lobe upon dehydration of the rat

Colchicine injected into the subarachnoidal pace before the local injection of (^{35}S)cysteine inhib ted the transport of r diolabelled material

The transport of neurohypophyseal prot ins in female rats was tudied under various phy iological conditions The implications of these findings will be discussed

21. MODE OF REGENERATION OF ADRENERGIC NERVES L. Olson Department of Histology Karolinska Institutet Stockholm Sweden

The different aspects of axonal growth of the sympathetic adrenergic neurons were studied with the Falck Hillarp fluorescence technique for hi tochemical localization of catecholamines in combination with ^{3}H-NA uptake measurements Three principally different types of growth occur 1 Outgrowth of axons and terminal systems during ontogenesis 2 Regeneration after axotomy 3 Collateral prouting when an intact drenergic neuron increases its field of innervation in esponse to various tinuli

The sympaticoblas ts eveal NA fluorescence from an early stage (13 day ecbryo) and the outgrowing axons and terminal nerve plexuses can be followed during development

Regeneration rates of non-terminal NA-axons were determined in the adult rat fter sciatic nerve compressions The main bulk of axons advanced about 1 5 mm/day the first week and 3 mm/day the second week Thin sprouting fibres showed initial growth rates a high 9

mm/day (Olson Hi tochem. 1969 17 349)

When a piece of peripheral tissue is transplanted to the anterior chamber of the rat eye the intrinsic adrenergic nerves of the transplant degenerates A rapid reinnervation will then take place by collateral sprouting from the adrenergic ground plexus in the iris of the host eye The time course of adrenergic reinnervation was followed in detail with histochemical nd bi chemical methods using autologous contralateral iri tran plants Reinnervation of irides was found to be a rapid process continuing until the normal amount of adrenergic nerve was restored after one month

A series of similar experiments using different types of tran plants and pharmacological and physiological techniques permitted the following conclusion Regeneration i specific in the sense that new nerves only grow into denervated tissues where adrenergic nerves normally exists and unspecific in the sense that any part of the adrenergic neuron system can reinnervate any adrenergic receptor tissue The newly formed nerves have an essentially normal transmitter pharmacology and are able to restitute neuromuscular transmission Neither chronic treatment with various drugs affecting the transmitter mechanisms nor chronic treatment with testosterone or cortisone influences the outgrowth Impulse flow is not necessary for regene ration Slight infections will often cause a pronounced hyperinnerva- tion of host irides even if no transplant is placed in the anterior chamber (Olson Malmfors Acta physs scand 1970 suppl 348)

22. AXONAL TRANSPORT IN CENTRAL AND PERIPHERAL AXONS J Sjöstrand and J -O Karlsson Institute of Neurobiology University of Göteborg Göteborg Sweden

The axonal transport in the retinal ganglion cells of the rabbit was studied after intraocular injection of labelled leucine by measuring the arrival and ccumulation of labelled proteins in the axon terminals of the lateral geniculate body Four different phases of axonal transport was found with a transport velocity of 110-150 40 7 and 1 5 2mm/day respectively The subc llular distribution and the life-span of the labelled proteins in these phase will be discussed

Mo t of the soluble proteins of the axons wa transported with the low (1 5 2 mm/day) phase whereas only some of the soluble proteins was transported with the rapid (110-150 mm/day) phase Triton X 100 extraction of the microsomal fraction (containing a considerable part of the rapidly transported proteins) solubilised highly labelled proteins belonging to the rapid phase

The xonal transport of labelled protains was studied in vagus and hypoglossal nerves of rabbits fter n intramedullary in je tion of (^{3}H) leucine Two migrating protein components were described Th rapid component moved at rate of about 400 mm/day and 300 mm/day nd the slow component at an average r te of 26 mm/day and 5 mm/day in the vagu and hypoglo sal nerve respectively

Cell fractionation tudies of the nerves showed that the rapidly migrating component wa larg ly associated with the particulate fraction with the highest pecific radioactivity in the microsomal fr ction In the low component the highe t specific activity wa found in the soluble protein fraction The effect of Triton X 100 on the subcellular di tribution will be discussed

When the axons had been crushed by a ligature the enzyme accumulated proximal to the ligature The transport velocity s calculated from the rate of accumulation was highest in the vagus nerve both for AChE and ChAc Approximately the same rates were observed for both enzymes i e 15 mm/24 h in the vagus nerve and 5 mm/24 h in the hypoglossal nerve These rates were of the same order as thos observed for the slow axoplasmic transport of radioactively labelled proteins in unligated nerve

CHAPTER I

INTRODUCTION

According to du Bois—Reymond (1877) Berzelius wrote to Lehmann in 1841 stating that he had found lactic acid in the muscles of exhausted game, and du Bois-Reymond explained the acidic reaction of tetanized muscles with this observation. According to the same reference, Berzelius has stated dass ein Muskel desto mehr Milchsäure enthält, je mehr er vorher an gestrengt worden ist." Berzelius did not continue these experiments on chemical events in muscle tissue, and an explanation of lactate formation could *not be given at that time.*

Araki was one of the first physiologists to conduct further studies into the *conditions of lactate formation in intact animals* (Araki 1891 a and b) In 1891 he demonstrated an increase in lactate concentration in urine and blood when dogs, rabbits or hens were subjected to hypoxia. Thus, he confirmed von Liebig's hypothesis (1847) that lactic acid accumulated in blood when the O supply was restricted. Several investigators concomitantly found lactic acid formation in other experimental situations (for ref see Bang 1935) e.g. when the liver was extirpated (Minkowski 1885)

No observations were made until the beginning of this century that defined in greater detail the conditions necessary for lactate accumulation in cells. Fletcher and Hopkins (1907) examined the relationship between lactic acid formation and the effect of an oxygen deficient milieu on contractions. Furthermore, using a frog muscle specimen, they demonstrated the removal of lactate in an oxygen rich environment. Similar results were obtained by Hastings (1921) when examining blood *lactate concentration in intact dogs* after brief intense exercise, indicating that the oxygen supply was insufficient during heavy exercise and that the circulatory system might be a limiting factor in the energy output of working muscle. With moderate work intensities, however very low blood lactate concentrations were obtained.

The intrinsic role of the circulatory system in the body's lactate formation was further illustrated by Groag and Schwarz in 1927 who showed in man that subjects suffering from cardiac failure had higher blood *lactate values* at a given submaximal work load than healthy subjects.

During the early 1920's Meyerhof and Hill advanced their concept of an oxygen debt. Meyerhof (1920 a, b and c) demonstrated on isolated stimulated frog muscle a decrease in glycogen content at the same time as lactate was formed. Removal of lactate was associated with a resynthesis of glycogen during the animal's recovery from exhaustion. Hill and his associates had shown that blood lactate concentration rose in the initial phase of work. When work ceased, lactate concentration disappeared at a rate similar to the decrement in the oxygen uptake (Furusawa *et al.* 1924 Hill, Long and Lupton 1924 a and b)

Both Hill and Meyerhof deduced that lactate formation was an indicator of O_2 lack during exercise, that the removal of lactate was directly responsible for postexercise excess O_2 uptake (oxygen debt) and that there was quantitative agreement between O deficit and O debt as originally concluded by Krogh and Lindhard (1920) It was subsequently demonstrated, however *that* O_2 *deficit was less than the oxygen debt* (*Schneider and Clarke* 1925 Asmussen 1946, Christensen and Högberg 1950)

Collazo and Lewicki had published results in 1925 which failed to fit the theory of oxygen lack as the significant cause of lactate formation in the body They gave normal subjects 100 g of sucrose orally and found elevated lactic acid concentrations in blood similar results were obtained by other investigators using a carbohydrate-rich diet. These results were confirmed in *animal experiments by Cori and Cori in 1929 who demonstrated lactic acid* formation when giving rats intravenous glucose infusions.

In the work by Ørskov (1931) the conditions necessary for lactic acid formation in the working muscle were studied, considering both local blood supply exercise and carbohydrate-rich diet. Many of his results are still relevant but are usually overlooked by later authors in the field of muscle biochemistry and physiology He showed that certain amounts of lactate (2—8 *mmoles* × kg^{-} *wet weight) were present in the muscles of the resting animal,* supposedly well-supplied with oxygen. The concentrations rose strikingly during exercise, and values about 20—30 mmoles × kg^{-} wet weight were obtained in the groups of working muscle of intact animals. Moreover he illustrated the effect of different diets on blood lactate concentration and showed an increase in blood lactate concentration to 3—4 mmoles × l following a carbohydrate-rich diet.

Lundsgaard (1930 a and b) was able to show that the Iodoacetate poisoned muscle performed lactic acid-free contractions at the same time as energy rich phosphate compounds were depleted in the muscle. Similar observations were made by Schwartz and Oschmann as early as 1924 but these results were evidently neglected and thus forgotten.

One of these compounds was then described as creatine phosphate (CP) (Eggleton and Eggleton 1927 and Fiske and Subbarow 1927) and the other one was described by Lohmann in 1931 as adenosine triphosphate (ATP) Nachmansohn (1928) demonstrated that CP was resynthetized very effectively by anaerobic glycolysis, and Meyerhof and Lohmann (1928) showed that breakdown of CP was an exothermic reaction. But it was not clearly demonstrated until Lundsgaard's studies that CP was a more immediate source of energy for muscular contraction than any of the intermediate by-products of glycolysis. Lohmann (1934) further defined the problem of how chemically bound energy is transformed into mechanical work and demonstrated that adenosine diphosphate (ADP) was a co-factor required for the breakdown of CP by dialyzed muscle extracts. The resynthesis of ATP (Lohmann 1935) by CP is often referred to as the "Lohmann reaction"

As a consequence of these studies on anaerobic energy output by muscle, the terms *lactacid and alactacid anaerobic energy output* were coined (Lundsgaard 1932) Margaria, Edwards and Dill (1933) and Dill *et al.* (1936) developed on this basis and in experiments performed on man the hypothesis of a lactacid and an alactacid portion of the oxygen debt. Thus, they further developed the concept of oxygen debt introduced by Hill and Meyerhof The energy of the lactacid part was derived from glycolysis ending up with lactate formation (anaerobic glycolysis) and of the alactacid part from the fast splitting of ATP and CP stored in the muscle. These two high energy phosphate compounds are usually referred to as *phosphagen*. On the basis of these concepts, total lactate formation during exercise was estimated in man. It has been postulated by Hill Long and Lupton (1924) that muscle lactate and blood lactate concentration would be the same in steady state conditions. Blood lactate concentration was then assumed by Margaria and co-workers to be representative of the concentration of the total body water they were then able to evaluate the alactacid portion of the O_2 debt using this calculation.

In animal experiments Sacks and Sacks (1937) tried to show that a (diffusion) equilibrium as suggested by Hill *et al.* did exist between muscle and blood in steady state conditions but failed. From their experiments they concluded that a lack of free diffusion of lactic acid existed since the plasma of the venous blood issuing from the muscles contains a significantly lower concentration of lactic acid than does the muscle itself" These authors argued that it was unnecessary to postulate any alactacid" mechanism as Margaria and co-workers had done since it was impossible, on the basis of their experiments, to conclude anything about lactate formation from blood lactate data. Similar results were obtained by Ørskov (1931) and Bang (1935)

As illustrated by the investigators in the 1920's, lactic acid could be formed without tissue hypoxia. Huckabee came to the same conclusion (1958 a and b) when he examined the properties of the enzymatic reaction in which lactic acid is formed pyruvic acid + NADH ⇆ lactic acid + NAD catalyzed by the enzyme lactate dehydrogenase (LDH) and advanced the hypothesis of "excess lactate based on these studies. According to formula and the mass action law lactate formation does not necessarily depend on an oxygen lack which would induce elevated extra mitochondrial concentrations of NADH, as later demonstrated by Chance and associates (for ref see Chance, Schoener of Schindler 1964) Increased pyruvate concentration in the cell would similarly cause lactate formation by the cell. Consequently the significance of blood lactate concentrations might be questionable as an indicator of an anaerobic metabolism. As early as 1941 Friedemann and Barbocka had pointed out the theoretical importance of considering the concentration of pyruvate at the same time as that of lactate.

The excess lactate value calculated from lactate and pyruvate concentrations determined simultaneously would better reflect the lactic acid concentration formed due to true tissue hypoxia. This excess lactate hypothesis has been the subject of intense discussion and its relevance has been questioned (e.g by Knuttgen 1962, Margaria *et al* 1963 Olson 1963 Alpert 1965)

In 1909 Krogh suggested that the diffusion rate of O_2 from blood to the muscle cell might be critical in an adequate O supply to the cell. Chance *et al.* (1962) calculated a critical low intracellular O tension of approximately 1 mm Hg necessary for the maintenance of a normal redox state for the mitochondrial fraction of NAD Stainsby and Otis 1964 demonstrated on dogs that an O tension of 10 mm Hg in venous blood was sufficient to provide an adequate O_2 supply Similar low O_2 tensions have, in fact been reported in venous blood draining the exercising muscles during maximal exercise in man (Saltin *et al.* 1968)

In recent years the different sizes of motoneurons in the central nervous system have been advanced as being specific for the innervation of different types of muscle fibers (Henneman, Somjen and Carpenter 1965 a and b, Henneman and Olson 1965) The motoneurons have individually different rated threshold and are activated in special recruitment patterns which are related to the strength of the electrical stimuli. Moreover Kugelberg and Edström (1968) have shown that the fibers of a motor unit have identical enzyme profiles and that relatively more glycolytic fibers are stimulated at high firing rates. It seems therefore reasonable to assume that mainly red muscle fibers are activated in man at low work intensities, but the greater the intensity the greater the number of white fibers activated. The red muscle

fibers have a pronounced aerobic metabolism while the white ones display a more pronounced glycolytic metabolism. Whether the recruitment pattern is related to O_2 tension in the muscle or not is a question frequently discussed but yet unanswered. Further it can be questioned whether lactate formation in the muscle cell as i function of a deficiency in the O supply to the cell or of the intensity of muscle contractions as well.

As early as 1907 Fletcher and Hopkins empirically found that a high lactate concentration occurred at the same time as muscle fatigue appeared. When a muscle specimen was exposed to an oxygen rich environment the muscle regained its irritability at the same time as the lactate formed was removed, thus indicating the key position of lactic acid in the state of muscular fatigue. However the causal relationship has not been established even if Meyerhof's experiments (1925) further emphasized the role of lactic acid as the cause of muscular fatigue by showing increased performance by a muscle specimen in an alkaline Ringer's solution. In 1936 Bang examined lactic acid concentrations in man at rest and with increasing work loads and found concentration of blood lactic acid increasing as work load increased. He postulated that intracellular muscle lactic acid concentrations must reach even higher levels than in blood. Asmussen *et al.* (1948) were of the same opinion. Moreover Asmussen and his associates suggested that the limiting factor for physical work of high intensity was set at a certain concentration level for lactate in the working muscle groups.

As illustrated by Bang (1936) blood lactate concentration tended to decrease if work were continued for longer than 10 min, even if the initial blood lactate concentration had been 8—10 mmoles $\times$ l^{-1}. Astrand *et al.* made similar observations in 1963 when studying the effects of prolonged heavy exercise consisting of cross-country ski racing lasting 1—8 hrs. Lower blood lactate concentrations were found in subjects given standardized submaximal and maximal work loads after the race than in control experiments after prolonged rest. The duration of work with the maximal test load was also reduced. These authors proposed an impaired ability to obtain energy from anaerobic sources, while Bang suggested an increased utilization of exogenous lactate induced by the prolonged work both the suggestions would result in a decreased blood lactate level.

With the re-introduction of the needle biopsy technique (Bergström 1962) originally described by Duchenne in the middle of the 19th century (for ref. see Natrass 1968) it was possible to determine local changes in the concentrations of certain metabolites such as lactate, ATP and CP in the working muscle. By means of this technique and enzymatic analytic methods, Hultman Bergström and McLennan Anderson 1967 were able to demonstrate a decrease in

the local stores of ATP and CP thus confirming the old contention originally advanced by Margaria, Edwards and Dill that anaerobic energy output was in part derived from a depletion of energy rich phosphate compounds stored in the muscle (phosphagen) Data were not, however presented for local lactate concentration in the working muscle, which is why an explicit picture of anaerobic energy yield by the working muscle could not be presented.

It was felt to be of interest to further develop the analytical methods used on muscle biopsy specimen of man in order to make it also possible to determine certain glycolytic intermediary metabolites such as glycogen, pyruvate and lactate in addition to ATP and CP With these methods it should be possible to estimate the alactacid anaerobic energy yield during exercise and to examine the relationship between muscle lactate and blood lactate concentrations and to clarify the extent to which lactate concentrations in muscle and blood are related to a hypoxic state in the working muscle. Moreover it was of interest to include several different work levels in the present report in order to illustrate phosphagen depletion and lactate formation in greater detail in relation to absolute as well as to relative work load and how work stress affected the subject.

More specifically the aims of the present studies may then be summarized as follows

1 to adapt methods for the determination of carbohydrate metabolites, i.e. chiefly glycogen, pyruvate and lactate, plus ATP and CP in small muscle biopsy specimens of human muscle (5—15 mg wet weight)

2 to examine whether or not lactate concentration gradients are present within the muscle during mild and severe exercise and to evaluate the extent to which a single biopsy specimen of the muscle can be considered as representing the muscle as a whole

3 to illustrate the interrelationship between O_2 deficit, phosphagen depletion and accumulation of lactate in the working muscle and

4 to investigate whether preceeding prolonged heavy exercise of several hours duration may influence LDH activity and lactate accumulation in the working muscles.

CHAPTER II

GENERAL LABORATORY METHODS

Abbreviations

ADP	= adenosine 5-diphosphate
AMP	= adenosine 5-monophosphate
atm	= standard physical atmosphere
ATP	= adenosine 5-triphosphate
a-v difference	= arterio-venous difference
BSA	= bovine serum albumin
CP	= creatine phosphate
F-6-P	= fructose-6-phosphate
F 1 6-P	= fructose-1 6-phosphate
g	= gram
G-6-P	= glucose-6-phosphate
hr	= hour
k_m	= the substrate concentration at which the velocity of a reaction is half the maximal
kpm × min	= kilopondmeter per min (= 0.163 Watt)
l	= liter
LDH	= lactate dehydrogenase
M	= moles × l^{-1} of solvent
max $\dot{V}O_2$	= maximal oxygen uptake
min	= minute
NAD	= nicotinamide-adenine dinucleotide
NADH	= nicotinamide-adenine dinucleotide, reduced form
NADP	= nicotinamide-adenine dinucleotide phosphate
NADPH	= nicotinamide-adenine dinucleotide phosphate, reduced form
P O	= arterial oxygen tension
PEP	= phosphoenolpyruvate
P_i	= inorganic phosphate
SD	= standard deviation
SE	= standard error of the mean
sec	= second
V_{max}	= maximal velocity of a reaction or similar process
$\dot{V}O_2$	= oxygen uptake
V	= volt

Definitions

aerobic processes	= chemical processes in which O_2 is the electron acceptor
anaerobic processes	= chemical processes in which other cellular constituents are electron acceptors
aerobic glycolysis	= glycolysis ending up with pyruvate formation
anaerobic glycolysis	= glycolysis ending up with lactate formation
anoxia	= a state with a complete absence of oxygen
hypoxia	= a state with a limited oxygen supply
lactacid anaerobic energy yield	= energy from anaerobic glycolysis
alactacid anaerobic energy yield	= energy from ATP and CP stores
maximal oxygen uptake ($max\dot{V}O_2$)	= the greatest oxygen uptake per unit of time according to the levelling off criterion (Åstrand and Saltin 1961) during physical work and breathing air at sea level
maximal (or supramaximal) work load	= exhaustive work load corresponding to or exceeding the individual $max\ \dot{V}O_2$ at observed mechanical efficiency
phosphagen concentration	= (ATP + CP) concentration
relative work load	= the per cent of the individual $max\ \dot{V}O_2$ demanded by the work load, assuming a complete aerobic energy yield (at submaximal work load = steady state $\dot{V}O_2$)
submaximal work load	= a work load, less than the work load corresponding to the individual $max\ \dot{V}O_2$
supramaximal work load	= see maximal work load

Statistics

Ordinary statistical methods were used to calculate mean, SD and SE.

The error of the methods employed was estimated from SD of a single experiment as calculated from double determinations. Residual error was estimated, if calculated, by means of the formula

$$SD_t = \sqrt{SD_a^2 + SD_b^2 + \quad + SD_n^2}$$

The statistical significance was tested, when possible, on intraindividual differences (Student's "t" test) and in other cases on differences between means. The level of significance is denoted with p values.

Subjects

Some anthropological and physiological data for the 49 subjects studied are presented in Table I. Fifteen of these subjects were studied immediately after induction into military service. They were sedentary while the remainder were physical education students or the equivalent who regularly participated in physical activities only a few subjects were nationally prominent competitors in endurance events.

Procedure

In preliminary tests several days before the experiment day subjects were "mapped" in respect to max $\dot{V}O_2$, maximal heart rate, maximal blood lactate concentration and the work load exhausting the subjects within 2—6 min. Exercise was performed on an electrically (Krogh's bicycle) (Nielsen and Fridrichsen 1938) or mechanically braked bicycle ergometer (von Döbeln 1954)

On the experiment day subjects reported to the laboratory early in the morning after only a light breakfast. After 45—60 min at rest in a supine position, rest measurements were made. Submaximal work loads, if included in the protocol, were chosen so as to elevate blood lactate concentration significantly over rest values, i.e. work load demanding an oxygen uptake exceeding 50 per cent of max $\dot{V}O_2$.

The submaximal work load was generally interrupted after 6—10 min. Immediately after completion of work, the subject still sitting on the bicycle a biopsy specimen was obtained from the lateral portion of the subject's quadriceps muscle. Repeated blood samples were simultaneously obtained

TABLE I Mean and range of pertinant anthropological and circulatory data of the subjects participating in the different investigations.

Series	n	Paper	Age years	Height cm	Weight kg	Maximal oxygen uptake l × min	ml × kg × min⁻¹

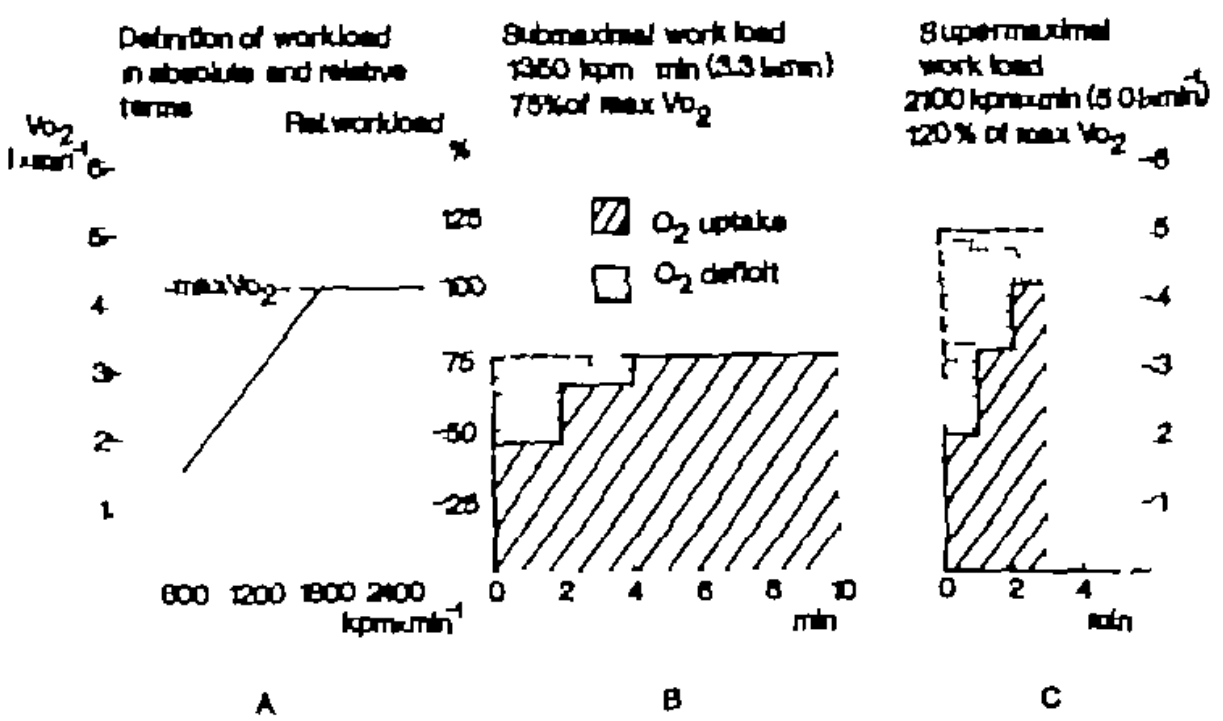

Fig. 1 Principles underlying calculation of relative work load and oxygen deficit. Left $\dot{V}O_2$ is related to work load, max $\dot{V}O_2$ being defined by the levelling off criterion. Centre: oxygen deficit at submaximal load ($\dot{V}O_2$ = 3.1 l × min^{-1} equivalent to 75 % of max $\dot{V}O_2$) Right: oxygen deficit with supramaximal work ($\dot{V}O_2$ = 5.0 l × min^{-1} for complete aerobic energy output, equivalent to 120 % of max $\dot{V}O_2$)

from a prewarmed hand (fingertip blood) The exhaustive work load was performed after 10—20 min of rest and biopsy specimens and blood samples were taken as above.

$\dot{V}O_2$ was determined in all these experiments, either throughout the whole work period or during the final min.

Assuming a mechanical efficiency of 22.5 % with the supramaximal work load relative work load was estimated as described in Fig. 1 a, in which the linear relationship $\dot{V}O_2$ — work load is extrapolated to supramaximal work loads. From this curve it is possible to predict the $\dot{V}O_2$, assuming complete aerobic energy yield even with work loads exceeding max $\dot{V}O_2$.

By definition, the measured $\dot{V}O_2$ with steady state conditions at a certain submaximal work load is equal to the amount of oxygen demanded for complete aerobic energy yield.

O_2 deficit calculations were performed in experiments in which total $\dot{V}O_2$ was determined. This is illustrated in Fig 1 b for a submaximal work load and is based on the assumption of a 22.5 % constant mechanical work efficiency during the initial phase of the work. The O_2 deficit is the difference between

a theoretical oxygen uptake with complete aerobic energy yield and the value actually determined. As shown in Fig 1 c the same calculations have been *made for the exhaustive, maximal and supramaximal work loads.*

Methods

The physical work of the exercise tests was performed on bicycle ergometer Oxygen uptake was determined with the Douglas bag method. The expired gas volume was measured in a Tissot spirometer and gas analyses were made using the *Enghoff Haldane technique.* The individual max $\dot{V}O_2$ was determined according to the levelling off criterion (Åstrand and Saltin 1961)

Blood lactate concentration was determined using an enzymatic method originally described by Scholz *et al.* (1959) on 0 1—0.2 ml of arterial fingertip blood taken from a prewarmed hand. Several blood samples were obtained after exercise.

The LDH activity of biopsy specimens of man was determined from tissue homogenates (in 0.5 ml of ice-cold TRIS-buffer pH 8 0) according to Lowry and Passonneau (1964) The accumulated changes in fluorescence (ΔE) when corrected for the blank values, were used to determine the moles of NADH oxidized according to the formula

$$(NADH) = \Delta E \times \text{fluorometer factor} \times V \times V_h \times V \times W$$

The fluorometer factor = the amount of spectrophotometrically determined NADH, causing a change of 1.0 scale divisions on the fluorometer

V volume of reagent in the fluorometer tube (1.00×10^{-3} l)

V volume of homogenate added to the fluorometer tube (1.58×10 l)

V total volume of the homogenate (0.50×10^{-3} l)

W_w wet weight of the muscle biopsy at zero time (Bergström 1962)

The LDH activity was defined as the initial velocity of the reaction. Two determinations were performed on four muscle specimens, giving values within 0.5 % of the first determination.

CHAPTER III

DETERMINATION OF ORGANIC MUSCLE METABOLITES

Enzymatic fluorometric analysis of muscle metabolites

Chemical analyses of the muscle tissue metabolites were performed mainly in accordance with the St. Louis method introduced by Oliver H. Lowry and co-workers (ref. see Table II)

Information concerning quality concentration in test medium and source of the reagents for the metabolites studied are presented in Table II

Enzymatic reactions were in general carried out in 3 ml prematched test tubes in 1 ml of reagent. The NADPH or NADH concentrations were fluorometrically determined in a Farrand fluorometer Model 24 The increase or decrease in the fluorescence thus obtained was compared in each determination with the corresponding increase or decrease obtained in identical test media with spectrophotometrically predetermined standard solutions. The net changes in concentration of the metabolites were arranged to read in excess of 5—10 % of the scale of the fluorometer

Table II also indicates whether or not reactions were started with the sample or any appropriate auxiliary enzyme. Approximately 20—25 samples were analyzed at a time, and the concentration of auxiliary enzymes was chosen to give a 1—2 min reaction halftime.

With the present methods, it was possible to obtain accurate determinations of metabolites present at concentrations in excess of 0.5 mmoles × kg wet muscle. This corresponds to test tubes concentrations of $1—2 \times 10^{-4}$ mM of NADH or NADPH.

The same analytical procedure was used to check the order of magnitude of the pyruvate concentrations. To obtain more accurate values an indirect method was applied (Lowry Roberts and Kapphahn 1957) using 100 µl of a medium as described in Table II. After a 15 min incubation duplicate samples were treated with 26 µl of 6 M HCl to destroy the remaining NADH. One ml of 6 M HCl was then added and the samples were allowed to remain at 60 C for 15 min before reading in the fluorometer (at room temperature)

The error in double determinations is presented in Table III for the analysis of the same supernatant as well as for separate samples of the same muscle biopsy specimen. Errors in enzymatic assays were 0.4—0.7 mmoles × kg^{-1} wet muscle, except for pyruvate and glycogen for which the errors were 0.006 mmoles × kg^{-1} wet weight and 2.5 mmoles of glucose units per kg, respectively

* mmoles × kg⁻ wet muscle
** mmoles × kg⁻ dry muscle

Comments

To evaluate the error of the method for separate analyses, residual error (SD) was calculated in each case from the standard deviation of a single determination of

a) the chemical part of the procedure (SD_a) and

b) the complete procedure, also including weighing and biological variations of duplicate samples (SD_t). The SD was never found to be less than the SD for the metabolites studied. As the weighing error was less than 1 % it is assumed that biological variations were responsible for the main part of the total methodological error. This assumption is supported by other methodological studies in which known amounts of different metabolites were added to the test medium which also included extract of biopsy specimen. Recovery was found to be 98 % (range 95—100)

Ill. 1 Cryostat for weighing frozen muscle biopsy specimen, constructed in collaboration with E. Nilsson Instrument, Solna, Sweden.

The interior of the cryostat — the weighing room (A) supplied with Cahn Electrobalance has temperature of —35 C.

The weight of the sample is tomatically registered outside the cryostat box (B)

The box is constructed with two lids (I and II) the small one (I) is for separat part of the box, divided from the weighing room by a screen This construction makes it possible to quickly put down or remove g biopsy samples from the cryostat without interferring the weighing room. The electrobalance and the interior of the weighing room can be manipulated from the outside (C)

Freezing and weighing of muscle biopsy specimens and extraction of metabolites

Muscle specimens from man were obtained from the lateral portion of quadriceps femoris muscle using a needle biopsy technique. All biopsy specimens were frozen in liquid nitrogen while still in the biopsy needle within 1—2 sec after the needle was withdrawn from the muscle.

The weighing procedure was performed on a Cahn Electro-balance at —20 C, or less either in a freezing room or in a specially constructed cryostat (Ill. 1) The biopsy specimen was dissected to remove blood and connective tissue, constituents easier to observe in a frozen state than fresh, and then powdered in a porcelain mortar After weighing the powder was transferred to frozen 3 M perchloric acid for further treatment.

The biopsy material, freed from frozen blood and connective tissue, powdered and weighed was extracted (deproteinized) in about 150 µl of 3 M $HClO$ at —20 °C. After 2—4 hrs the temperature of samples was raised to + 4 C samples were neutralized with approximately 250 µl of 2 M $KHCO_3$ (to obtain a final pH ranging from 7.8—8.5) and centrifuged. The supernatants were saved for determination of water soluble metabolites. The residues were dissolved and made up to 1.0 ml with 1 M HCl and hydrolyzed for 2 hrs in carefully sealed tubes in a 100 °C water bath for subsequent glycogen determination.

The degree of extraction of the water soluble metabolites was studied by treating various amounts of the same muscle powder with the same volume of $HClO_4$ (see Fig. ?) A muscle tissue specimen with a lactate concentration of 6.9 mmoles × kg wet muscle was divided into several portions with varing weights. The amount extracted (presented as scale readings on the fluorometer of the analysis kit) was plotted against the wet weight of each portion. It may be concluded that lactate was linearly extracted from specimens weighing 2—25 mg of wet muscle, indicating a complete extraction of water soluble metabolites. Re-extraction of the perchlorate precipitate supported the assumption that extraction was complete. In the present study all samples used ranged between 2.8 and 16.4 mg of muscle powder and, consequently were within the linear part of the curve. Similar curves were also obtained for ATP and CP

To test whether or not phosphate compounds were destroyed or were lost by $HClO$ extraction and subsequent neutralization, known amounts of ATP and CP were treated at low temperatures in the same manner as the biopsy specimens. Little or no loss (< 2 per cent) was observed. Lowry *et al.* (1964) previously showed that the procedure employed in deproteinization did not influence endogenous ATP and CP levels.

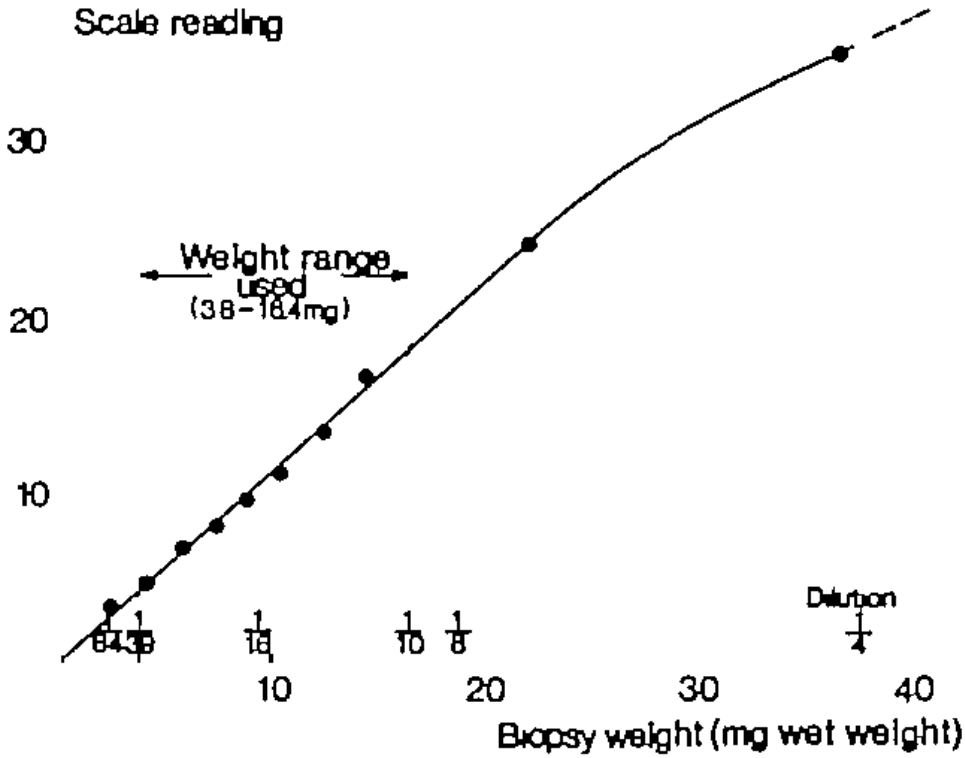

Fig. 2. Extraction of muscle lactate in biopsy specimens ranging between 2.5—38 mg wet weight. Extraction is expressed as the fluorometer scale reading (net) which is proportional to the lactate concentration. The actual weight range used in the present studies is 2.8—16.4 mg, which is within the linear part of the extraction curve.

Comments

The storage of supernatants for longer periods of time at —20° C was observed to depress the concentration of ATP and CP (a 50 % loss was found after six months storage) P_i levels were elevated at the same time, but not stoichiometrically Further measurable amounts of AMP could be detected. In the present study care was taken to check for ATP and CP in the supernatant within a few days after the extraction. None of the other supernatant metabolites was found to change during the time needed for complete analysis.

To evaluate the influence of the freezing procedure s duration of latency on certain muscle metabolites such as ATP CP and lactate, specimens from the canine gracilis muscle were frozen at intervals ranging from zero to 30 min after extirpation (see Fig 3)

Briefly these experiments with delayed freezing produced the following results a very small decrease in CP concentration may occur in the first

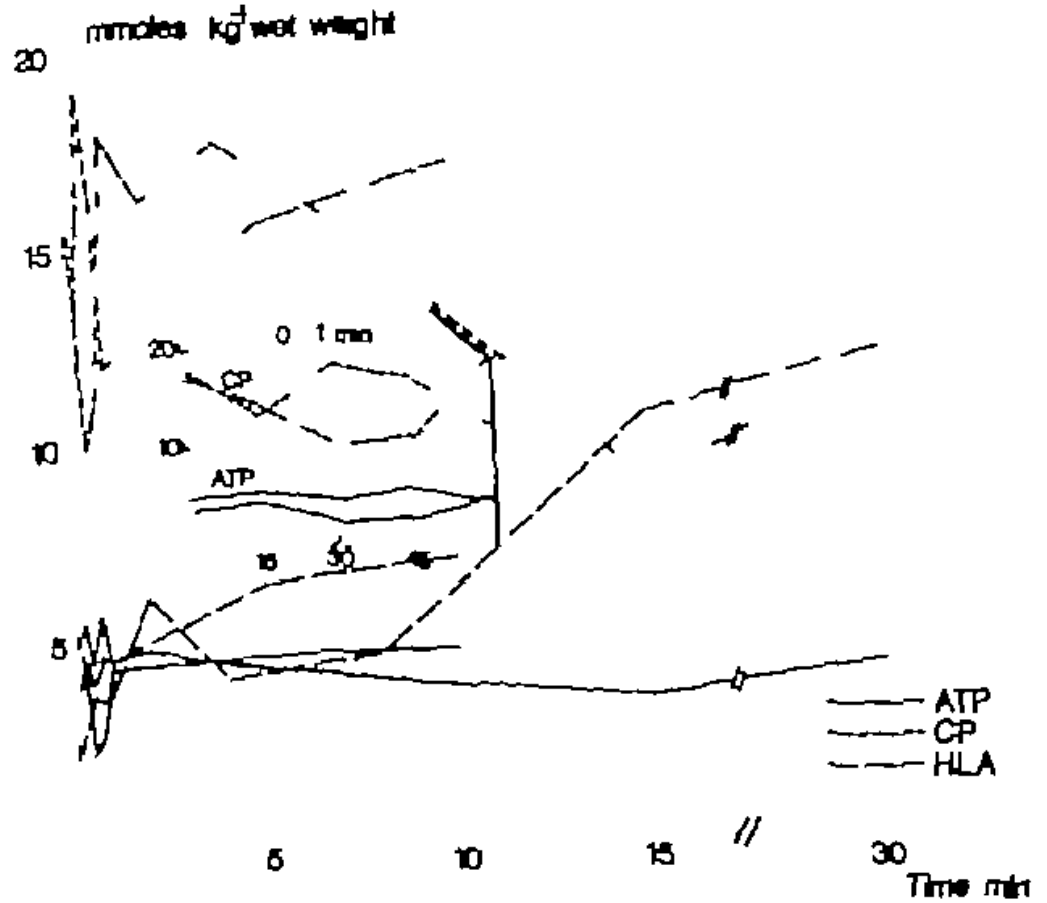

Fig. 3 Changes in ATP CP and lactate concentrations at different time intervals between extirpation of the biopsy specimen and freezing in liquid nitrogen.

3—4 sec before the freezing of the specimen. ATP concentration did not decrease during the time studied, but there was an increase in lactate concentration. This increase was initially (during the first min) rapid but, with time, the rate of increase declined. Thus, lactate values obtained averaged 1.5 mmoles × kg⁻ wet weight at zero time, about 4 mmoles × kg⁻ wet weight after 1 min and 7 mmoles × kg⁻ wet weight after 10 min.

Concentration differences for lactate in a single biopsy specimen and in the contracting muscle

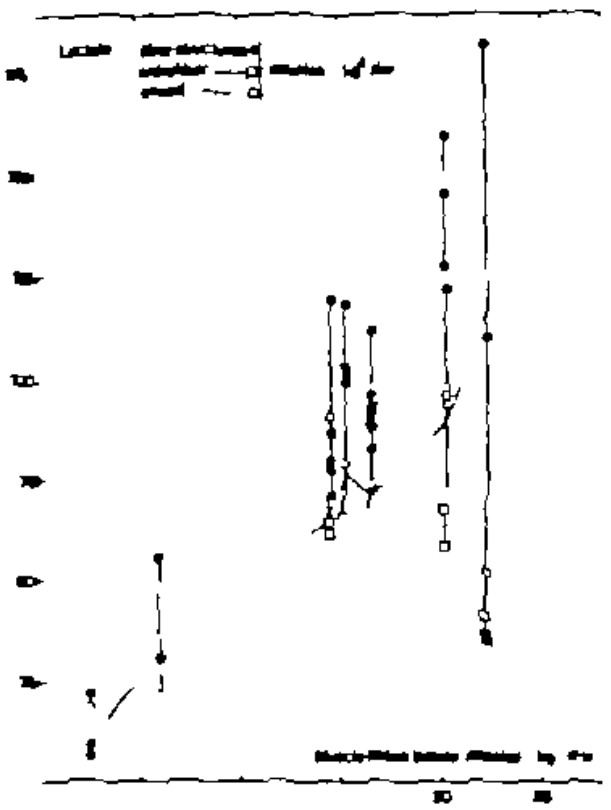
Even if the analytical methods applied were accurate enough for reproducible determinations, the question may arise as to whether or not concentration gradients within contracting muscle in particular influence the extent to which the sample is representative of the muscle as a whole.

Ill 2. A freeze dried slice of biopsy specimen and the definition of different portions analysed for lactate concentration
A fiber tructures
B extra-fiber tructures
C mixed structures

To analyze further the biological significance of lactate determinations, the following items were studied

1 concentration differences within the biopsy specimen
2 concentration differences within a contracting muscle (the studies were performed on canine gracilis muscle stimulated in situ)
3 repeated biopsies from the vastus lateralis of man at rest and after exercise of increasing intensities.

Lactate concentration differences within the biopsy specimens were studied by examining the lactate concentration of separate samples dissected from freeze-dried sections as illustrated in Ill. 2. These sections were obtained with a microtome at —20 C freeze-dried for 36—48 hrs and dissected under light microscope at a magnification of 20 x. After weighing dissected material was put into test tubes for determination of lactate, as described in Table II The error introduced by this modification of the lactate method was 0 78 nmoles × kg⁻ dry weight.



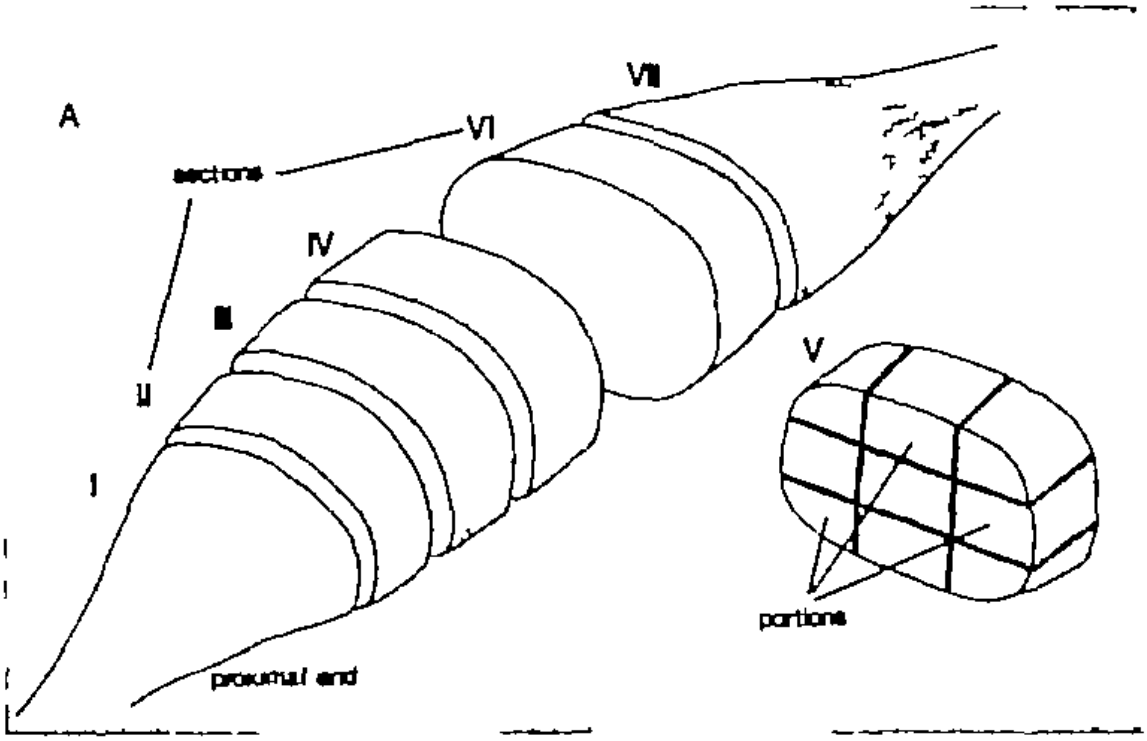


Fig. 4. Lactate concentration in different muscl tissue structures, as defined in Ill. 2, in relation to the muscle lactate concentration of the specimen. The curve connecting the examined specimens denote the lactate concentration analyzed for the whole slice.

In Fig. 4 results are presented expressed in mmoles × kg^{-1} dry weight for the dissected material plotted versus a corresponding sample treated according to the general procedure. Thus, it is possible to compare the lactate content obtained in the biopsy specimen with certain portions of the specimen

The dissected material was classified in three categories according to its appearance in the microscope

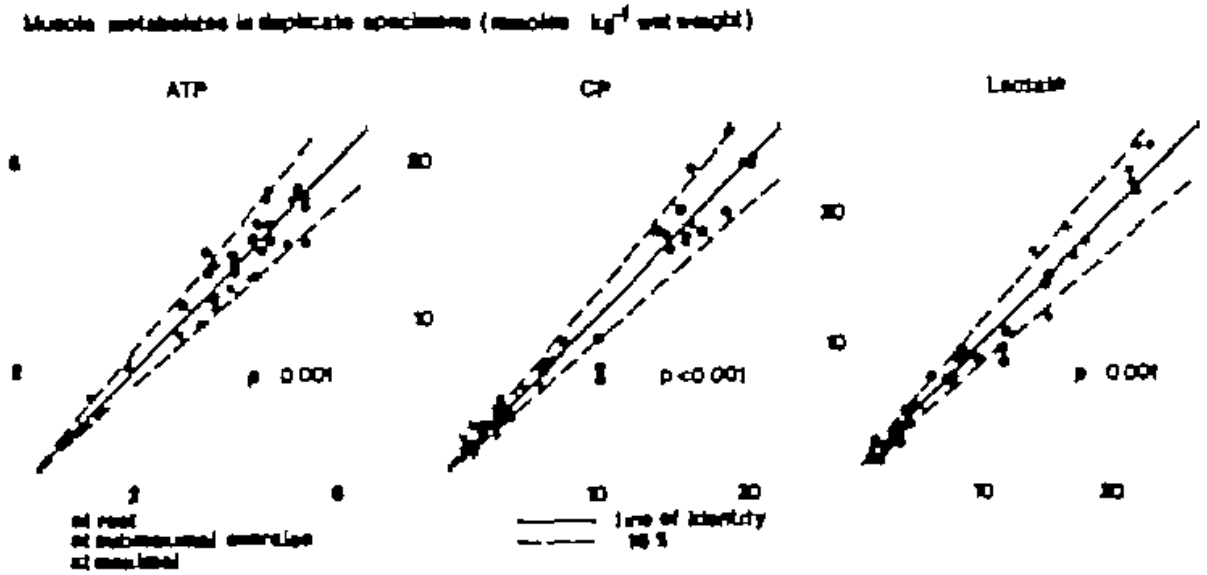
a. material consisting of muscle tissue only — fiber structures
b. tissue elements surrounding fiber bundles — extra-fiber structures
c. material containing both these constituents — mixed structures.

In all samples studied the highest lactate concentration value was obtained in the fiber structures and the lowest in all but two samples of mixed or extra fiber structures. This was most evident when the lactate content in the biopsy specimen exceeded 20 mmoles × kg^{-1} wet weight. Thus, in two samples the highest lactate concentrations obtained were 187 and 160 mmoles × kg^{-} dry weight or 37 and 32 mmoles × kg^{-} wet weight respectively while the lowest values obtained were 35 and 39 mmoles × kg^{-} dry weight or 7 and 12 mmoles × kg^{-} wet weight respectively assuming 77 % of the wet weight to be water Lactate concentration in the contracting elements of muscle performing heavy exercise would then correspond to values 3—5 times greater than the lowest concentration observed in the muscle specimen.

B

C

Fig 5 Schematic illustration of the dissection of canine gracilis muscle (A) and muscle lactat concentration in the portions of the section after 15 min timulation to contractions using 4/sec 4V and 0.1 msec (B) and 15/sec, 4V and 0.1 msec (C)



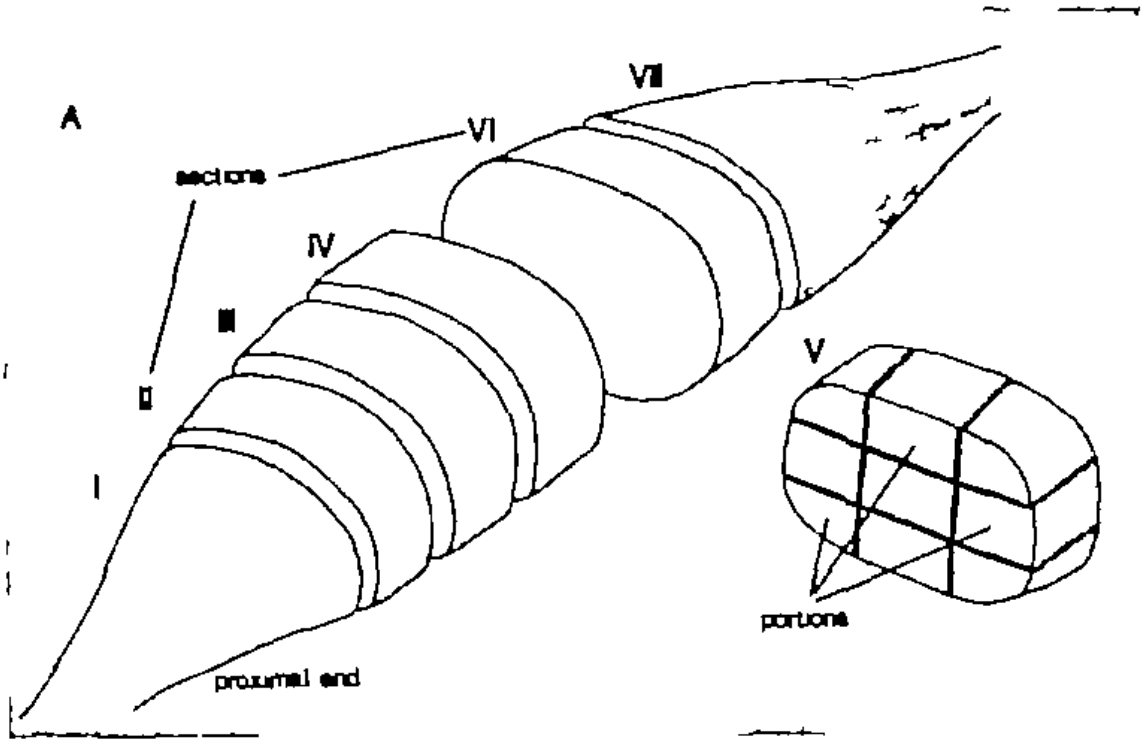


Fig. 6. ATP, CP and lactate concentrations in duplicate muscle biopsy specimens of man obtained from different parts of the quadriceps femoris muscle at rest, after submaximal and brief exhaustive work intensities. The duplicate samples, presented on the x-axis and y-axis respectively were obtained simultaneously at rest and at submaximal work rather than after brief exhaustive work in which the test load was repeated twice with at least 1 hr of rest in between.

SD for a single experiment were for ATP, CP and lactate concentration 0.55, 0.83 and 0.67 mmoles × kg⁻¹ wet muscle respectively.

The question may arise as to whether or not these gradients influence the extent to which the biopsy specimen is representative of the whole muscle examined. To pursue this question further, two canine gracilis muscles were electrically stimulated to contract (4/sec, 4V for 0.1 msec and 15/sec, 4V for 0.1 msec, respectively). After 15 min. stimulation the entire muscle was quickly frozen in liquid nitrogen and then prepared according to Fig. 5 A. The lactate concentration was found to average 7.8 and 22.9 mmoles × kg^{-1} wet weight respectively and SD of a single determination was 0.5 and 0.8 mmoles × kg^{-1} wet weight, respectively within sections II—IV.

Repeated biopsies were obtained from different sites in the thigh at rest and after bicycle work of different submaximal intensities (Fig. 6) in order to investigate whether there was a regional variation in lactate concentration in the vastus lateralis of the quadriceps femoris muscle of man. Repeated work loads were performed so as to obtain similar values after brief maximal exercise and biopsies were included in the protocol. At least one hr of recovery was allowed between each experiment.

Lactate concentration in resting muscle ranged from 1.0—2.7 mmoles × kg^{-1} wet weight in four muscles examined. However, the differences between

B

C

Fig. 3 Schematic illustration of the dissection of canine gracilis muscle (A) and muscle lactate concentration in the portions of the section after 15 min stimulation to contractions using 4/sec 4V and 0.1 msec (B) and 15/sec, 4V and 0.1 msec (C)

TABLE IV Constituents of the muscle biopsy specimens presented as mean ± SE and SD

Solids*)	Protein	N	Na	K
% of wet weight	g × kg^{-1} wet muscle		mEq × kg^{-1} wet muscle	
n = 17	n = 12	n = 12	n = 18	n = 18
23.0 ± 0.4	170 ± 6	28.4 ± 0.6	26 ± 1	84 ± 2
1.7	22	2.0	5	9

*) The biopsy specimens were obtained at rest as well as after exercise. Considering this the corresponding value for subjects at rest, with submaximal and maximal exercise was 22.9 ± 0.6, 23.9 ± 0.9 and 22.3 ± 0.6 respectively

Sodium and potassium concentrations

Muscle concentrations of sodium (Na) and potassium (K) were determined with a flame spectrophotometer on supernatants of muscle specimens homogenized in redistilled water using a Potter Elvehjelm homogenizer with teflon pistills. In specimens assumed to be made only of muscle tissue, sodium concentration averaged 26 mEq × kg^{-1} wet weight and the potassium concentration 84 mEq × kg^{-1} wet weight (Table IV)

Potassium levels lower than 60—65 mEq × kg^{-1} wet muscle were found when a specimen was contaminated with blood (Fig 7)

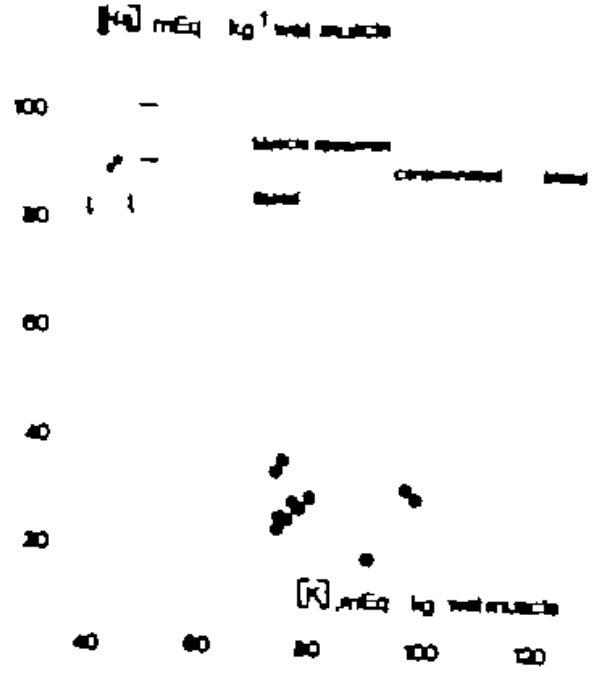

Fig. 7 Sodium (Na) concentration in relation to potassium (K) concentration in the same biopsy specimen of man consisting of muscle tissue or muscle tissue contaminated with blood. The dotted line and the arrows denote the highest potassium and lowest sodium concentrations in blood respectively

Comments

The present values for sodium and potassium agree with those previously reported (summarized by Bergström 1962). The relatively high values found in Bergström's own study calculated at an average at 25 and 99 mEq × kg wet weight respectively were obtained using another technique (activation analysis) which might explain the difference between the present and Bergström's mean potassium values. The activation analysis technique may include potassium present in the muscle cell bound to e.g. proteins. The present methods might be assumed to establish the amount of potassium present in the water phase.

On the basis of these figures intracellular Na—K space can be calculated and was found to range between 76—79 % of tissue water which should be compared to the approximately 75 % obtained by Hollosy and Narahara (1965) (3-methylglucose-^{3}H space) with frog muscle and the 83—91 % (chloride space) found by Bergström, Guarnieri and Hultman in 1971 for man at rest and after 20 min exercise respectively.

Nitrogen and protein content

The specimen's nitrogen content was determined according to the Kjeldahl technique (Jacobs 1965) and the specimen's protein content according to the Folin reaction, modified by Lowry *et al.* (1951) using BSA as a standard.

Nitrogen content averaged 1.0 moles N × kg^{-1} wet muscle, which is equivalent to 28 g N × kg^{-1} muscle. Protein amounted to 170 g × kg^{-1} wet muscle (Table IV).

Comments

In 1962 Bergström reported a N content amounting to approximately 28 g × kg^{-1} wet muscle. A factor of 6.25 for conversion of protein N into protein would provide a protein content corresponding to ca. 178 g × kg^{-1} wet muscle.

General comments on the methods to study muscle metabolites

Assuming approximately the same ratio for water content and solid material in the fiber and extra-fiber structures respectively a marked concentration gradient seemed to exist for lactate as soon as the average concentration of the specimen was elevated compared to resting values. This gradient was

evidently greater with higher tissue levels of lactate. This may indicate that the translocation process for lactate is not fast enough to establish a diffusion equilibrium for lactate between the fiber and extra fiber structures during moderate and heavy exercise of short duration (up to 10 mm)

Kübler *et al.* (1967) demonstrated a $Q_{10} > 2$ for the translocation of lactate from the heart to the venous blood with hypothermic dog heart, indicating that the process was of a nondiffusing type. Similar findings have been reported by Hirche, Langohr and Wacker (1970) and Karlsson, Rosell and Saltin (1971) (Fig. 8) with canine gracilis muscle which, stimulated to contractions, demonstrated a levelling off of venous lactate release related to the increase in muscle lactate concentration. Approximately the same values for V_{max} and K_m were obtained for lactate release in these two studies.

If it is assumed that blood lactate concentration represented extracellular fluid and that conditions were unchanged in respect to total cellular water and the relationship between intra and extracellular water then a saturation relationship must be present in the mechanism for lactate translocation from muscle to blood. Glaviano (1965) Tranquada (1966) and Kübler *et al.* (1967) have even suggested that an active process is involved.

Bergström, Guarnieri and Hultman (1971) demonstrated increased total tissue water content in human biopsy specimens taken from subjects after moderate exercise (1000 kpm × min) and calculated, using chloride space determinations, an increased intracellular water content which was linear to the increased muscle lactate concentration. It must be pointed out, however that the increase is less than 5 % of the wet weight. In the present material, in which the water content of specimens was determined in samples selected at

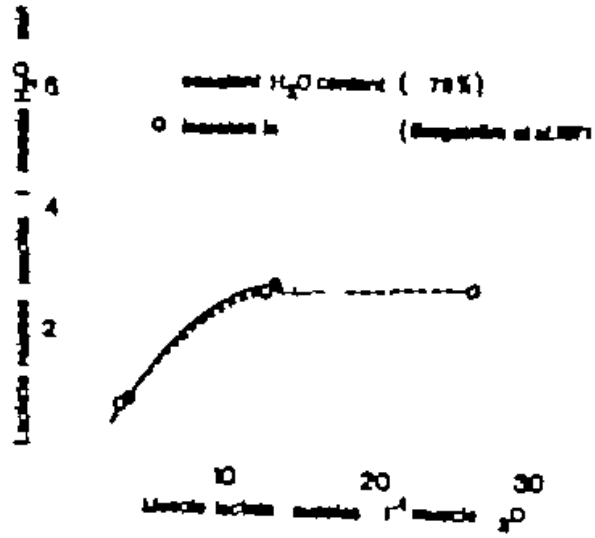

Fig. 8. Lactate release from contracting canine gracilis muscle in relation to muscle lactate concentration. The solid curve denotes the assumption of muscle water content corresponding to 76 % of the wet weight and the dotted curve an increase in muscle water content during contractions according to Bergström, Guarnieri and Hultman (1971) V_{max} of the release is 0.28 mmoles × l⁻ muscle water × min⁻ and the $k_m \sim 6$ mmoles × l⁻ muscle water

random from a number taken from subjects at rest and after exercise, no such tendency was found. Assuming an increase in total tissue water during exercise of the magnitude suggested by Bergström, Guarnieri and Hultman (1971) the data in Fig 8 were recalculated. As illustrated the levelling off in the relationship between venous lactate release to the capillary blood and muscle lactate concentration was more pronounced when considering the increase in muscle water during exercise.

Whether or not arterial finger tip blood obtained in man represents blood concentrations in the legs, especially after brief maximal work can be questioned. The lactate concentration in blood from the brachial artery in man has shown to be of the same order of magnitude as blood from the femoral vein which was simultaneously drawn immediately after submaximal and maximal work (Saltin *et al* 1968) The same experiment also illustrated that lactate concentration in femoral venous blood was only approximately 1 mmole × l⁻ higher than in femoral artery blood after maximal exercise, indicating that there is also a limitation on the translocation of lactate from muscle to blood in man.

Values for the individual muscle metabolites obtained in the lateral portions of quadriceps femoris muscle of man at rest were in good agreement with data previously reported (glycogen, ATP and CP concentration) from other laboratories using different techniques (Hultman 1967) It is concluded that reliable methods have been applied to the muscle biopsy specimen to make quantitative determinations of ATP CP G-6-P pyruvate and lactate in the same supernatant and of glycogen in the residue after perchloric precipitation.

CHAPTER IV

RESULTS

Lactate accumulation and phosphagen depletion with submaximal and maximal exercise

(Papers I, II and IV)

In order to illustrate the breakdown of phosphagen (ATP + CP) and lactate in the working muscle, 28 subjects were examined, 13 trained and 15 untrained.

There was a marked breakdown of the CP stores even with the submaximal work loads in both subject groups, while ATP depletion could only be observed with maximal or near maximal work loads. (Fig 9)

Although there was a marked difference between the two groups of subjects when work loads were expressed in absolute terms (Table V) no difference could be demonstrated between the groups in respect to the degree of CP depletion with the same relative work load (75 % and 100 % of max $\dot{V}O_2$

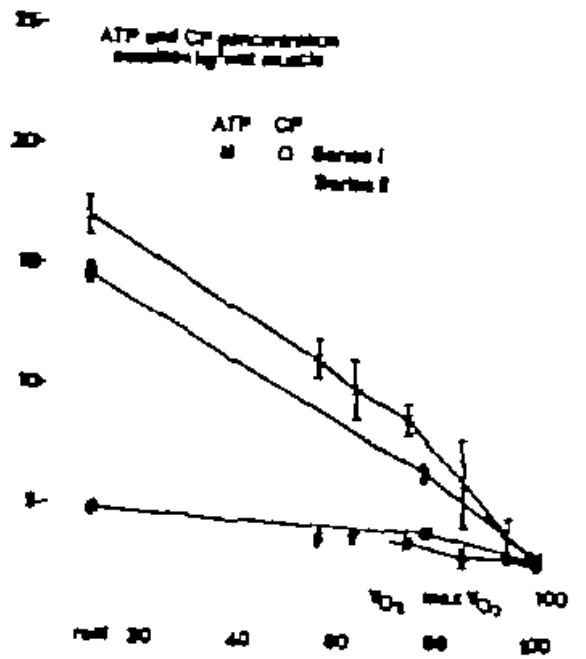

Fig. 9. Mean value ± SE for ATP and CP in relation to the relative work load, i.e. the oxygen uptake expressed as per cent of the individuals' maximal oxygen uptakes. In Series II (untrained subjects) mean values were calculated from the individual results and presented according to the following groupings: 50—59 60—69 70—79 80—89 90—99 and ≥ 100 % of maximal oxygen uptake. There were five or more subjects in each group.

TABLE V Mean values and range for the work loads and oxygen uptakes are given. The muscle metabolite and blood lactate values are presented as means ± SE and SD. The p-values denote the significance level between the observed results at different work loads. These calculations are based on intra-individual values.

	Workload kpm · min	Oxygen uptake l × min	ATP	CP	Glycogen glucose units	Muscle lactate	Blood lactate

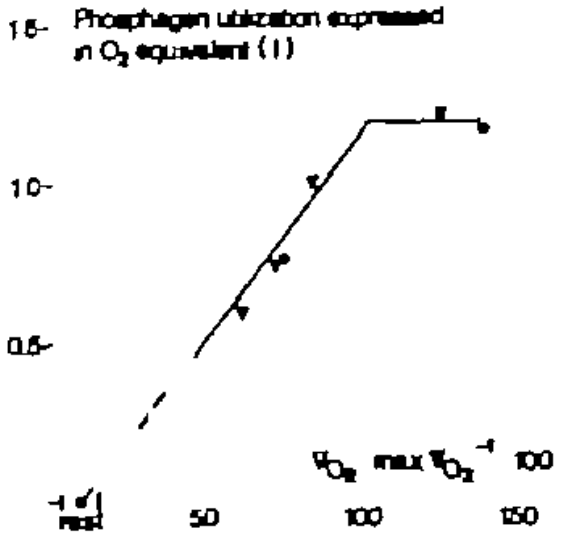

Fig. 10. Total estimated phosphagen depletion expressed in O equivalents in relation to the relative work load. Data are included from Series I (dots) Series II (triangles) and Series IV (data obtained after 2—3 min squares)

respectively) Total phosphagen depletion in the working muscle groups can be expressed in O_2 equivalents, assuming

a) concentration values for ATP and CP are representative of 25 kg of working muscles
b) the formula for complete carbohydrate combustion ($C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H\,O + 38$ ATP) is valid for the calculation of ATP in O_2 equivalents.

The connection between phosphagen depletion and relative work loads (Fig 10) might indicate that there is a linear relationship between alactacid anaerobic energy output and work intensity up to approximately 90—100 % of max $\dot{V}O_2$. With heavier work loads depletion seemed to be limited to approximately 1.3 l of O_2.

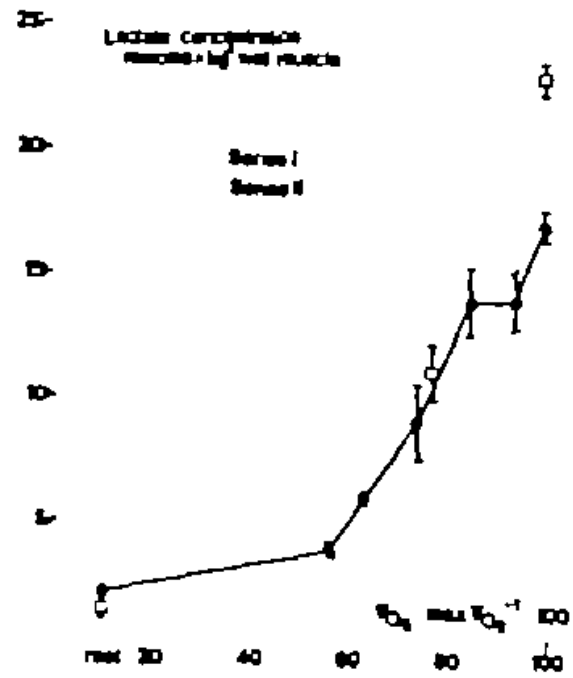

Fig. 11 Mean value ± SE for muscle lactate concentration in relation to the relative work load for Series I (squares) and Series II (dots)

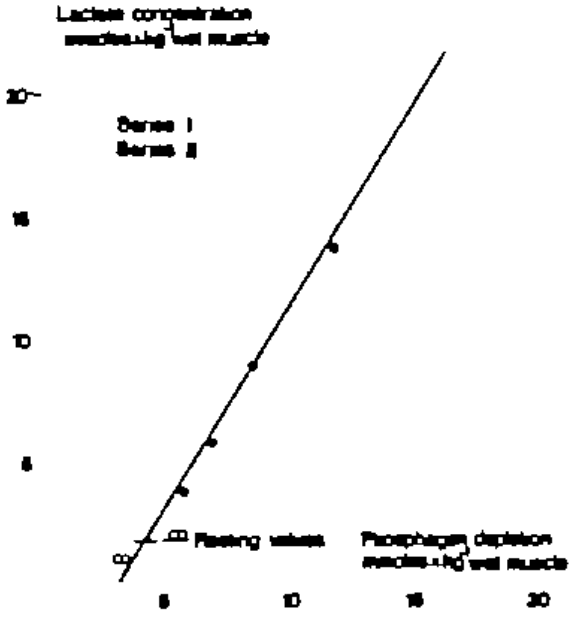

Fig. 12. Muscle lactate concentration in relation to phosphagen depletion for the same subjects as in Fig. 11 The equation for the regression line calculated for the exercise values is $y = 1.6 \times - 5.0$, $r = 0.88$, $p < 0.01$ Open circles, not included in the statistics, denote data obtained by Knuttgen and Saltin (to be published)

A certain lactate concentration was present in the resting muscle, but no marked increase was observed until work loads exceeded 50—60 % of max $\dot{V}O_2$ (Fig. 11) A rapid increase in the accumulation of lactate took place above this work level, reaching maximal values with brief maximal exercise. No difference was demonstrated between trained and untrained subjects in muscle lactate concentration at rest and with a submaximal work load corresponding to 75 % of max $\dot{V}O_2$. There was a significant difference ($p < 0.001$) with the exhaustive work load, however and the mean values obtained were 16.9 and 22.7 mmoles × kg⁻ wet muscle in untrained and trained subjects respectively

With increasing work load phosphagen stores in the muscle display certain depletion before lactate starts to increase beyond values at rest. A regression line can be calculated using the exercise values which intersect the x-axis at a numeric value of 3 1 (Fig. 12)

If muscle lactate concentration is taken into account these results would appear to indicate that phosphagen depletion in the order of 4—5 mmoles × kg⁻ wet muscle must be present before lactate concentration increases beyond rest values.

Repeated maximal or near maximal bursts of activity of 1 min duration led to maximal muscle lactate concentrations as early as at the end of the first exercise period and amounted to 23.2 (range 19 1—26.3) mmoles × kg^{-1} compared to an average value of 22.5 (range 21 1—24.5) mmoles × kg^{-1} wet muscle obtained (individual figures in Fig. 13) after the fifth and last exercise period. These concentrations are comparable to those obtained in the

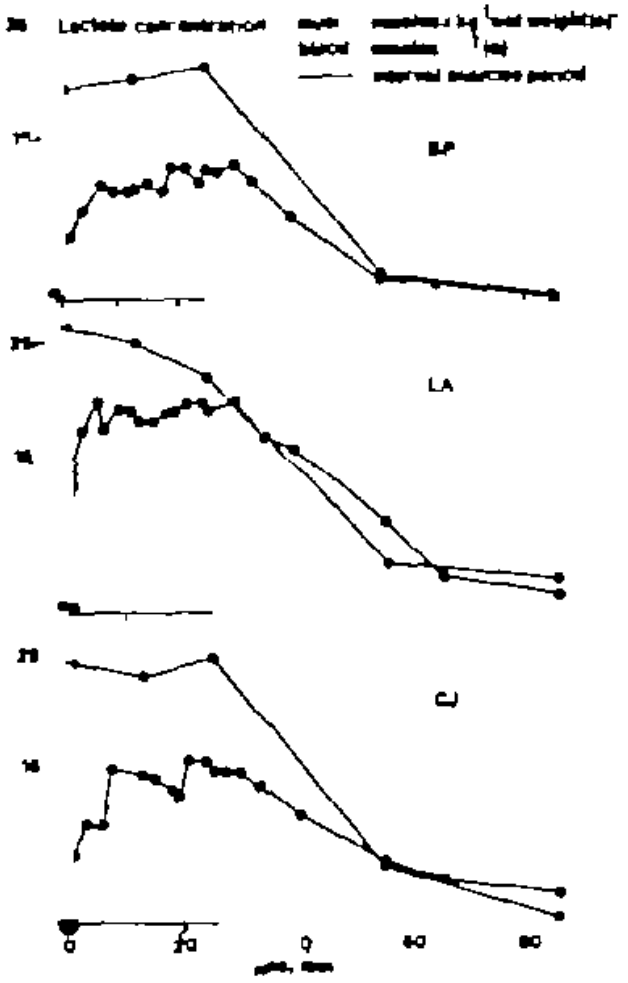

Fig. 13. Lactate concentration in muscle tissue (dots) and blood (circles) for three subjects (Series V) before, during and after intermittent exercise consisting of 5 maximal or near maximal bursts of 1 min duration with 5 min rest between each exercise period.

aforementioned Series II with the brief exhaustive work load (22.7 mmoles × kg^{-1} wet muscle) and those obtained in four other subjects (Series III, 19.1 mmoles × kg^{-1} wet muscle) after brief maximal exercise without any warm-up period.

The fact that a maximal anaerobic requirement was induced by the first burst of activity during the intermittant exercise is further emphasized by ATP and CP concentrations which averaged 2.1 and 2.8 mmoles × kg^{-1} (ATP) and 4.5 and 7.4 mmoles × kg^{-1} (CP) wet muscle respectively after the first and fifth exercise periods respectively.

Comments

The existence of lactate accumulation in the working muscles, despite incomplete phosphagen depletion, suggests that there was energy yield from anaerobic glycolysis at the same time as there was phosphagen depletion. As the breakdown of phosphagen was linearly related to the relative work load (Fig. 10) even with heavy work loads, it seems reasonable to assume that anaerobic glycolysis was relatively less important as an energy

delivering process as long as phosphagen depletion was not maximal. Anaerobic energy yield and the processes by which it is produced may then be summarized as follows

a) by phosphagen depletion with low work intensities (< 50 % of max $\dot{V}O_2$) with a relatively modest anaerobic energy yield
b) partly by phosphagen depletion and partly by anaerobic glycolysis with moderate work intensities (> 50 % but < 90 % of max $\dot{V}O_2$)
c) by maximal phosphagen depletion and anaerobic glycolysis, resulting in very high muscle lactate concentration, with heavy and exhaustive work loads (> 90—100 % of max $\dot{V}O_2$)

It may be concluded that the muscle lactate concentration obtained from muscle after brief exhaustive exercise is the highest attainable, i.e. that the term "maximal muscle lactate concentration" is relevant for use with the value obtained with brief maximal work loads for 1 to ca. 10 min.

Lactate accumulation and phosphagen depletion in relation to the oxygen deficit during exhaustive exercise

(Papers I III and VII)

Muscle lactate concentrations at the end of work were found to be the same, whether exhaustion time was 2—3 min or about 7 min, but were lower when exhaustion time amounted to 10—20 min (Fig 14)

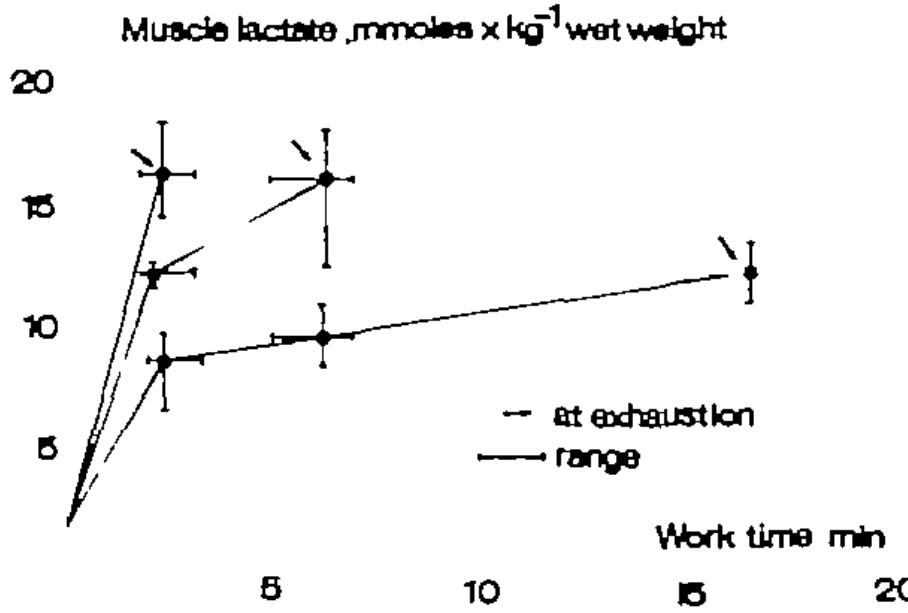

Fig. 14 Mean value and range for muscle lactate concentration with the three different work loads in three subjects (Series IV) in relation to work duration. Not each point in the graph was obtained in separate experiment.

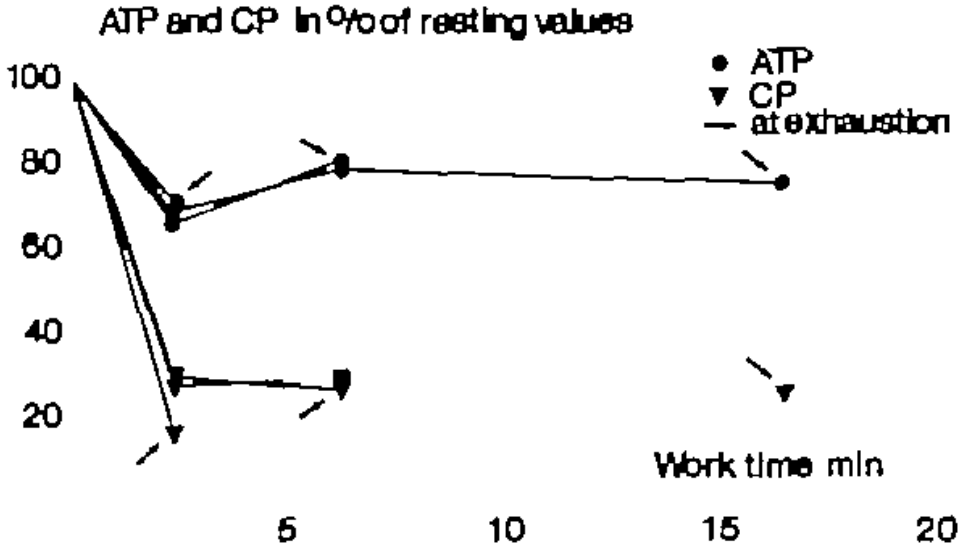

Fig. 15 Mean value and range for ATP and CP concentrations in the exercising muscle during and immediately after exhaustive exercise expressed as per cent of the value at rest. For further information see Fig. 14.

After 2—3 min at the three different test loads muscle lactate concentrations were about 8.5 with the lowest load and about 16.1 mmoles × kg⁻ wet muscle at the highest work load, indicating differences in total anaerobic energy output. However the ATP and CP concentrations obtained simultaneously were evidently reduced to the same extent (Fig 15) pointing to the same alactacid anaerobic energy output, irrespective of work load. ATP and CP concentrations were not depleted further if work continued.

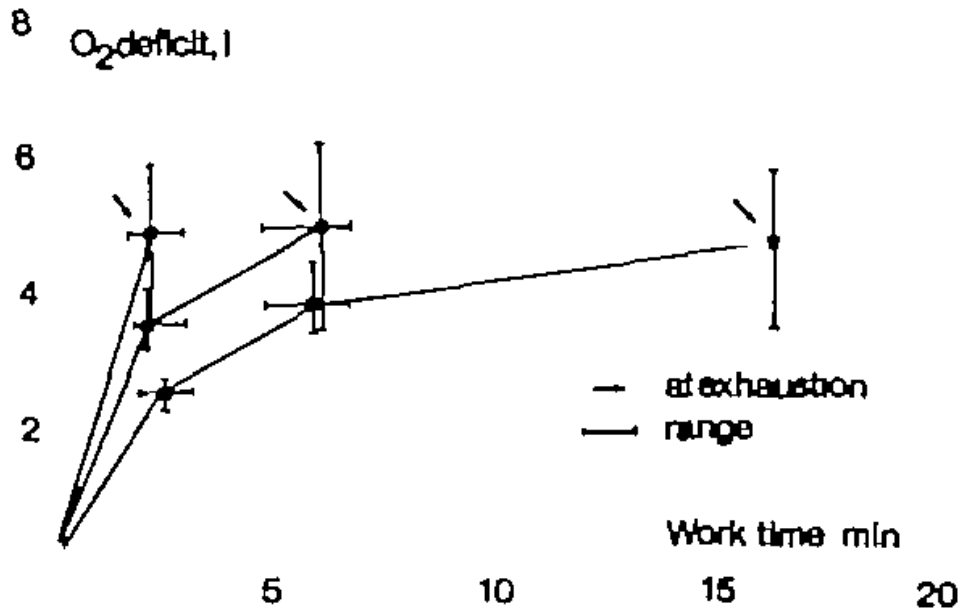

Fig. 16. Mean value and range for O deficit in relation to work time. For further information see Fig. 14

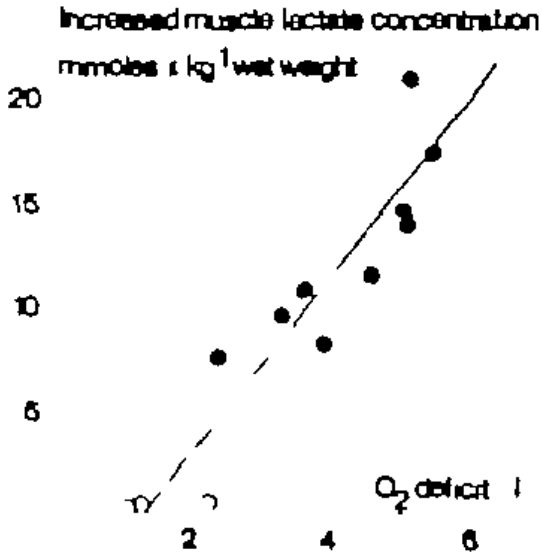

Fig 17 The mean increase in muscle lactate concentration in Series IV in relation to the corresponding oxygen deficit. Data from Series I and from Agnevik *et al.* 1969 are also included. The equation of the regression line is $y = -5.2 + 4.1x$ ($r = 0.88$) The intercept of the x-axis is 1.3 l. This figure may represent the alactacid portion of the oxygen deficit. For explanation of open circles (not included in the statistics) see Fig. 12.

The O deficit values obtained at exhaustion with the three test loads showed an identical total anaerobic energy output (Fig 16)

However after 2 min there was considerable variation in the O_2 deficit which amounted to 2.6, 3 6 and 4.9 l respectively at the three loads.

Since ATP and CP depletion was constant in all six experiments, even if muscle lactate concentration increased, it should be possible to estimate the order of magnitude of the alactacid and lactacid portions of the O_2 defict value by relating the increase in muscle lactate concentration to the corresponding O_2 deficit values. (Fig 17)

Assumng a linear relationship the equation of the regression line was $y = -5.2 + 4.1x$ ($r = 0.88$, $p < 0.01$) the intersection of the x-axis corresponding to 1.3 l. This value would theoretically correspond to total anaerobic energy output without any lactate accumulation in the working muscle, i.e. the total alactacid portion of the oxygen deficit. The excess would then correspond to the lactacid portion. This value agrees with calculated alactacid energy output from maximal phosphagen depletion, which would amount to 1.2—1 3 l of O_2 as presented in the preceding paragraph (Fig 10) Phosphagen depletion in relation to the corresponding O deficit indicated that these stores were not utilized to a maximum until O_2 deficit values were greater than 2—3 l (Fig 18)

Comments

As shown in the preceding paragraph (Fig 10) phosphagen depletion was almost linearly related to work load. The submaximal work loads in that study were interrupted after 6—10 min and it was impossible to establish whether or not ATP and CP concentrations exhibited a gradual decrease. The present data indicate that on work loads exceeding approximately 90—100 %

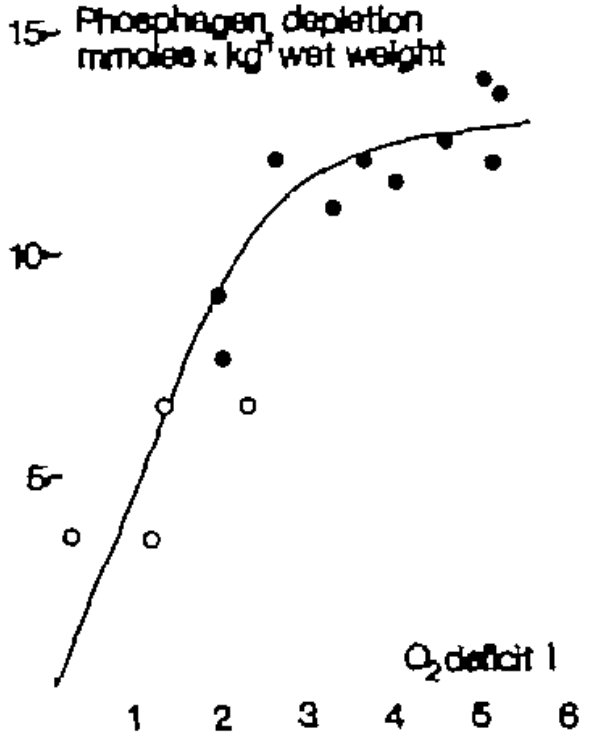

Fig. 18. Phosphagen depletion in relation to the oxygen deficit. Each point represents data from Series I and IV Data from Agnevik *et al.* 1969 Knuttgen and Saltin (open circles, to be published) and Saltin and Karlsson (to be published) are also included.

of max $\dot{V}O_2$, phosphagen stores were depleted to a maximum after only 2 min, whether a subject was exhausted or not. Similar findings have been obtained at lower work loads with less striking CP depletions which stabilized after 4 min and remained constant at that level for 1—2 hrs (Saltin and Karlsson, in preparation)

The portion of the oxygen deficit that could not be accounted for as lactacid anaerobic energy output amounted to a maximum of 1 3 l of oxygen. This figure would then correspond to the alactacid anaerobic energy yield but myoglobin oxygen stores and the decrease in venous oxygen saturation compared to values at rest may modify its magnitude. Human muscle contains myoglobin whose significance has been discussed but it has not been shown that there is any emptying of oxygen stores bound to myoglobin during heavy exercise, even if there are some indications to this effect (Christensen, Hedman and Saltin 1960) The physiological role of myoglobin in muscle tissue is presumably to facilitate the transport of oxygen from capillary blood to the mitochondria (Scholander 1960) and during heavy exercise certain reduction of oxygen stores bound to myoglobin may be expected because of the more pronounced oxygen pressure gradient here (for further information see Wittenberg 1970) However this must be of quantitatively limited importance, amounting to a maximum 0.3 l according to data presented by Björck (1949) Moreover an estimation suggests that approximately 0.3 l of the oxygen deficit may be contributed by a lowering of the oxygen content

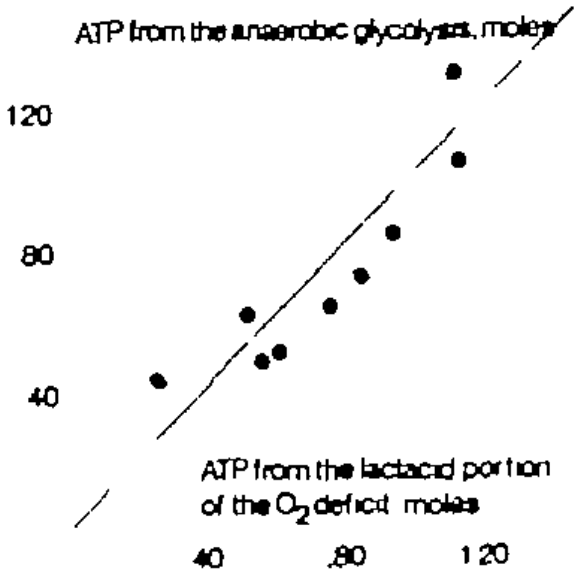

Fig 19 The calculated total mean increase in lactate in the body expressed as ATP formed by concomitant anaerobic glycolysis in relation to the amount of ATP corresponding to the lactacid portion of the oxygen deficit values (actual oxygen deficit — 1 3 l) Data presented in Fig. 17 are used in the calculations.

of venous blood. Thus, maximal O deficit values (4—6 l) would be contributed to 10—15 % of O_2 from myoglobin and venous blood and it seems reasonable to assume that this relative contribution will not increase with submaximal O_2 deficit values. It is therefore concluded that the dominant fraction of the oxygen deficit corresponding to the intercept accounts for alactacid anaerobic energy output. A quantitative relationship was shown to exist between the calculated amount of energy (expressed in oxygen equivalents) which could be derived from phosphagen depletion and the estimated portion of the oxygen deficit contributed by alactacid anaerobic energy yielding processes.

Studies similar to the present one have recently been undertaken in detail in animals (the canine gastrocnemius-plantaris muscle group) by Cerretelli, di Prampero and Piiper (1969) and di Prampero Piiper and Cerretelli (1970) but the results are at variance with the present in several main points. These authors found that lactate formation started only after the complete depletion of phosphagen, which is in accordance with the hypothesis advanced by Margaria (1967) The finding of increased muscle lactate concentrations at an earlier stage was supposedly related to the preparation technique and insufficiencies thus induced.

As an estimation of total lactate production from the present data would be of some interest, the following assumptions have to be made

a) the biopsy is representative of all the muscle groups involved during exercise
b) the involved muscle mass amounts to about 25 kg and the water soluble muscle metabolites would then be diluted in approximately 20 l of water

c) blood lactate concentrations obtained at the same time as the biopsies represent remaining total body water ($\sim$ 20 l)

The total lactate content may then be estimated and the amount of ATP resynthesized by this lactate production (1 lactate molecule = 1.5 ATP molecule) is plotted in Fig 19 in relation to the lactacid portion of the oxygen deficit (oxygen deficit — 1.3 l) expressed in moles of ATP according to the formula on p 37

On the basis of these calculations, there appears to be agreement between the estimated lactacid portion of the oxygen deficit and the amount of lactate present in muscle and blood

Pyruvate and lactate concentrations in muscle and blood and the effect of exercise

(Paper V)

Muscle pyruvate concentration in subjects at rest averaged 0.06 mmoles × kg^{-} wet muscle and increased to 0 13 mmoles × kg^{-} after a brief maximal work load (Table VI) Blood pyruvate concentration started at 0.11 mmoles × l^{-} at rest and ended up at 0.39 mmoles × l^{-} immediately after the maximal load. Thus, a small increase in muscle pyruvate concentration corresponded to a pronounced increase in muscle lactate concentration (Fig. 20)

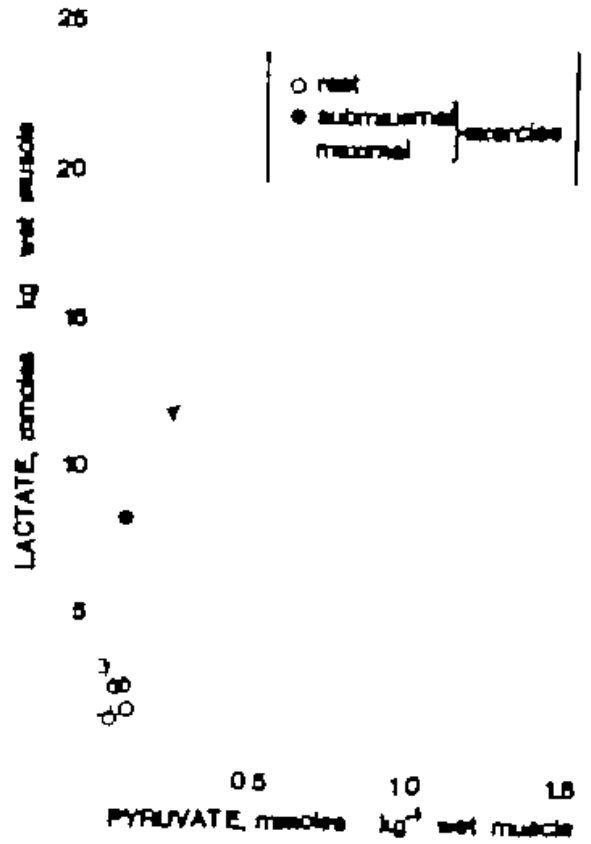

Fig. 20. Muscle lactate concentration in relation to muscle pyruvate concentration at rest and immediately after submaximal and brief maximal exercise in Series VI.

TABLE VI. Mean value ± SE and SD are presented for pyruvate and lactate concentration in muscle and blood in subjects at rest, at submaximal and a maximal work load. The work load and the oxygen uptake are presented as mean value and range

[1] mmoles × kg⁻¹ wet muscle

[2] mmoles × l⁻¹ blood

Comments

Present data would indicate a concentration gradient from blood to muscle for pyruvate on per l of water comparison. Whether or not this would result in an uptake cannot be established since pH differences between the blood and the cell might favour such a gradient (Sjesjö Granholm and Kjällquist 1968)

However *in situ* experiments on the contracting canine gracilis muscle (Karlsson, Rosell and Saltin 1971) disclosed a positive a-v concentration difference for pyruvate at the end of a 50 min stimulation period in five dogs. This immediately changed to a negative a v difference at the beginning of the recovery period, pointing to an uptake of pyruvate during contraction with subsequent release during the recovery period.

Observations at present are too few to make it possible to draw any definite conclusions concerning the relationship between intracellular and extra cellular pyruvate concentrations and their role in the transport of electrons within the intact organism especially when oxygen transport is limited to one organ or organ system. However the increase in muscle pyruvate concentrations observed after exercise is too small to induce a measurable effect on muscle lactate concentration according to the mass action law. It is, therefore, concluded that the excess lactate calculated according to Huckabee (1958) is of no significance in the interpretation of blood and lactate concentrations after muscular exercise.

LDH activity in skeletal muscle after prolonged exercise

(Paper VI)

The mean LDH activity in the vastus lateralis averaged 0 73 (range 0.54—0.88) $\times 10^{-4}$ moles NADH $\times$ g^{-} wet muscle $\times$ min^{-1} which would correspond to a maximal lactate formation rate of 73 mmoles lactate $\times$ kg^{-} wet muscle $\times$ min This value is 3—5 times greater than the rate of formation calculated from the lactate concentrations in muscle and blood after brief maximal work.

LDH activity obtained after endurance work averaged 0.88 $\times 10^{-4}$ moles NADH $\times$ g^{-} wet muscle $\times$ min indicating an increase of the enzyme activity corresponding to 21 % ($p < 0.001$) as shown for two of the subjects in Fig 21

Comments

Studies were not performed to evaluate whether LDH activity depended on a true increase in the amount of enzyme protein or on some change in the

(5—7 hrs not determined after 2—4 hrs work) rose from 3.3 l in the control study to 4.7 l due to a slower rate of acceleration for the O_2 transport system, indicating increased anaerobic energy output. A slower rate of acceleration was observed even at the maximal test loads, resulting in a faster development of O_2 deficit. After moderately prolonged exercise, the O_2 deficit was similar to that in the control study. Thus, there was no tendency for anaerobic energy output to decrease. On the other hand, after the extremely prolonged heavy exercise O_2 deficit was reduced from 5.8 l in the control study to 4.7 l.

Prolonged heavy exercise did not influence phosphagen concentrations before and after the standardized tests performed after the prolonged heavy exercise periods pointing to the same alactacid anaerobic energy output as in

the *control experiments* (Table VII) Muscle tissue lactate concentration at rest and at the standardized work loads was of the same order of magnitude as in the control experiments (Table VII) with the exception of the maximal test load performed after extremely prolonged exercise (5—7 hrs) (13.3 mmoles compared to 22.0 mmoles × kg^{-1} wet muscle in the control study) Highest concentrations of blood lactate were significantly lower in the standardized tests, except at the submaximal load after moderately prolonged exercise (2—4 hrs) at which a tendency to a decrease was present, however (Table VIII) Blood lactate data consequently confirmed observations reported by Astrand *et al.* (1963)

Comments

Blood lactate concentration decreased at the standardized work loads performed after a preceding prolonged work. The most reasonable explanation for this finding is that prolonged heavy exercise caused an increase in the metabolism of extracellular lactate as earlier suggested by Rämmal and Ström (1949) Increased utilization of blood borne lactate, resulting in a lower blood lactate concentration may facilitate the translocation of lactate from the muscle. *Thus, it seems reasonable to assume an enhanced lactate flux with* standardized work loads after prolonged heavy exercise.

Muscle lactate concentration at the standardized work loads was, with one exception, unchanged by the preceding prolonged heavy exercise period. According to the findings above this should be indicative of at least the same lactate formation as in the control experiments. The decrease in muscle lactate concentration with the brief maximal load after extremely prolonged exercise *was greater than expected from the decrease in the O deficit (for comparison* see Fig 17) The hypothesis of an increased utilization of blood-borne lactate and a subsequent increased release of lactate from the muscle would contribute to an explanation of the lowered muscle lactate concentration with the brief maximal load after extremely prolonged exercise, but a definite explanation cannot be given. The reason why the decrease in muscle lactate concentration was not present with the brief maximal load after moderately prolonged exercise can be explained by the shorter period of work (1.2 compared to 1 7 min) which would minimize the effect of an increased lactate flux.

The short period of work in the present studies is the most probable reason for the higher blood lactate concentration after maximal work preceded by prolonged exercise as compared to the results reported by Astrand *et al.* (1963) In these experiments maximal work of about 5 min duration was used.

Since preceding prolonged heavy exercise did not influence ATP and CP depletion, indicating an intact alactacid anaerobic energy output as compared to that in the control experiments, changes in O_2 deficit may reflect altered

TABLE VIII. lactacid anaerobic energy output. The observed increase in O_2 deficit at the submaximal work load after extremely prolonged heavy exercise would then be reflected by a higher muscle lactate concentration. This is not the case even if a tendency was present at the submaximal test load after moderately prolonged exercise. In view of the decreased blood lactate concentration an increased flux would be the most reasonable explanation.

CHAPTER V

GENERAL DISCUSSION

The significance of lactate formation

When man starts to perform dynamic physical work, chemically bound energy is transformed into mechanical work by the muscles. As first demonstrated by Cain and Davies (1962) ATP stored in the muscle cell is the immediate energy source for muscular contraction. The dominant ATP fraction is formed by resynthesis of ATP from ADP in the mitochondria, which however need O_2 to capture electrons from the oxidative processes. As indicated by Chance and his associates (for ref see Jöbsis 1964) the electron transfer systems of the muscle cell are reduced at the onset of a muscular contraction as an indication of increased mitochondrial breakdown of substrates to meet the demand for ATP This demand may vary many hundredfold over a range of isotonic contraction tensions (Davies 1967)

ATP and CP stores in the resting muscle of man are very limited and can only provide energy briefly during intense contractions. Energy in the form of ATP quanta must, therefore, be delivered by other cellular processes, as man can perform extremely heavy exercise for a period longer than fractions of a min. An increased rate of mitochondrial ATP resynthesis will take place since an elevated O supply to the muscle is induced by the work, but the resynthesis of ATP by glycolysis also is of significance in this context. Anaerobic energy yielding processes can supply more than 50 % of the total energy yield at high loads resulting in exhaustion within 2—3 min (Paper III) A considerable amount of energy in ATP equivalents must be generated by glycolysis in such exercise. The present data indicate that breakdown of ATP and CP on the one hand, and anaerobic glycolysis, on the other hand provide amounts of energy equivalent to approximately 1 l and 3—5 l of O_2 respectively This should be comparable to a max $\dot{V}O_2$ in the order of 3—6 l × min the lowest value representative for sedentary subjects and the highest value for athletes (Saltin and Åstrand 1967)

The significance of lactate formation is two-fold

1 it is the end product of anaerobic glycolysis, which is one of the ATP yielding processes

? it is a constituent of the coupled redox processes between pyruvate and lactate and extra mitochondrial NAD and NADH, which are necessary in the maintenance of glycolysis under anaerobic conditions.

The factors involved in the regulation of lactate production have been frequently discussed but are still not well understood. The following factors may be mentioned as being of importance

a. The enzyme LDH is present in mammalian tissue in 5 forms with different affinities for pyruvate and lactate respectively (for ref. see Sund 1968) The M form favours lactate formation under physiological conditions, while the H form favours the formation of pyruvate from lactate and is the most frequent form in heart muscle. Present data on the total LDH activity in the skeletal muscle of man (lateral portions of the quadriceps femoris) indicate that enzyme activity may not be a limiting factor in lactate formation in the working muscle, since this enzyme activity exceeded the highest observed rate of lactate formation by a factor of 3—5

b Pyruvate concentration in the muscle may reach very high levels and influence lactate formation. This was earlier thought to be a mass action effect as suggested by Huckabee (1958) However the present experiments produced an increase of 0 06 to only 0 14 mmoles × kg⁻ wet muscle. Thus, the increased pyruvate concentration may be ignored as a significant cause of lactate formation.

c. Extra mitochondrial concentration of NADH increases and this has been shown in most tissues to depend on the fact that the rate of oxidation by the mitochondria is insufficient when oxygen supply is inadequate (for ref. see Jöbsis 1964) Of necessity this fraction of NADH in the muscle cell is oxidized by pyruvate.

During exercise of relatively brief duration (< 30 min.) no change in muscle LDH activity may occur (Gollnick, Struck and Bogyo 1967) Moreover the increase in NADH concentration in the cell seems to be the most probable cause of increased lactate formation during exercise since the increase in muscle pyruvate concentration is negligible. However the redox system or systems involved seem to be complex in nature, since working muscle producing lactate is also able to oxidize blood-borne labelled lactate in significant amounts (Jorfeldt 1969) In the present studies it seems reasonable to conclude that at start of exercise in man conditions are such as to cause lactate formation in the muscle cell with subsequent accumulation and release. Moreover lactate formation occurs when the total energy yield exceeds that which can be derived from aerobic processes operating at a maximum. In this situation reduction of pyruvate is the only way to oxidize extra-mitochondrial NADH.

The correlation found between O deficit and lactate concentration in working muscles suggests that lactate formation during exercise is caused by a lack in oxygen transport in mainly two situations

a. at the start of exercise and until a steady state level is obtained

b. with supramaximal work loads.

This is in agreement with Lundin and Ström (1947) and their findings when studying the effect of nitrogen-oxygen mixtures on blood lactate concentrations with exercise.

Recently studies have been published which are at variance with this generally accepted view concerning the limiting factors of oxygen supply to the working muscle

Kaijser (1970) reported elevated O_2 tensions in the deep veins of man during rhytmic contractions of the forearm muscle in a hyperbaric oxygen (3 atm) atmosphere (P O 1840—1900 mm Hg compared to 96—100 mm Hg in the control experiments at 0 21 atm PO) However blood lactate concentrations were only moderately reduced in deep venous blood with subjects breathing oxygen at 3 atm as compared to the results of control experiments. The author concluded that the links in the O transport system must be saturated with O_2 and the main limiting factor in the rate of utilization of O would consequently be found at the mitochondrial level. Disregarding the consequence of the aforementioned findings concerning the role of circulatory functions as limiting factors, these results failed to establish whether or not hypoxia was still present in the contracting muscle fibers and whether or not high O_2 levels had a toxic influence on muscle enzymes. In contrast to the results presented by Kaijser Wyndham and associates recently reported an increase in max $\dot{V}O_2$ amounting to 17 % by descending to 3,000 m below surface in mines (Wyndham *et al* 1970) The increase in max $\dot{V}O_2$ was linearly related with increase in barometric pressure between 630—865 mm Hg, which further supports the hypothesis of the circulatory system as the main limiting factor for the oxygen transport to the working muscles.

The occurrence of hypoxia in resting muscle as well has been demonstrated by Bolme and Novotny (1969) with canine gastrocnemius-plantaris preparation. By stimulating the sympathetic cholinergic vasodilator nerve they observed increased blood flow as well as increased O_2 uptake. Similar findings were obtained by Whalen and Nair (1969) who using an O electrode in resting feline skeletal muscle, reported an average PO of 6.6 (range 0—45) mm Hg 56 of 371 of their measurements on 17 animals did not significantly differ from zero. These findings should provide a satisfactory explanation of the lactate formation and release in resting canine gracilis muscle specimens

observed by Costin *et al.* (1971) and Karlsson, Rosell and Saltin (1971) as being due to partial hypoxia in resting muscle tissue. However the final explanation why there is a certain lactate concentration in the resting muscle and release to extracellular compartments cannot be provided at present. It might be that lactic acid is a significant constituent of the metabolic vasodilator mechanism suggested by Renkin and Rosell (1962)

Relation between muscle lactate concentration and the perception of exhaustion

Exhaustion during brief maximal exercise has been thought to be caused by high muscle lactate concentrations (Asmussen, Döbeln and Nielsen, 1948) and also from considerations of the results of animal experiments (Fletcher and Hopkins 1907 Meyerhof 1925) From the present studies, it can be concluded that the highest muscle lactate concentrations are found after exhaustive exercise of 1—7 min duration and that repeated maximal work periods do not increase muscle lactate concentration further In two subjects participating in three of the present studies, each consisting of maximal work, muscle lactate concentration reached 20.2—22 0 mmoles × kg⁻ and 21 1—24 8 mmoles × kg^{-1} wet muscle respectively

Similar high values have been reported after brief maximal isometric contractions, which brought the subject to exhaustion within 5 min (Bergström *et al* 1971) and after exhaustive leg extensions with heavy weights (Ollander personal communication) In contrast to this, muscle lactate concentrations greater than 7 mmoles × kg wet muscle have not been observed in exhaustion after eccentric work (sometimes referred to as negative work) (Bonde Petersen, personal communication) It seems reasonable to conclude, therefore that a close correlation exists between maximal muscle lactate concentration and perception of exhaustion during brief maximal concentric exercise, indicating that muscle lactate concentration or secondary changes are direttly or indirectly responsible for muscular fatigue.

Since proportionately lower muscle and blood lactate concentrations are found when the time to exhaustion is approximately 16 min, any explanation which demands a causal relationship between muscle lactate concentration and exhaustion is difficult to accept

A plausible explanation to exhaustion after 15—20 min exercise might be that maximal muscle temperature here in contrast to brief maximal exercise is reached (Saltin, Gagge and Bergh 1971) Similar high values (40—41 C) have been observed after brief maximal eccentric exercise, which then would

lactate concentrations obtained after brief maximal running in seven subjects are presented. Muscle lactate concentration averaged 15 6 mmoles × kg^{-1} wet muscle and blood lactate 9.3 mmoles × l indicating the same relationship as illustrated in Fig 22

Chapter II presented results concerning lactate concentration gradients from the muscle fiber structures to extra fiber structures surrounding the fiber bundles, indicating some impediment to the immediate translocation of the lactic acid molecule from the muscle cell to the interstitial space. In experiments on dog heart and skeletal muscle respectively Kübler *et al* (1966) and Hirsche Langohr and Wacker (1970) showed that the lactic acid translocation process was evidently not simple diffusion, and Kübler *et al.* postulated that an active transport mechanism might be involved. Similar experimental results have been found (Karlsson Rosell and Saltin 1971) when studying muscle, arterial and venous lactate concentrations in canine gracilis muscle specimens at rest and during electrically stimulated contractions.

The findings in intermittant exercise with supramaximal bursts of activity may be explained by the circumstance that muscle lactate concentration reached the highest value sustainable with each exercise period. Blood lactate concentration, on the other hand, increased during the interval periods until it reached equality with or a value close to the plateau muscle lactate concentration. Thus, a higher blood lactate concentration would be expected to occur with repeated maximal or near maximal, brief work loads than with a single load.

The present results make it possible to conclude that the highest blood lactate concentration reflects muscle lactate concentration fairly well after brief single exhaustive dynamic work and is, therefore, useful as an indicator of maximal exercise in similar experimental situations.

After extremely brief exercise of 10—20 sec duration at supramaximal work intensities, high muscle lactate concentrations are not indicated by high blood lactate concentrations (Saltin and Essén 1971) This has also been found to be true after exhaustive isometric exercise for 1—4 min (Ollander personal communication)

Elevated blood lactate concentrations have previously been used as an indicator of anaerobic metabolism in working muscle Even though this has been questioned (Huckabee 1958) blood lactate concentration has been of practical value in evaluations of whether or not oxygen transport has been stressed to a maximum (Astrand 1952) In the present material an almost linear relationship was found between the highest blood lactate concentration and the muscle lactate concentration obtained immediately after cessation of work (Fig 23) However there was a difference on submaximal work loads

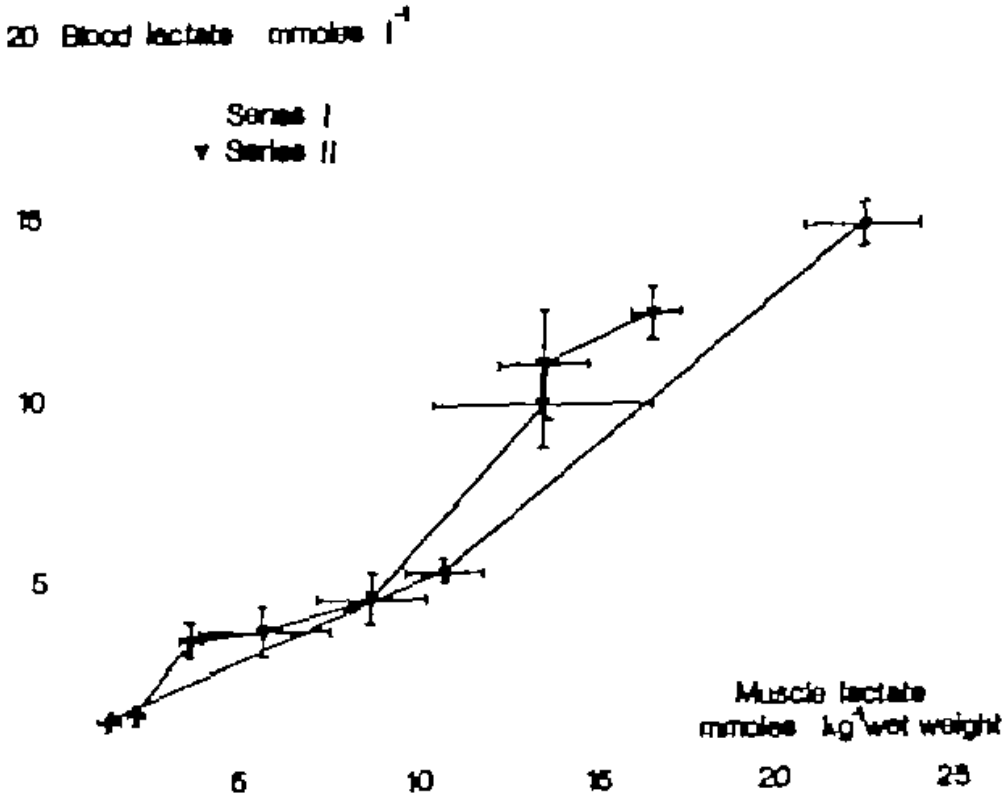

Fig. 23 The highest observed blood lactate concentration after work related to the muscle lactate concentration in Series I (trained subjects) and Series II (untrained subjects) respectively The mean value ± SE is presented.

between the two groups of subjects studied which indicated a comparatively lower blood lactate concentration in trained subjects versus the muscle lactate concentration. This occurred despite longer work durations at submaximal loads by untrained subjects (10 min compared to 6 min) The difference in training condition, in terms of a higher max $\dot{V}O_2$, might explain the difference between the two subject groups. At the maximal work load blood lactate concentration was higher ($p < 0.05$) in the trained subjects (14 6 mmoles × l⁻ compared with 12.3 mmoles × l⁻ in the trained subjects) but the differen ce was less than might be expected from the muscle lactate concentration (22.7 and 16.9 mmoles × kg⁻ wet muscle in the trained compared to the untrained subjects respectively)

Glycogen depletion and anaerobic glycolysis

Glucose G-6-P and lactate are the only glycolytic intermediary metabolites found to accumulate in the muscle in significant amounts (Paper II) But none of these except lactate is found in concentrations greater than approx

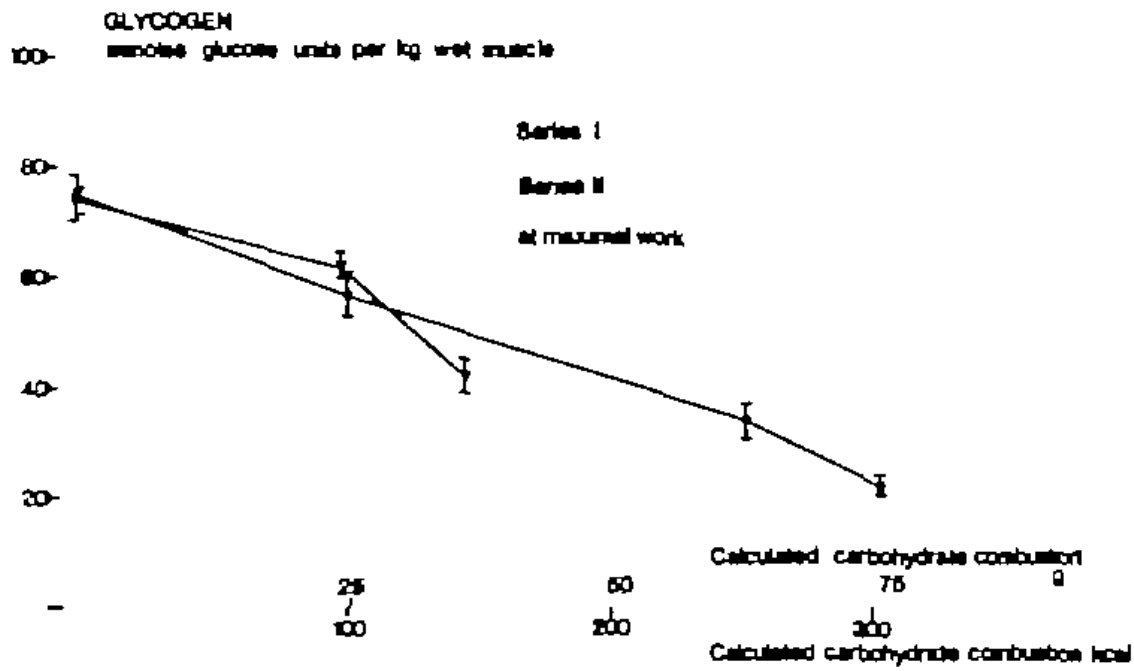

Fig. 24 Glycogen depletion (mean value ± SE) in the working muscle in relation to the carbohydrate utilization expressed in kcal or g of glycogen. Series I (trained subjects) and Series II (untrained subjects) respectively. These latter values are calculated from the oxygen uptake and RQ values, assuming a caloric output of 4.1 kcal × g glycogen

imately 4 mmoles × kg wet muscle while the lactate concentration in similar *situations ranges between 15—30 mmoles × kg wet muscle.*

After brief maximal exercise glucose concentration amounts to approximately 2 mmoles × kg wet muscle and G-6-P concentration to approximately 4 mmoles × kg. As indicated by the demonstrated release of glucose (Wahren 1970) glucose concentration might reach values corresponding to or somewhat greater than that in the blood.

Glycogen content at rest and after the separate work loads is presented in Table V for Series I and Series II and shows a significant depletion with each load. The depletion is further presented in Fig. 24 in relation to the calculated amount of carbohydrate oxidized. The calculations are based on $\dot{V}O_2$ and ventilatory exchange ratio (RQ) data. Similar curves were obtained for the two groups of subjects, illustrating a tendency for enhanced glycogen depletion in relation to the amount oxidized in brief maximal exercise and indicating relatively increased anaerobic glycolysis.

No quantitative relationship between glycogen depletion and the accumulation of different glycolytic intermediates could be established since the magnitude of glucose release and accumulation of F-6-P were not determined in

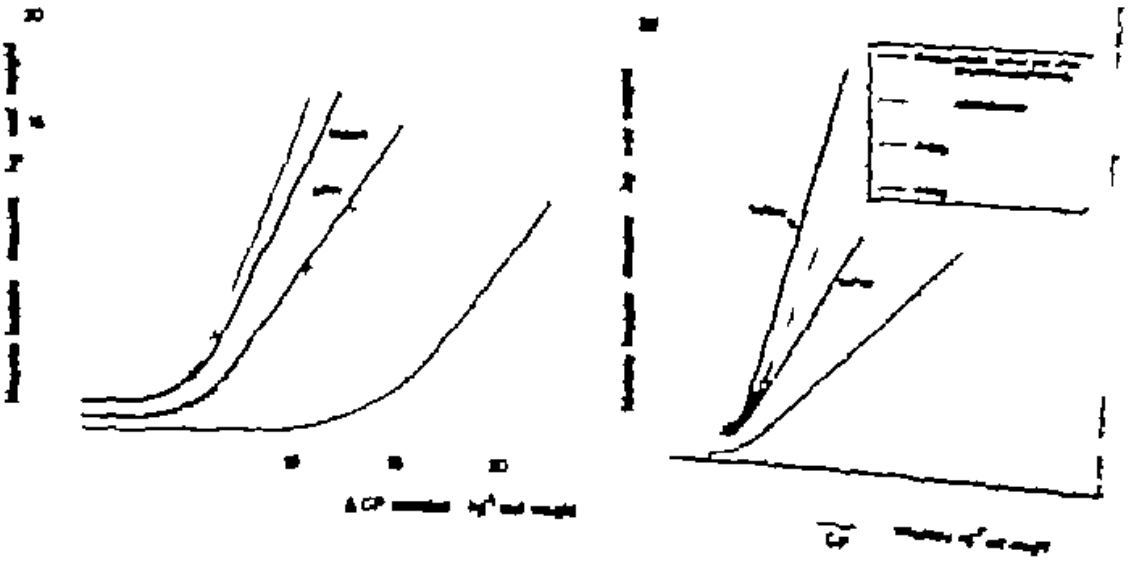

Fig. 25. Left graph: Muscle lactate concentration in relation to CP [illegible] during exercise or stimulations to contractions in man (Saltin and Karlson [illegible]) in boys (Eriksson, Karlsson and Saltin 1971) in dog (Karlsson, Rowell and Sa[illegible]) and in frog (Danforth 1965). Right graph. Muscle lactate concentration in [illegible] the corresponding reciprocal CP concentration.

the present studies. In isolated canine gracilis muscle, on the other hand, good agreement has been found between glycogen breakdown and the contribution, accumulation, uptake and release of different glycolytic intermediary metabolites (Karlsson, Rosell and Saltin 1971).

Possible factors regulating glycolytic activity

The present results indicate that the increase in lactate concentration starts after the initial decrease in phosphagen stores. Whether there is a causal relationship between these two processes, possibly triggered by the production of metabolites e.g. P is questionable.

A similar relationship has been described for muscle lactate and CP in frog sartorius muscles stimulated to contractions and frozen at different intervals after the onset of work (Danforth 1965). This is illustrated in Fig. 25 a (concentration values recalculated in relation to wet weight). Similar data obtained in the dog, adolescent boys and adult men before and after physical conditioning are included in the same figure. These data were obtained in various experiments with different work intensities as contrast to the experiments with frog sartori in which the same standardized procedure was used throughout. The same tendency was apparent in all these different muscles: a given CP depletion precedes an increase in lactate concentration

Further depletion caused different muscle lactate concentrations, suggesting that different kinetics were involved in the activation of glycolysis. The presence of different rates in the separate muscles is further emphasized by plotting muscle lactate concentration versus reciprocal CP concentration (Fig. 25 b)

Two separate glycolytic enzymes have been postulated to regulate the activity of the breakdown phosphorylase and phosphofructokinase (for ref see Danforth 1965) Phosphorylase b is transformed into its a form by means of a phosphorylation catalysed by the enzyme phosphorylase kinase, (Helmreich and Cori 1965) In 1956 Cori suggested that this reaction might be facilitated by the increase in cellular pH caused by the initial CP depletion. This increase in pH is then changed into a decrease as soon as lactic acid starts to accumulate in the cell (Karpatkin, Helmreich and Cori 1965) The importance of tissue pH as a regulatory factor has been further documented by Danforth (1965)

Rulon, Schottelius and Schottelius (1961) demonstrated that phosphorylase is activated at a sufficient rate to mobilize substrate to meet the increased energy demand. This was confirmed by Danforth, Helmreich and Cori (1962) who showed a 100 % activation of the enzyme in frog sartorius muscle 3 sec *after the onset of stimulation. Danforth and his associates suggested further* on the basis of their experiments, that two mechanisms were involved in activating the enzyme muscle contractions per se and adrenalin. Drummond Harwood and Powell (1969) showed that the mechanism of phosphorylase activation by muscle contractions is basically different from that involving adrenergic amines which would function via activation of an enzyme phosphorylase kinase. Thus, during exercise in man there seems to be two different mechanisms operating to activate phosphorylase muscle contractions and increased sympathetic tone (von Euler and Hellner 1952, Häggendahl, Hartley and Saltin 1970) presumably at a rate which is sufficient to furnish the cell with glucose residues. It seems reasonable to assume, therefore that the enzyme phosphorylase is not rate-governing during exercise but of significance in the initiation of glycolysis at start of contractions.

The other enzyme phosphofructokinase was suggested by Cori in 194 as being the most important regulatory factor in glycolysis. Passonneau and Lowry (1962) presented studies which showed how conditions similar to those present in the anaerobic cell activated the enzyme. It has also been shown that enzyme activity is inhibited by ATP in high concentrations (Passonneau and Lowry 1962) citrate in high concentrations (Randle Denton and England 1967) or by decreased pH (Danforth 1965) Thus, the enzyme seems to possess some of the characteristics necessary to the main regulatory system of glycolysis.

In the present studies (Paper II and IV) findings have been made which indicate that a regulatory function similar to that described above also holds true for human skeletal muscle, as an accumulation of G-6-P could be demonstrated during brief exhaustive exercise. Similar findings have been reported in heavily stimulated frog sartorius muscle (Karpatkin, Helmreich and Cori 1964) and, recently in man (Bergström *et al.* 1971). The latter authors also found an increase in F-6-P but not in F 1 6-P which is in agreement with our own findings (Karlsson, unpublished results) and further supports the hypothesis that phosphofructokinase is the most important regulatory mechanism during exercise. The present studies were not directly aimed at establishing whether or not true equilibrium states, as defined by Guldberg Waage's law or flows" of substrates through different metabolic pathway determine concentrations of metabolites in the cell. Some of the findings, however such as the G-6-P accumulation with brief maximal exercise and the concentration gradient for lactate between muscle and blood during exercise support the view that flows" rather than equilibria determine concentrations of muscle metabolites, as suggested by Olson (1963) and Lowry and Passonneau (1964).

SUMMARY

Methods have been adapted to determine muscle metabolites such as e.g. ATP CP glycogen and lactate in small muscle specimens (10—15 mg wet weight) obtained in the lateral portions of quadriceps femoris muscle of man.

Methodological studies in respect to the chemical analysis and the extent to which the sampling technique was representative of the muscle investigated have shown that the methods applied are adequate.

Thus, it has been possible to study the effect of exercise on these metabolites in the working muscle and to evaluate in greater detail the relative importance of the alactacid and lactacid portions of anaerobic energy yield with submaximal and brief, maximal work loads. These studies have been applied to trained as well as to untrained subjects thus covering a considerable range of individual maximal oxygen uptakes (41—72 ml × kg⁻ × min).

It was demonstrated that phosphagen concentration and the accumulation

of lactate were the same at identical relative, submaximal work loads even if great differences in absolute load existed.

With test loads greater than 90—100 % of the individual maximal oxygen uptake phosphagen stores seemed to be maximally reduced as early as 2—3 min after the start of exercise there being no further decrease over the next 10—15 min.

The highest muscle lactate concentrations were observed at exhaustion. On a per l of water basis they were approximately twice as great as the blood lactate concentrations determined simultaneously indicating that the translocation process for lactate does not immediately equilibrate the lactate concentration of the muscle cell with the lactate concentration of the extra-cellular space.

It was demonstrated that the observed increase in blood pyruvate concentration with exercise did not reflect a corresponding increase in muscle pyruvate concentration. On the contrary at rest as well as after brief maximal exercise, muscle pyruvate concentrations were obtained which were lower than blood concentrations.

Phosphagen depletion as well as muscle lactate concentration were closely related to the calculated O_2 deficit. An estimate of the total breakdown of ATP and CP and the amount of ATP resynthesis by the glycolysis corresponding to the lactate content in muscle and blood agrees in magnitude with the O deficit expressed in ATP equivalents.

Since venous oxygen tension during exercise may reach a critically low level it can be concluded that O deficit at the start of work reflects a true anaerobic state. This deficit is not due to anaerobic energy output resulting from an overflow of glycolysis with concomitant pyruvate and lactate formation. Thus, lactate formation during exercise is caused by the necessity to reoxidize extramitochondrially formed NADH in order to avoid a complete arrest of glycolysis.

With standardized work loads performed after a prolonged heavy exercise period, blood lactate concentrations were lower than in a control study after prolonged rest. On the other hand muscle lactate concentrations were unchanged. The most plausible explanation for these findings is that the preceding prolonged heavy exercise induced an increased utilization of blood-borne lactate. The lowered blood lactate concentrations might enhance lactate flux from the working muscle to the blood.

ACKNOWLEDGEMENTS

To the heads of the departments where the present investigations have been carried out, Professor Per Erik Lundahl, Professor Börje Uvnäs and Professor Per-Olof Åstrand, I am very indebted for economical and laboratory facilities.

I also wish to express my deep gratitude to

my present superior Associate Professor Bengt Saltin, who introduced me into this field of physiology — work physiology — and whose support in every phase of the investigations has been encouraging,

Associate Professor Bertil Diamant, who introduced me to the analytical techniques and whose valuable advice has been of great value the investigations,

Associate Professor Sune Rosell for stimulating discussions and whose previous work in the field of muscle physiology has been of guidance

the entire staff of the department of physiology Gymnastik och idrottshögskolan, for their generous and skilful assistance in collecting, analyzing and presenting the data. Especially my thanks are due to Birgitta Essén, B Sc, for her assistance in performing most of the biochemical analyses.

Finally I wish to express my gratitude to the former head of the department of physiology Gymnastik -och idrottshögskolan Professor Erik Hohwü Christensen, for introducing me originally to the principles of scientific research and for continued interest in my work. Further his own position in and knowledge about the development of work physiology has been of great importance to me when writing the present thesis.

The work was made possible by grants from the Swedish Medical Research Council (14X — 2203) and the Swedish Sports Federation.

VII Effects of variations in the extracellular osmolality on the ionic permeability of vascular smooth muscle. Jonsson, O., *Acta physiol. scand.* In press.

The papers are referred to by their Roman numerals in text.

Introduction

Alterations in osmolality of extracellular fluid occur under physiological conditions. For instance, enhanced metabolism in different tissues causes an increased release of osmotically active substances which, in turn, results in local hypertonicity (Barcroft and Kato 1915 Hill and Kupalov 1930) Only recently however have such increases in tissue osmolality been suggested to be involved in the metabolic control of blood flow In a symposium on skeletal muscle circulation in 1966 Mellander proposed, for the first time, a possible role of hypertonicity in exercise hyperemia. (see Mellander 1968) Staunby and Fregly (1968) also discussed the importance of osmolality in blood flow autoregulation in skeletal muscle at that time.

The involvement of hyperosmolality in exercise hyperemia has later been investigated in a series of studies by Mellander and collaborators (Mellander *et al.* 1967 Gray Lundvall and Mellander 1968 Lundvall 1969 Lundvall Mellander and White 1969 Mellander and Lundvall 1970) In cat skeletal muscle, exercise was found to be associated with an increase in the osmolality of the venous effluent by up to 40 mOsm/kg Also in man clearcut increases in osmolality were found in cubital venous blood during forearm exercise. Hyperosmolality of similar degrees, produced by intra arterial infusions of inert hypertonic solutions, elicited marked dilatation of the resistance vessels and the pattern of vascular response resembled also in other respects that produced by exercise. Earlier studies (*e g* Marshall and Shepherd 1959 Overbeck, Molnar and Haddy 1961) had demonstrated blood flow increases in response to arterial infusions of hyperosmotic solutions but had not clarified whether this was due to passive dehydration of the vascular wall or to inhibition of smooth muscle tone. The observation by Mellander *et al.* (1967) that hyperosmolality failed to increase blood flow if superimposed on a supramaximal dose of papaverine indicated, however that passive dehydration is not the essential mode of action

The mechanisms by which increased osmolality interferes with vascular tone remained to be clarified. From studies of other types of muscle it was known that hyperosmolality could dissociate electrical and mechanical activity (*e g* Hodgkin and Horowicz 1957 Tomita 1966 a) and interfere

with myogenic intercellular propagation (*e g* Barr Dewey and Berger 1965 Johansson and Ljung 1967) but very high tonicities had then been used. It was therefore important to analyse the actions of more moderate osmolality variations on isolated vascular smooth muscle, if possible taken from resistance vessels. These, however are not easily prepared for direct studies. It was for this reason necessary to use as an experimental model a more conveniently isolated vessel which exhibited functional similarities to the resistance vessels The rat portal vein, with its spontaneous myogenic activity (Funaki and Bohr 1964) seemed suitable from these points of view

In a first series of experiments on the portal vein (Mellander *et al* 1967), we observed that hyperosmolality markedly inhibited the spontaneous electrical and mechanical activity evidently as a result of membrane hyperpolarization. A more complete analysis indicated the existence of an intimate relationship between the volume of the smooth muscle cells and their level of activity (I) This and the subsequent series of studies (II—VII), summarized in the present survey are concerned with the nature and background of this relation between cell volume and cell activity

Aim of the present studies

The first step in the present series of studies was to investigate in more detail the effects of alterations in extracellular osmolality on the electrical and mechanical activity of the rat portal vein. Indirect evidence was thereby obtained for a close relationship between cell volume and degree of spontaneous activity of the smooth muscle osmotic procedures which could be expected to cause cell shrinkage led to inhibition, and *vice versa* (I) Further penetration of this problem required however quantitative information concerning the influence of altered tonicity on muscle cell volume. Studies on other types of smooth muscle have revealed that the cells adapt their volume almost like perfect osmometers on exposure to moderately hyperosmotic solutions, while the changes caused by lowered tonicity seem to be more complex (Bozler 1965 Brading and Setekleiv 1968)

A possible explanation for the effects of altered osmolality on portal vein activity might be secondary changes in the membrane potential as a result of an ionic redistribution across the cell membranes. This hypothesis could be tested in experiments where both the osmolality and the ionic composition of the extracellular medium were varied. An alternative or perhaps, additional explanation would be a change in membrane permeability as a result of osmotically induced cell shrinkage or swelling. For example, if hypo-osmolality led to a more pronounced increase in the permeability constant for sodium (P_{Na}) as compared with that for potassium (P_K), this would contribute to the depolarization observed in hypo-osmotic solutions. However before such a hypothesis could be tested experimentally information on the ionic distribution in the vascular smooth muscle was required.

The purpose of the present studies was thus to find answers to the following questions:

1) How is the spontaneous electrical and mechanical activity of the isolated rat portal vein influenced by alterations in extracellular osmolality?

2) Do the smooth muscle cells beha e like perfect osmometers on tonicity changes?

with myogenic intercellular propagation (e g Barr Dewey and Berger 1965 Johansson and Ljung 1967) but very high tonicities had then been used. It was therefore important to analyse the actions of more moderate osmolality variations on isolated vascular smooth muscle, if possible taken from resistance vessels. These, however are not easily prepared for direct studies. It was for this reason necessary to use as an experimental model a *more conveniently isolated vessel which exhibited functional similarities* to the resistance vessels The rat portal vein, with its spontaneous myogenic activity (Funaki and Bohr 1964) seemed suitable from these points of view

In a first series of experiments on the portal vein (Mellander *et al* 1967) we observed that hyperosmolality markedly inhibited the spontaneous electrical and mechanical activity evidently as a result of membrane hyperpolarization A more complete analysis indicated the existence of an intimate relationship between the volume of the smooth muscle cells and their level of activity (I) This and the subsequent series of studies (II—VII) summarized in the present survey are concerned with the nature and background of this relation between cell volume and cell activity

Aim of the present studies

The first step in the present series of studies was to investigate in more detail the effects of alterations in extracellular osmolality on the electrical and mechanical activity of the rat portal vein. Indirect evidence was thereby obtained for a close relationship between cell volume and degree of spontaneous activity of the smooth muscle, osmotic procedures which could be expected to cause cell shrinkage led to inhibition, and *vice versa* (I) Further penetration of this problem required, however quantitative information concerning the influence of altered tonicity on muscle cell volume. Studies on other types of smooth muscle have revealed that the cells adapt their volume almost like perfect osmometers on exposure to moderately hyperosmotic solutions, while the changes caused by lowered tonicity seem to be more complex (Bozler 1965 Brading and Setekleiv 1968)

A possible explanation for the effects of altered osmolality on portal vein activity might be secondary changes in the membrane potential as a result of an ionic redistribution across the cell membranes. This hypothesis could be tested in experiments where both the osmolality and the ionic composition of the extracellular medium were varied. An alternative or perhaps, additional explanation would be a change in membrane permeability as a result of osmotically induced cell shrinkage or swelling For example, if hypo-osmolality led to a more pronounced increase in the permeability constant for sodium (P_{Na}), as compared with that for potassium (P_K) this would contribute to the depolarization observed in hypo-osmotic solutions. However before such a hypothesis could be tested experimentally information on the ionic distribution in the vascular smooth muscle was required.

The purpose of the present studies was thus to find answers to the following questions.

1) How is the spontaneous electrical and mechanical activity of the isolated rat portal vein influenced by alterations in extracellular osmolality?

2) Do the smooth muscle cells behave like perfect osmometers on tonicity changes?

3) How are sodium, potassium and chloride ions distributed in this vascular smooth muscle?

4) Can the osmolality effects on the spontaneous muscle activity be explained solely on the basis of altered ionic concentration gradients across the cell membranes?

5) Do alterations in P_{Ir} and P_K contribute to the changes in spontaneous activity that are elicited by altered osmolality?

Methodological considerations

Preparations The experiments carried out in the present series of studies were all performed *in vitro* which has the following advantages as compared to an *in vivo* situation 1) Stable environmental conditions can be maintained. 2) *Single* factors in the surrounding environment can be changed. 3) Repeated determinations of wet weight can be made on one and the same preparation. 4) Both electrical and mechanical activity can easily be recorded simultaneously 5) Tracer techniques can conveniently be applied to problems of ionic concentrations and membrane permeability

Even though the *in vitro* situation is basically "unphysiological" a portal vein preparation will "survive" and exhibit normal activity for at least 10 hours in normal Krebs solution at 37°C.

The rat portal vein was chosen as a test preparation for these studies since its smooth muscle exhibits characteristics similar to those of the functionally important precapillary resistance vessels with regard to myogenic activity spread of excitation, *etc* Thus, observations on this "single unit" preparation might be relevant also for the vessels that are mainly responsible for the important control of flow resistance and flow distribution. It should, however be stressed that from the pharmacological point of view for instance with regard to the responses to acetylcholine and histamine, the isolated portal vein is not a representative model of resistance vessels. A spontaneously active portal vein is found in many vertebrates, *e g* rat (Funaki and Bohr 1964), rabbit (Holman, Kasby and Suthers 1967) guinea pig (Nakajima and Horn 1967) baboon (Cuthbert 1966) It is interesting to note that in the primitive myxine there exists a true portal heart (Fänge, Bloom and Östlund 1963)

The rat was chosen for the present series of investigations since it is easily available, relatively cheap and supplies a portal vein preparation of suitable size.

As the methods used in each study are described in detail in the corresponding Methods sections, only some points of general interest will be discussed in this connection.

Solutions. A modified Krebs solution was used as standard incubation medium. Osmolality was increased by adding sucrose or other nonelectrolytes and decreased by reducing the NaCl concentration. In I and II ap-

proximate changes in osmolality were deduced on the basis of changes in concentrations. In IV a manual device for determination of the freezing point was available which allowed direct measurements of osmolality. In VI and VII it was replaced by an automatically recording osmometer which gave highly reproducible results.

Mechanical activity The mechanical activity of the preparations was recorded isometrically in the longitudinal direction of the veins with a passive tension of approximately 400 dynes. Histological examination has revealed that the muscle tissue in the part of the vein used for the present studies is mainly longitudinally oriented (Johansson *et al* 1970).

Electrical activity The membrane events were recorded extracellularly with the sucrose gap technique. This metod was originally described by Stampfli (1954) for recording on nerves and was later modified for smooth muscle by Burnstock and Straub (1958). It has certain advantages in comparison to the microelectrode technique in that it is more convenient to handle and allows a more undisturbed recording of the mechanical events. It does not, however permit exact measurements of the membrane potential since the degree of short-circuiting between the recording electrodes in the extracellular space is not known. Action potentials and *relative* changes of the membrane potential can, however readily be recorded. The consistent correlation in time between electrical and mechanical events (I, III) suggests that the phasic mechanical activity is normally triggered by the bursts of electrical activity. It also implies that a simple mechanical recording can be used as an indicator for changes in the electrical events.

Extracellular space In general, two different procedures have been used to determine the extracellular space, 1) estimations from electron microscopic sections and 2) measurements in uptake experiments with extracellular markers. The former method tends to yield lower values than the latter one (for ref. see Goodford 1968) which is more often used. The value for the extracellular space, obtained in tracer uptake studies, varies with the size of the tracer molecule — large molecules giving smaller spaces (Barr and Malvin 1965). For instance, in circular intestinal muscle of the dog the sucrose space exceeds the inulin space by 4 ml/100 g wet weight (Barr and Malvin 1965) and in the guinea pig taenia coli the sorbitol space exceeds that of inulin by 6 ml/100 g wet weight (Brading and Jones 1969). This apparent inhomogeneity of the interstitial space might be due to an inability of larger tracer molecules to fully penetrate the extracellular mucopolysaccharide lattice (Ogston 1958, Ogston and Phelps 1960). Furthermore, the size of the preparation is of importance for the measured

space, as the influence of the superficial film of solute becomes increasingly important in smaller preparations due to their larger surface to volume ratio Also the relative proportion of damaged cells probably increases in small preparations, leading to an overestimation of the extracellular space For example, Goodford (1968) found that the sorbitol space decreased by 0.7 ml/100 g wet weight per mg increase in weight of the taenia coli preparation

In the present experiments, sucrose (mol. wt. 342) was chosen as the extracellular marker As distinguished from inulin, another commonly used tracer substance, sucrose is a single molecular species. Uptake experiments show that ^{14}C sucrose is almost completely equilibrated in the portal vein within 15 min (II) Therefore, the "15 min sucrose space" has been taken to represent the extracellular volume, expressed in ml/100 g wet weight and calculated in the following way

$$\frac{\text{cpm/mg tissue} \times 100\,000}{\text{cpm/ml incubation medium}}$$

With respect to a recently introduced tracer for extracellular space, Co EDTA, a tendency for adsorption has been noted, manifesting itself as a decrease in space with increasing tracer concentrations (Brading and Jones 1969) Preliminary experiments indicated a similar tendency concerning the ^{14}C sucrose space of the rat portal vein, but only when the tracer concentration was below 0.2 mmoles/l. No such correlation was found in the range of concentrations applied in the present studies (0.2—0.6 *mmoles/l*)

Rinsing and drying In II and IV the veins were rapidly rinsed in inactive solution after exposure to radioactive media. The purpose of the procedure was to remove the surface film of active solution and to immediately interrupt the exposure which is of importance when shorter periods of incubation are used. In later studies (V VI and VII) this rinsing procedure was omitted, mainly to allow a comparison between the results obtained in ^{24}Na and ^{42}K uptake experiments and the results of Na and K determinations with flame photometry Thus figures for the ^{14}C sucrose space in V VI and VII *are somewhat higher than those in II and IV* However the calculations of cell water content in different environmental situations, presented in II and IV would not be significantly altered if the sucrose space had been determined in unrinsed veins.

Before weighing, all preparations used in tracer exchange experiments were gently blotted between two pieces of filter paper Such a "drying" procedure was necessary due to the greatly varying amounts of adhering

proximate changes in osmolality were deduced on the basis of changes in concentrations. In IV a manual device for determination of the freezing point was available which allowed direct measurements of osmolality In VI and VII it was replaced by an automatically recording osmometer which gave highly reproducible results.

Mechanical activity The mechanical activity of the preparations was recorded isometrically in the longitudinal direction of the veins with a passive tension of approximately 400 dynes. Histological examination has revealed that the muscle tissue in the part of the vein used for the present studies is mainly longitudinally oriented (Johansson *et al* 1970)

Electrical activity The membrane events were recorded extracellularly with the sucrose gap technique. This method was originally described by Stampfli (1954) for recording on nerves and was later modified for smooth muscle by Burnstock and Straub (1958). It has certain advantages in comparison to the microelectrode technique in that it is more convenient to handle and allows a more undisturbed recording of the mechanical events. It does not, however permit exact measurements of the membrane potential since the degree of short-circuiting between the recording electrodes in the extracellular space is not known. Action potentials and *relative* changes of the membrane potential can, however readily be recorded. The consistent correlation in time between electrical and mechanical events (I III) suggests that the phasic mechanical activity is normally triggered by the bursts of electrical activity It also implies that a simple mechanical recording can be used as an indicator for changes in the electrical events.

Extracellular space In general, two different procedures have been used to determine the extracellular space, 1) estimations from electron microscopic sections and 2) measurements in uptake experiments with extracellular markers. The former method tends to yield lower values than the latter one (for ref see Goodford 1968) which is more often used. The value for the extracellular space, obtained in tracer uptake studies, varies with the size of the tracer molecule — large molecules giving smaller spaces (Barr and Malvin 1965) For instance, in circular intestinal muscle of the dog the sucrose space exceeds the inulin space by 4 ml/100 g wet weight (Barr and Malvin 1965) and in the guinea pig taenia coli the sorbitol space exceeds that of inulin by 6 ml/100 g wet weight (Brading and Jones 1969) This apparent inhomogeneity of the interstitial space might be due to an inability of larger tracer molecules to fully penetrate the extracellular mucopolysaccharide lattice (Ogston 1958 Ogston and Phelps 1960) Furthermore, the size of the preparation is of importance for the measured

space, as the influence of the superficial film of solute becomes increasingly important in smaller preparations due to their larger surface to volume ratio. Also the relative proportion of damaged cells probably increases in small preparations, leading to an overestimation of the extracellular space. For example, Goodford (1968) found that the sorbitol space decreased by 0.7 ml/100 g wet weight per mg increase in weight of the taenia coli preparation.

In the present experiments, sucrose (mol. wt. 342) was chosen as the extracellular marker. As distinguished from inulin, another commonly used tracer substance, sucrose is a single molecular species. Uptake experiments show that ^{14}C sucrose is almost completely equilibrated in the portal vein within 15 min (II). Therefore, the "15 min sucrose space" has been taken to represent the extracellular volume, expressed in ml/100 g wet weight and calculated in the following way

$$\frac{\text{cpm/mg tissue} \times 100\,000}{\text{cpm/ml incubation medium}}$$

With respect to a recently introduced tracer for extracellular space, Co EDTA, a tendency for adsorption has been noted, manifesting itself as a decrease in space with increasing tracer concentrations (Brading and Jones 1969). Preliminary experiments indicated a similar tendency concerning the ^{14}C sucrose space of the rat portal vein, but only when the tracer concentration was below 0.2 mmoles/l. No such correlation was found in the range of concentrations applied in the present studies (0.2—0.6 mmoles/l).

Rinsing and drying. In II and IV the veins were rapidly rinsed in inactive solution after exposure to radioactive media. The purpose of the procedure was to remove the surface film of active solution and to immediately interrupt the exposure which is of importance when shorter periods of incubation are used. In later studies (V, VI and VII) this rinsing procedure was omitted, mainly to allow a comparison between the results obtained in ^{24}Na and ^{42}K uptake experiments and the results of Na and K determinations with flame photometry. Thus figures for the ^{14}C sucrose space in V, VI and VII are somewhat higher than those in II and IV. However, the calculations of cell water content in different environmental situations, presented in II and IV, would not be significantly altered if the sucrose space had been determined in unrinsed veins.

Before weighing, all preparations used in tracer exchange experiments were gently blotted between two pieces of filter paper. Such a "drying" procedure was necessary due to the greatly varying amounts of adhering

fluid. Another commonly used drying technique is to drag the tissue across a plexiglass surface until no trace of moisture is seen A comparison between these procedures reveals that tissues blotted with the filter paper method are "drier" (Hagemeijer Ronve and Schoffeniels 1965 a, Brading and Setekleiv 1968) This method appears to be more appropriate for a flat preparation like the slit portal vein since it would probably coil during the dragging procedure. Accordingly the latter procedure gives highly unreliable results for strips of rat aorta but not when cylindrical" preparations, like the taenia coli, are used (Hagemeijer Ronve and Schoffeniels 1965 a, Brading and Setekleiv 1968)

Cell water Changes in cell water were calculated from direct measurements of wet weight, dry weight and ^{14}C sucrose space in II In IV and VI changes in the wet weight were indirectly estimated from alterations in dry weight and extracellular space on the assumption that the weight of intracellular solids and solutes remains essentially constant during exposure to the different test solutions. Comparisons of the directly and indirectly estimated values revealed good agreement between the two methods. By combining the different steps of calculations into a single equation, the standard deviation and significance could be estimated for the variations in cell water as a result of changes in tonicity

Ionic contents The ionic contents were determined by flame photometry (Na, K) (V) and by studying the uptake of ^{24}Na, ^{42}K and ^{36}Cl (V VII) Both for sodium and potassium the radioactive uptake technique gave somewhat lower values than the flame photometry determinations (see further below)

Wash-out experiments The efflux of the tracer substances was determined in VI and VII by transferring the "loaded" preparations through a succession of flasks containing inactive solution The different components of the curve representing the decrease in tissue activity were analysed mathematically with a calculator (Hewlett Packard 9100 A) Permeability coefficients in cm/sec for the nonelectrolytes were estimated by Fick's law of diffusion applying the rate constants for the transmembrane effluxes and the ratio between cell volume and cell surface. When the permeability coefficients for ions were calculated, a correction had to be included in the equation for the influence of the membrane potential Since the membrane potential was not measured directly the correction had to be approximate

Damaged preparations. Some of the preparations in V and VII were frozen and thawed or subjected to poisoning by cyanide and iodoacetate in order to destroy the barrier function of the cell membranes. The purpose

of these procedures was to provide a homogenous fluid phase throughout the preparation in equilibrium with the external medium. The use of such damaged preparations should facilitate the study of the "bound" ionic fractions as to their magnitude and exchange kinetics. The observation that sucrose as well as ^{24}Na and ^{42}K were equilibrated with the *total* water content of these preparations strongly indicates that their normal membrane function had really been lost. The finding that the size of the bound Na and K fractions were similar in the two types of damaged preparations despite the fact that the procedures applied to impair the cell membrane function were quite different, might indicate that the characteristics of the binding sites were not affected by these manipulations. If so, results obtained with these frozen and thawed or poisoned veins should be relevant even for normal tissues. In these damaged preparations, all binding sites should be equilibrated with the ionic composition of the incubation medium, that is, in normal Krebs, the sequestration of Na should be favoured in comparison to that of K. A multiplication of *i. e* the Na concentration in the Krebs solution with that part of the distribution space of ^{24}Na that exceeds the volume of total water should thus yield the bound sodium component in meq/unit wet weight in this kind of preparation. However evidence was obtained that in normal tissues a fraction of the binding sites is equilibrated with the intracellular fluid which thus should favour the sequestration of potassium. Since the ratio between the sites in contact with the intra and extracellular fluid, respectively is not known, the estimation of the bound amounts of ions in normal portal veins becomes quite complex. These problems will be further discussed below

Results and Comments

The effects of altered extracellular osmolality on the spontaneous activity of vascular smooth muscle.

The normal, spontaneous electrical activity of the portal vein consists of bursts of spike potentials, lasting 5 to 10 sec and appearing at a rate of 2—3 per min. Strictly correlated to these electrical events, phasic mechanical contractions of the longitudinal muscles occur with peak tensions of 400—800 dyn (I and III) Increasing the extracellular osmolality by adding sucrose to normal Krebs solution reduced the contractile activity with regard to both amplitude and frequency (I) Although most pronounced during the first min, this effect was sustained until osmolality was normalized again When on the other hand, extracellular osmolality was instead increased by urea, the inhibition lasted only 2—3 min after which normal activity was regained in spite of the continuous presence of urea. Thus sucrose led to a sustained inhibition whereas urea did not. Another clearcut difference in the muscle responses to hyperosmotic urea and sucrose media became apparent on return to normal osmolality After exposure to urea, an intense shortlasting increase of electrical and mechanical activity was seen, whereas only a moderate sluggish excitation was obtained after exposure to sucrose (I and II).

The interpretation was that shrinkage of the smooth muscle cells inhibits their spontaneous activity while they are stimulated by swelling. The difference between the responses to the hyperosmotic urea and sucrose media would then be due to a more rapid penetration of the smaller urea molecule through the cell membranes, which thus makes it unable to exert a maintained osmotic influence on the muscle cells. Sucrose, on the other hand, was considered to be effectively excluded from the intracellular domain. The excitation obtained when extracellular osmolality was normalized after urea exposure would then be due to a shortlasting cell swelling until urea had again left the cells by diffusion. This interpretation was supported by the observation that the excitatory phase was abolished by replacing extracellular urea with equiosmolal amounts of sucrose instead of returning to normal Krebs (I)

Furthermore, when extracellular osmolality was reduced by decreasing

the NaCl concentration of the Krebs solution a marked and sustained excitation was obtained (I and III) If the subtracted amounts of NaCl were replaced by an equiosmolal quantity of sucrose, no excitation was obtained indicating that it was due to the low osmolality and not to the reduced ionic concentration. If however NaCl was replaced by equiosmolal urea, an excitation followed as during hypo-osmolality again suggesting that urea penetrates the cell membranes.

These suggestions concerning the distribution of urea and sucrose in the portal vein were confirmed in II by uptake studies of ^{14}C urea and ^{14}C sucrose. Urea quickly equilibrated in a space corresponding to the volume of the total tissue water i. e about 79 ml/100 g wet weight whereas the sucrose space was less than 50 ml/100 g wet weight (see further below)

The duration of exposure to hyperosmotic urea and sucrose media was also varied to explore its effect on the excitation that followed upon normalization of the osmolality (II) For urea, this excitation increased with the preceding period of exposure, but only as long as it was shorter than the equilibration time for ^{14}C urea in the total water The excitation obtained after incubation in hyperosmotic urea therefore seems to depend on the shortlasting cell swelling bound to occur upon normalization of the osmolality In the case of sucrose, on the other hand the excitation increased with the duration of the preceding hypertonicity exposure without any correlation to the equilibration time for ^{14}C sucrose uptake. Therefore, another type of mechanism seemed to be involved in this case. In V it was found that the muscle cells lose potassium on longer exposures (60 min) to hypertonic sucrose. Normalization of the cell volume upon return to isotonicity could then lead to a subnormal ratio of $[K^+]_i$ to $[K^+]$ which, in turn, would cause depolarization and increased activity

Further evidence for a correlation between smooth muscle cell volume and activity was obtained in II and IV where it was demonstrated that the cells actually shrink in a hyperosmotic sucrose solution and swell in hypo-osmotic media. These volume alterations will be considered from a quantitative point of view in the next section.

Osmotic reduction of cell volume is thus associated with hyperpolarization and decreased frequency and duration of the spike bursts. Conversely osmotic swelling leads to depolarization and increased spike activity It is conceivable that these reactions to alterations in cell volume represent manifestations of a general mechano-electrical coupling. This response to osmotic deformation might thus be related to that induced by passive stretch, seen in many smooth muscles of the "single unit" type, e g ureter (Bozler 1947) taenia coli (Bülbring 1953) portal mesenteric

veins (Sparks 1964 Axelsson, Johansson and Jonsson 1966 Holman *et al.* 1968) small arteries (Johansson and Bohr 1966) and cerebral and umbilical arteries (Sparks 1964) Reactions to passive stretch and to osmotic deformation have also been discussed for stretch receptors as manifestations of a unitary mechanism of mechano-electrical coupling (Ottosson 1965) As to the details of the cellular events behind the mechano-electrical transduction, some interesting theories have been proposed (see *e g* Teorell 1966) but much remains to be elucidated in this respect.

Beside the influences of hyperosmolality on membrane potential and spike activity the portal vein also shows an impaired intercellular propagation, referred to above (Johansson and Ljung 1967) and a negative inotropic response (Mellander *et al* 1967) when osmolality is doubled or more. As to this inotropic effect of altered tonicity many studies have been carried out on skeletal and cardiac muscle preparations. Hodgkin and Horowicz (1957) reported that single action potentials failed to elicit a mechanical twitch in the frog semitendinosus muscle when extracellular tonicity was 2.5 times normal while trains of action potentials could still initiate weak contractions. Later studies indicate that this impaired contractility of the striated muscle in strongly hypertonic media is, in part, due to impaired electro-mechanical coupling This is suggested for instance by the finding that caffein, assumed to act directly on intracellular Ca^{++} stores, is able to induce a contraction even in a hyperosmotic medium while an increment in $[K^+]_o$, acting *via* the membrane potential, fails to do so (Caputo 1966)

It has been shown, however that increased osmolality beside this uncoupling effect exerts a direct influence on the contractile machinery This is indicated by the observation made by Howarth (1958) and Podolsky and Sugi (1967) that the shortening of striated muscle fibres in a hypertonic environment is extremely slow compared to control. The authors ascribed their findings to, alternatively an increased intracellular viscosity or to an inhibition of the myofibrillar ATP ase activity as a result of raised intracellular ionic strength

The inotropic effects of hyperosmolality on cardiac muscle are somewhat more complex as indicated by the fact that a pronounced raise in tonicity elicits quite the opposite type of response as that induced by a more moderate degree of hyperosmolality For instance Koch-Weser (1963) and Wildenthal Skelton and Coleman (1969) reported a depressed contractile strength in isolated cat papillary muscles exposed to two times the normal tonicity and more powerful contractions than in an isotonic medium when the same tissues were incubated at osmolalities up to 100—

150 mOsm/kg above normal. Moreover the latter authors found that the rate of shortening was changed in a similar manner *i e* a faster velocity of shortening as compared to control at the moderate degree of hyper osmolality and *vice versa* at a tonicity of two times the normal or more. By a thorough analysis of the mechanisms involved Wildenthal, Skelton and Coleman (1969) could demonstrate that these effects of hyperosmolality were exerted through influences on both the contractile and the series elastic elements of the myocardial fibres. It has been suggested that the increase in contractile force and velocity of shortening observed at lower degrees of hypertonicity is the result of an increase in the Ca^{++} concentration near the muscle membrane. The opposite effects observed at higher osmolalities would then be due to a dominating role of increased intracellular viscosity and raised interfilamentary friction (Koch-Weser 1963 Wildenthal Skelton and Coleman 1969)

In summary then, the results referred to in this section point to a correlation between the volume of the vascular smooth muscle cells and their degree of activity Shrinkage is associated with inhibition and swelling with excitation. Possible explanations for the mechanisms involved will be discussed in the following sections but the changes in the volume of the smooth muscle cells caused by alterations in tonicity will first be considered from a quantitative point of view

The osmotic behaviour of vascular smooth muscle cells.

The effects of changes in extracellular osmolality on the intracellular water content were analysed under different experimental conditions in II IV and VI to elucidate whether the muscle cells behave as osmometers. If so their volume would adapt to alterations in the osmolality according to the equation given by Ruck6 and McCutcheon (1932)

$$P\,(V-b) = P_o(V-b) = \text{constant} \qquad (1)$$

P denotes the original external osmotic pressure, V the original cell volume while P and V denote the same parameters in the new environment. The non solvent volume of the cell is represented by b which is assumed to be constant throughout. Thus, for a perfect osmometer V plotted against $\frac{1}{P}$ should yield a straight line with an intercept at b when $\frac{1}{P}$ approaches 0

The concept of the muscle cell as an osmometer assumes that it is surrounded by a semipermeable membrane, which separates an intracellular isosmotic solution of colloids and crystalloids from the extracellular medium. This membrane theory" is, however not generally accepted (see further below)

The volume of cell water (w) at different tonicities was analysed in the present series of experiments. If muscle cells adapt themselves to an altered osmotic environment like perfect osmometers and their entire water content participates as a solvent (no "bound" water) the experimentally determined w values would equal V — b in the equation of Lucké and McCutcheon In II it was demonstrated that w decreased to 66 per cent of control on exposure to Krebs plus 150 mmoles sucrose/l, in good agreement with the value of 64 per cent calculated from equation (1) It may be concluded, therefore, that the vascular smooth muscle cells behave as almost perfect osmometers on exposure to hyperosmolality of this degree. A similar osmotic behaviour has been reported for intestinal smooth muscle (Brading and Setekleiv 1968) as well as for amphibian skeletal muscle (Boyle and Conway 1941 Dydynska and Wilkie 1963 Blinks 1965 Bozler 1965) These uniform results in different preparations thus seem to support the concept of the cell as a semipermeable bag" filled with a fixed amount of relatively impermeant solutes and solids. Furthermore, they allow calculations of the concomitant alterations in transmembrane ionic concentration gradients that are bound to occur on shrinkage of the muscle cells. Such data will be used below when the mechanism responsible for the correlation between cell volume and degree of muscle activity is discussed

The fact that the cells behave as if surrounded by semipermeable membranes on increases of osmolality does not mean that the membranes are permeable to water alone Such an osmotic behaviour should be expected also if the cell membranes were permeable to ions as long as their inward and outward fluxes were equal, thus keeping the internal solute amount constant.

The alterations in the cell water of the vascular smooth muscle induced by reductions in the extracellular tonicity are more complex, as demonstrated in IV and VI At 37°C the cell water increased by 14 per cent in muscles stretched to their *in situ* length but by 35 per cent in unstretched preparations on exposure to Krebs minus 60 mmoles NaCl/l. When the same experiment was performed at such a low temperature (1°C) that muscle activity was virtually abolished the cell water increased by approximately the same value (35—40 per cent) in both stretched and

unstretched veins. These results indicate that the increased active tension induced by hypo-osmolality at 37°C could oppose cell swelling in the stretched veins where the contractile response should be more pronounced than in unstretched preparations, according to the length-tension relationship (Speden 1960 Sparks and Bohr 1962) However this factor cannot alone explain the restricted swelling since the cell water did not increase to the extent expected for a perfect osmometer on exposure to Krebs minus 60 mmoles NaCl/l even at 1 C (40 compared to 58 per cent) This might indicate that tension develops in the cell membranes so that a hydrostatic pressure difference becomes established at more pronounced swellings of the cells. However since muscle cells exposed to this drastically hypotonic medium were found to lose ions, they appear to obtain transmembrane osmotic equilibrium despite a fairly restricted swelling

On the other hand, on exposure to more moderately hypo-osmotic environments (Krebs minus 30 mmoles NaCl/l) at 1°C, the cell water increased to an extent expected for a perfect osmometer and, moreover remained essentially constant during prolonged exposure. Thus, when the restricting influence of the contractile response on the swelling of the cells is eliminated, the cells exhibit an almost perfect osmotic behaviour on reductions in osmolality as long as these are not too drastic.

In summary the results presented in II IV and VI concerning the adaption of the portal vein cell volume to alterations in the extracellular tonicity demonstrate that the cells shrink in hyperosmotic media and swell in hypo-osmotic ones which thus supports the conclusions drawn in I II and III. The extent of volume change is in accordance with what could be expected for perfect osmometers on increases in osmolality and also on moderate decreases in osmolality provided the contractile response is hampered. Even on drastic reductions in tonicity the results do not contradict the concept of muscle cells as semipermeable bags filled with an aqueous solution of crystalloids and colloids, if it is assumed that they then adapt to hypo-osmolality by losing ions when they cannot swell any more.

Concerning other types of muscle cells exposed to hypo-osmolality Blinks (1965) reported a perfect osmotic behaviour for amphibian *skeletal muscle* while Bozler (1965) stated that they swell less than expected. Bozler explained this as due to a loss of ions and to the presence of bound, osmotically inactive water Most authors seem to agree that amphibian and mammalian *smooth muscle* do not swell to an extent predicted from the osmotic laws, at least not when the tonicity reductions are pronounced (e g Bozler 1965 Brading and Setekleiv 1968). In both these studies a

certain loss of cellular ions was observed which is in agreement with the present findings on the portal vein Bozler proposed that the restriction in cell swelling was due to the development of strong cross-linked gels in the cytoplasm on exposure to hypotonicity while Brading and Setekleiv suggested that it depended on limited distensibility of the cell membranes.

As mentioned earlier the membrane model for the cell is not generally accepted. As an alternative, the "sorptional theory" has been advocated particularly by a group of Russian authors (for review see Troshin 1966) According to this view cell permeability is not a function of the membrane but of the sorptional activity of the protoplasm This concept includes the solubility of substances in the protoplasm as well as their adsorptional and chemical binding by cellular colloids. The sorptional activity of the protoplasm is considered to be regulated by the cell metabolism A substance penetrating the cell would then be either in a dissolved or in a bound state depending on the actual sorptional ability of the protoplasm Normally the greater part of cellular potassium, magnesium and calcium would be bound and therefore incapable of free diffusion while the binding and, consequently the cellular content of sodium would be small. Upon excitation or damage of the cells, a shift in the sorptional activity would occur leading to a decrease in the binding of some substances like potassium to the cell colloids, while that of others, like sodium, would be increased Consequently the permeability to sodium would then be increased and that to potassium decreased.

Further according to Troshin s concept most of the cell water would prevail in an organized "bound" form implying that its properties would be different from those it has in a normal aqueous solution. The alterations in cell water content, induced by exposure to hyperosmotic media, are ascribed to a decrease in the hydration of the cellular colloids as a result of solute penetration into the cells. Thus, according to this sorptional theory cell shrinkage upon exposure to hypertonicity is ascribed to the penetration of the extra" solute into the cells while, according to the membrane theory it is explained by the inability of the solute to penetrate into the cells.

Troshin enumerates several investigations performed on different kinds of tissues where results have been obtained that support the sorptional theory For instance, Nasonov and Aizenberg (1937) found that the ability of a Ringer solution, made hypertonic by addition of non-electrolytes to withdraw water from the frog leg muscle, increased with the molecular weight of the added solute. Even urea and glycerol, known to penetrate muscle cells easily (Overton 1902) could make them shrink

permanently However when isovolumetric (*i. e* a constant ratio between volume of solutes and volume of solvent) instead of isosmotic concentrations were applied, equal reductions in muscular volume were caused irrespective of the mol. wt. Similar results were obtained on egg cells by Aizenberg (1939) In accordance with these results, Troshin (1953) found that the water content of erythrocytes, suspended in hypertonic galactos-Ringer solutions, decreased simultaneously with and in proportion to the entrance of the solute Troshin concluded that the erythrocytes lost water not because the sugar did not penetrate them, but because it did.

These results, which no doubt are difficult to explain on the basis of the membrane model alone, do not seem to be relevant for the portal vein For instance, in II it was demonstrated that a hyperosmotic urea Krebs medium is unable to permanently withdraw water from the smooth muscle cells, as no change in the wet weight of the preparation could be measured. In general, the sorptional theory has been challenged by several authors on the basis of considerable experimental evidence incompatible with it. For instance, Hodgkin and Keynes (1953) demonstrated that the self diffusion coefficient and ionic mobility of potassium ions inside a cuttlefish axon is only a few per cent lower than the corresponding values in an aqueous solution. These findings contradict the hypothesis that the greater part of the cellular K prevails in a bound form. Furthermore, electrical measurements of the cable constants of nerve and striated muscle fibres have demonstrated that the cytoplasm behaves as a good electrolytic conductor surrounded by an insulating membrane (Hodgkin and Rushton 1946, Katz 1948) Similar electrical properties have been revealed for bundles of smooth muscle fibres (Tomita 1966 b, 1967 Abe and Tomita 1968).

It thus seems justified to discuss the present results as to the effects of altered osmolality on the vascular smooth muscle cells on the basis of the membrane model The present results thus indicate a perfect osmotic behaviour on increases of tonicity while the swelling as a result of hypotonicity was less than expected. This could, at least partly be ascribed to a restricting influence of the contractile response When prevented from adapting themselves to hypo-osmolality by swelling, the cells seem to be able to do so by adjusting their intracellular ionic amounts.

The distribution of ions in the vascular smooth muscle

The total amounts of sodium and potassium in the isolated portal vein were determined in V by flame photometry The tissue contents of these

elements remained essentially constant for considerable periods (270 min) of incubation in normal Krebs solution at 37°C. A comparison between values obtained with flame photometry and the distribution volume of ^{24}Na after different periods of exposure to the radioactive medium showed that ^{24}Na after only a few min equilibrated in a space corresponding to about 90 per cent of the total Na content. No significant increase in the distribution volume of ^{24}Na was obtained with longer periods of exposure. A similar comparison for K showed that the ^{42}K uptake was much slower and after six hours of exposure to radioactivity the ^{42}K distribution space was still significantly lower than expected from the total K content suggesting the existence of a slowly exchanging potassium fraction. The total content of chloride was not determined in the present series of studies. The plateau value of the ^{36}Cl uptake curve which was reached within 15 min, was therefore used for calculations on chloride distribution.

If these values for *total* Na, K and Cl amounts and the values for tissue water and extracellular space were used to calculate the intracellular ionic concentrations on the basis of a two compartment tissue model the following values, in meq/l cell water were obtained $[Na^+]_i$ 90 $[K^+]_i$ 163 and $[Cl^-]_i$ 114. These concentrations are, however too high to allow an osmotic equilibrium across the cell membranes, which led to the assumption that some fraction of the total ionic contents prevails in a bound osmotically inactive form.

This possibility was investigated in V by two different approaches. In the first series of experiments the absolute amounts of Na and K in the portal vein were determined by flame photometry after 5, 30 and 60 min of incubation in an isotonic sucrose solution containing 2.5 mmoles $CaCl_2$/l as its only ionic constituent. The tissue content of Na decreased rapidly in this medium and after one hour it was below the measurable level. With the method used, this implies a Na content below 2 meq/kg wet weight. The decrease in the potassium content was less pronounced, and even after 60 min approximately 40 per cent of the original K content remained in the tissue. These results speak against the existence of any *sizeable* component of *firmly* bound Na. The more gradual decline in the potassium content was probably due to the fact that this ion is mainly located intracellularly and thus has to pass the cell membranes. No definite conclusions concerning bound fractions of K can therefore be drawn from these results.

The second series of experiments in V intended to give information on bound ions, involved studies of the uptake of ^{24}Na, ^{42}K and ^{36}Cl in portal

veins after interference with the cell membrane function by freezing and thawing or by poisoning. In such preparations the entire fluid phase of the tissue appeared to be homogenous and equilibrated with the external medium. *The ability of the tissue to bind ions would then be revealed by* a distribution volume of the tracer substances greater than the volume of total water The effectiveness of these procedures to bring about the intended effect on the cell membranes was indicated by the findings in the damaged veins that sucrose could equilibrate in the entire fluid phase and that the distribution volumes of ^{24}Na and ^{42}K were approximately equal. The existence of bound fractions of sodium, potassium and chloride were indicated by the observation that the spaces of ^{24}Na and ^{42}K and that of ^{36}Cl in these damaged preparations exceeded total water by approximately 13 13 and 7 ml/100 g wet weight, respectively The binding sites *did not seem to discriminate between the two cations since the* ^{42}K *space* was essentially unaltered when the uptake experiments were performed in a medium where NaCl had been replaced by KCl.

If the characteristics of the binding sites in normal veins were identical to those of the damaged preparations and their localization in the tissue were known, it would be possible to calculate the amounts of bound ions in the former kind of tissue by multiplying the "excess" electrolyte space with the ionic concentration in that fluid compartment with which the binding sites are considered to be equilibrated. However since no information was available concerning the localization of the binding sites it *was simply assumed that the ratios of free* Na^+ K^+ *and* Cl^- *to the total* amounts of the respective ions in normal veins would be reflected in the damaged preparations by the ratio of tissue water to total space of tracer ion. The intracellular ion concentrations obtained by such correction for bound fractions were for $[Na^+]$ 44.8 meq/l, $[K^+]_i$ 138 meq/l and $[Cl^-]_i$ 86.5 meq/l. Similar calculations based on an assumption that all binding sites are equilibrated with the extracellular solution gave the following intra *cellular concentrations in meq/l cell water* $[Na^+]_i$ *13.7* $[K^+]_i$ *163 and* $[Cl^-]_i$ 83

In VII the efflux of ^{24}Na and ^{42}K was studied under different experimental conditions. By extrapolating to zero time that part of the washout curve thought to represent the transmembrane efflux, an estimate of the intracellular concentration of the actual ion could be made. The value for $[K^+]_i$ calculated in this way agreed satisfactorily with those found in V *However for* $[Na^+]_i$ *a value of 13 meq/l* was obtained in the washout experiments which is considerably lower than the figures reported in V as referred to above. Furthermore, this low estimate of $[Na^+]_i$

was obtained at 15°C and since a gain of sodium and loss of potassium on cooling have been reported for other types of smooth muscle (e g Freeman Narrod and Goodford 1962, Friedman and Friedman 1967) it is possible that the corresponding value at 37°C would be somewhat lower still. However since the spontaneous activity of the portal vein was affected to a surprisingly small extent by lowering the temperature to 15°C it seemed unlikely that more drastic alterations in the transmembrane ionic concentration gradients had occurred and 13 meq/l might therefore be an approximate estimate of $[Na^+]_i$ even at 37°C.

The reason for this discrepancy between the values for the intracellular sodium concentration obtained in V and VII is probably that, in the former study $[Na^+]_i$ was calculated by subtracting the extracellular and bound amounts of Na determined in ^{24}Na uptake experiments from the total sodium content determined by flame photometry. If there is a second sequestered sodium fraction for which the exchange with ^{24}Na is very incomplete over the actual exposure periods it would, with this mode of calculation, become included in the value for the free intracellular sodium ions. In fact, the observation that the ^{24}Na uptake curve did not quite reach the plateau predicted from flame photometry does suggest the occurrence of a small slowly exchanging fraction.

For this reason it might be more appropriate to use the total *exchangeable* Na fraction instead of the values from flame photometry when $[Na^+]_i$ values are estimated by subtracting extracellular and "bound" Na from the total amounts. "Bound" Na in this context would not correspond to the sequestered, "non-exchangeable" pool but would represent a more loosely adsorbed fraction exchanging freely with Na^+ in the fluid phases. Such calculations have recently been performed by Bäth, Johansson and Jonsson (1971) in a study where the sodium distribution in the portal vein was more closely examined. The distribution volumes of ^{24}Na and the tissue water content as well as the ^{14}C sucrose spaces were investigated in normal and in frozen-thawed preparations of portal vein at different concentrations of sodium in the incubation medium. It was demonstrated that the maximal capacity of the damaged preparations to bind sodium was approximately 22 meq/kg wet weight, a value reached at an $[Na^+]$ of 212 meq/l. The corresponding figure obtained when the binding sites were equilibrated with the $[Na^+]$ of the normal Krebs solution was 18 meq/kg wet weight. The total amount of exchangeable bound Na in intact preparations will evidently depend on the relative distribution of the binding sites between extracellular structures exposed to the Na rich medium, and intracellular structures being in contact with

Na low fluid. These results indicate that all Na binding sites are not equilibrated with [Na^+] since the amounts of bound and extracellular Na would then exceed the total exchangeable Na content. Therefore it seems probable that Na binding occurs both intra and extracellularly This conclusion is in good agreement with the results in VII which indicate the presence of a small (0.3 meq/kg wet weight) slowly exchanging, sequestered Na fraction located inside the cells, and a larger one which was equilibrated with [Na^+] and washed out together with the extra cellular solutes.

An integrated interpretation of the results reported in V VII and in the study by Bäth, Johansson and Jonsson (1971) suggests the following pattern of Na distribution in the portal vein

1) Extracellular ionized Na 68 meq/kg wet weight.
2) Intracellular ionized Na: 3—4 meq/kg wet weight.
3) Intracellularly bound, slowly exchanging Na 0.3 meq/ kg wet weight.
4) Extracellularly bound, rapidly exchanging Na: 8—9 meq/kg wet weight.
5) Possibly a non-exchangeable Na fraction not exceeding 10 meq/kg wet weight. This fraction, whose localization is unknown, might, after all *be of the same nature as 3*

The calculated values for the potassium chloride and sodium equilibrium potentials are —84 —12 and +62 mV respectively when the intra cellular concentrations given in V are used for the former two ions and 13 1 meq/l cell water for [Na^+] Since the membrane potential in the portal vein is approximately —50 mV (Nakajima and Horn 1967) these estimates indicate that it is mainly but not solely determined by the distribution of the potassium ion across the cell membrane. Furthermore, the chloride ion may not be distributed according to a passive Donnan equilibrium, but the presence of spontaneous activity makes this question difficult to decide.

This picture of the ionic composition of the portal vein will now be considered in the light of similar studies on other types of smooth muscle.

Concerning arterial smooth muscle, several authors have reported the occurrence of sequestered fractions of ions (Headings, Rondell and Bohr 1960, Friedman and Sréter 1963 Garrahan Villamil and Zadunaisky 1965 Friedman and Friedman 1967 Friedman *et al* 1968 Friedman Gustafson and Friedman 1968 Keannge 1968 Villamil *et al* 1968 Schoffeniels 1969 Ronive 1969) Headings, Rondell and Bohr (1960) found that the dog carotid artery had a considerable capacity to bind cations, Na^+ K^+ and H^+ appearing to compete for the anionic binding

sites. They concluded that these sites were equilibrated with the extracellular sodium-rich medium and that therefore, in the normal state, only Na binding occurred. It was proposed that this binding occurred in the mucopolysaccharides of the ground substance.

The assumption that the sequestered Na was located extracellularly was supported by the results of Garrahan, Villamil and Zadunaisky (1965) who studied washout of ^{22}Na from dog carotid artery They found that the first, rapid component in the curve representing the decline in remaining activity contained considerably more Na than could be extracellularly dissolved and concluded that the excess represented bound Na. Analyses performed later have indicated the occurrence of four or five different Na compartments in arterial wall (Friedman and Friedman 1967 Friedman *et al.* 1968 Friedman, Gustafson and Friedman 1968 Rorive 1969) of which two to three represent sequestered Na. The opinions concerning their magnitude and characteristics do however vary considerably as reflected in the scatter of the values for $[Na^+]_i$ reported by different authors 7 mmoles/l (Keatinge 1968) 20—30 mmoles/l (calculated from Friedman *et al* 1968), 44 mmoles/l (Schoffeniels 1969) 50 mmoles/l (Garrahan, Villamil and Zadunaisky 1965), 84 mmoles/l (Hagemeijer Rorive and Schoffeniels 1965 a) Binding of Cl and of smaller K components have also been reported (Friedman and Friedman 1967 Villamil *et al* 1968 Surprisingly high $[Cl^-]_i$ values have been given suggesting again that this ion is not passively distributed according to a Donnan equilibrium in vascular smooth muscle (Villamil *et al* 1968) The $[K^+]_i$ estimates are somewhat more uniform than in the case of sodium: 125 meq/l (Headings, Rondell and Bohr 1960), 114 meq/l (Hagemeijer Rorive and Schoffeniels 1965 a) 151 meq/l (Villamil *et al* 1968) 99 meq/l (Schoffeniels 1969)

Also for intestinal smooth muscle the ionic content does not seem to be distributed according to a simple two compartment model (Durbin and Jenkinson 1961 Durbin and Monson 1961 Goodford and Hermansen 1961 Freeman Narrod and Goodford 1962, Goodford 1962, 1964 1965 1966 1970 Buck and Goodford 1966, Brading, Bülbring and Tomita 1969 Brading and Jones 1969) The occurrence of bound fractions of both cations and anions have been established. For instance Goodford has demonstrated a competition between Na^+ K^+ Mg^{++} and Ca^{++} for superficial anionic charges, probably located at the cell membranes (Goodford 1965 1966, 1970) Besides these rapidly exchanging fractions of "counter cations" the occurrence of more firmly bound ions in the intestinal smooth muscle has been established (*e g* Goodford and

Hermansen 1961 Buck and Goodford 1966) As for vascular smooth muscle, the values reported by different authors for $[Na^+]_i$ and $[K^+]_i$ vary due to divergent interpretations of the magnitude of the sequestered fractions and of the amounts of the cellular fluid (Goodford and Hermansen 1961 Casteels 1969) Casteels and Kuriyama (1966) reported rather high values for $[Cl^-]_i$ in the taenia coli and concluded that Cl^- is not passively distributed according to a Donnan equilibrium in the smooth muscle. However in taenia coli preparations made quiescent by cooling, the distribution of chloride may be represented by such a passive equilibrium as pointed out by Buck and Goodford (1966) These observations indicate that the equilibrium potential for Cl^- ought to be compared to a mean potential during a period of spontaneous activity rather than to the highest polarization observed. Although such an analysis no doubt would cause the Cl^- distribution in smooth muscle to deviate less from a Donnan equilibrium, the findings made by Casteels and Kuriyama (1966) that $[Cl^-]_i$ is not increased on exposure of the tissue to high potassium concentrations until E_{Cl^-} is less positive than the membrane potential, suggest a more complex mechanism For instance, an active inward movement of Cl^- was proposed by Casteels and Kuriyama (1966) to explain the high values of $[Cl^-]_i$ in the normal state. The question whether Cl^- is passively distributed in smooth muscle is intimately connected to the estimate of $[Cl^-]_i$ which in turn is dependent on the evaluation of the magnitude of the bound chloride fraction Since the latter has not been as extensively studied as is the case for the cations, more information is required before it can be definitely decided whether a Donnan equilibrium prevails for Cl^-

It may thus be concluded that the ionic distribution in vascular as well as intestinal smooth muscle is best represented by a multicompartment model. When due attention is paid to the sequestered amounts of electrolytes the calculated values for the intracellular ionic concentrations seem to conform to the concept of an osmotic equilibrium across the cell membranes.

The importance of altered ionic concentration gradients for the muscle responses induced by osmolality variations.

Evidence has been presented above for a correlation between cell volume and degree of activity in vascular smooth muscle. The alterations of spontaneous contractile activity caused by variations in extracellular tonicity could be ascribed essentially to changes in the pattern of electrical

activity (I and III) Therefore, in looking for the underlying mechanisms behind these effects, attention should be paid to factors which regulate the electrical behaviour of the cell membranes.

As pointed out above the membrane potential of the portal vein is, in regard to ionic distribution, principally influenced by the equilibrium potential for potassium. However due to the relatively high permeability of smooth muscle to sodium (Kuriyama 1963) this ion will also influence the membrane potential. Furthermore, since the chloride distribution may not be passive in smooth muscle (Casteels 1965 1969 Casteels and Kuriyama 1966, V) this ion must be taken into account as well.

In a system where ions move across a membrane only under the influence of potential and concentration gradients, and where the voltage gradient through the membrane is constant, the "net" potential (E) caused by the combined influence of K^+ Na^+ and Cl^- is given by the "constant field equation" (Goldman 1943 Hodgkin and Katz 1949)

$$E = \frac{RT}{F} \ln \frac{[K^+]_i + \alpha[Na^+]_i + \beta[Cl^-]}{[K^+] + \alpha[Na^+] + \beta[Cl^-]_i}$$

α and β denote the relative permeabilities for Na^+ and Cl^- compared to that for K^+ taken as unity Thus, if the sodium pump of smooth muscle cells was electrically neutral, *i. e.* if it transferred Na^+ outwards and K^+ inwards in a one to one fashion, the membrane potential of the portal vein would be given by this formula. However evidence has been presented for an electrogenic function of the Na pump in smooth muscle, at least under some circumstances, implying that it extrudes a net amount of positive charges and thus contributes to the membrane potential directly (Casteels, Hendrickx and Droogmans 1969 Taylor Paton and Daniel 1969) Furthermore, increased activity of such an electrogenic pump has been proposed to explain the hyperpolarization of intestinal smooth muscle induced by adrenaline (Burnstock 1958) If so the actual membrane potential would be determined by some combination of "passive" diffusion potential and the rate of "active net transfer of positive charges out from the cells.

Casteels (1969) obtained a value for the membrane potential of —37 mV in the taenia coli by inserting into the constant field equation the ionic concentrations and the permeability constants for the ions deduced from estimated fluxes of ^{42}K, ^{24}Na and ^{36}Cl. This value is approximately 20 mV lower than that measured by the microelectrode technique. The difference was ascribed either to the presence of a partly electrogenic sodium pump or to "single file diffusion" of K^+ as was suggested to occur in giant axons from *Sepia officinalis* by Hodgkin and Keynes (1955)

Such single file diffusion of K^+ would lead to an underestimation of the permeability constant for this ion.

In spite of the possibility of an electrogenic Na pump and of the lack of information concerning the voltage profile in the cell membranes of smooth muscle, the "constant field" equation might still be used as a starting point for the discussion of osmolality-induced effects on the electrical activity

A shrinkage of the muscle cells caused by increased extracellular tonicity should result in raised intracellular ionic concentrations. The question arises whether the changed transmembrane ionic gradients are the cause of the inhibited spontaneous activity. According to the constant field equation, an increase of $[K^+]_i$ and $[Na^+]_i$ should lead to hyperpolarization, and an increase of $[Cl^-]_i$ to depolarization. Since the electrical activity of the portal vein is relatively slightly influenced by changes in the $[K^+]_i$ to $[Na^+]_i$ ratio when induced by changes in $[K^+]_i$ (Axelsson *et al* 1967 I and III) and since a raised $[Cl^-]_i$ would tend to cause excitation, it is probably sufficient to consider the potassium ion alone in this particular context. The question can then be simplified as to whether the increased $[K^+]_i$ to $[K^+]_o$ ratio can entirely explain the suppressed spontaneous activity in hypertonic media. Brading and Sneddon (1968) measured the changes in the ionic content of taenia coli on alterations in osmolality and concluded that the hyperpolarization of 10—15 mV recorded by Tomita (1966) on exposure to two times the normal tonicity could be fully explained by the concomitant increase in $[K^+]_o$. Furthermore, for striated muscle, Adrian (1956) reported that the membrane potential was altered to an extent that could be expected for a potassium electrode when the extracellular tonicity was raised. Direct measurements of the resting membrane potential have not been carried out in the present series of studies and the following discussion of the importance of the potassium gradient is therefore based on observations concerning the pattern of phasic electrical activity. The discussion thus rests on the assumption that the relationship between the level of the membrane potential and the spontaneous burst activity is not materially affected by osmolality.

In I, III and in a preceding article (Mellander *et al* 1967) the role played by an altered $[K^+]_i$ to $[K^+]_o$ ratio in the activity responses of portal veins as a result of variations in osmolality was elucidated by making combined changes in $[K^+]_o$ and in tonicity. The purpose of this procedure was to investigate whether a normalization of the $[K^+]_i$ to $[K^+]_o$ ratio could outbalance the effects of the anisosmotic media on the spontaneous activity. If so, the K^+ concentration gradient

adequately and completely account for the relationship between cell volume and degree of activity It could be clearly demonstrated, however that such a simple relationship does not prevail, at least not at the normal $[K^+]$ level. For instance, $[K^+]$ had to be raised from the normal value 5 9 meq/l by two to three times to compensate for the inhibitory effect exerted by a 30 per cent tonicity increase (I) In this case a $[K^+]$ rise to about 8 meq/l would have been sufficient to normalize the transmembrane concentration gradient. Since a far more pronounced increment was required to restore normal activity this strongly suggests the involvement of additional mechanisms. A similar conclusion was drawn in III concerning the excitation induced by hypo-osmolality at the normal range of potassium concentrations. In fact, here it was even more obvious that the excitation could not be solely ascribed to an altered $[K^+]_i$ to $[K^+]$ ratio. For instance, the response to a tonicity reduction of 55 mOsm/kg was stronger than that caused by a fourfold $[K^+]$ increment. As judged by the changed amount of cell water obtained on exposure to such a lowered tonicity the $[K^+]_i$ to $[K^+]$ ratio would decrease only some 10—20 per cent (IV VI)

However at higher levels of extracellular potassium ion concentrations, the effects of anisosmotic media are cancelled by roughly proportional alterations in $[K^+]$ (I III) The inhibitory effect induced by the addition of 100 mmoles sucrose/l to a medium containing 24 meq K^+/l could then be completely eliminated by an increment of the latter constituent to 30—36 meq/l. Thus, in this case, a tonicity rise of 30 per cent could be completely compensated by a corresponding increase of $[K^+]_o$, just as would be expected for a potassium electrode exhibiting a perfect osmotic behaviour

A similar increase in the importance of the potassium concentration gradient for the responses to lowered osmolality was demonstrated in III The reason for this shift in the relation between the effects of altered $[K^+]$ and changed osmolality when the potassium concentration in the control situations is high, may be the fact that the membrane potential of smooth muscle cells is more influenced by the $[K^+]_i$ to $[K^+]$ ratio at higher levels of $[K^+]$ (Holman 1958 Marshall 1962, Axelsson *et al.* 1967) It has been proposed that this "potassium electrode — like behaviour" of smooth muscle in K rich media is due to a relatively higher membrane permeability for K under these circumstances.

It can thus be concluded that the concomitant changes in the ratio of $[K^+]_i$ to $[K^+]$ on alterations in cell volume, can fully explain the activity responses when $[K^+]$ is initially supranormal, but that some

additional mechanism must contribute to the events at the normal range of $[K^+]_o$ which, of course, is most relevant for the *in vivo* situation. According to the constant field equation, not only changes in the ionic concentration gradients but also alterations in ionic membrane permeability can influence the membrane potential The question now arises as to whether such alterations occur upon osmotically induced shrinkage or swelling of the smooth muscle cells. These problems were investigated in VI and VII and are discussed below

Permeability properties of smooth muscle cell membranes at different osmolalities

As discussed above the changes in portal vein activity produced by alterations in osmolality could not be solely ascribed to the concomitant variations in transmembrane ionic concentration gradients. An additional factor might be variations in the passive permeability properties of the cell membranes associated with alterations in the cell volume. For instance, it seems possible that stretching of the cell membranes in connection with osmotic swelling, might lead to a thinning of the lipoid membrane structures, or to widening of the aqueous pathways ("the pores") Furthermore, it is conceivable that such modifications in the membrane structures might facilitate the passage of a larger penetrating ion (*e g* the hydrated Na^+) relatively more than that of a smaller one (*e g* K^+) If so, the ratio P_{Na}/P_K would increase during osmotically induced swelling of the muscle cells, an adjustment which would lead to depolarization according to the "constant field equation" The hyperpolarization caused by raised tonicity may also be explained along these lines.

The possibility of such alterations in permeability upon swelling and shrinkage of the smooth muscle cells was examined in VI and VII. In VI some general aspects of membrane permeability were considered by investigating the effects of tonicity on the exchange kinetics of two non-electrolytes, urea and erythritol. In VII the specific permeabilities for Na^+ and K^+ under different environmental conditions were examined. The methods used involved "loading" of the portal veins in radioactive medium until the actual tracer substance had equilibrated in the tissue, followed by examination of the decay in tissue radioactivity during exposure to a non-active medium. The washout curves were analysed with the purpose of identifying a monoexponential term that could be considered to represent the transmembrane exchange. It was then assumed that the cell membranes exert a rate-limiting barrier function which

predominantly determines the permeability for the different penetrating substances. This view is the most widely accepted one although some authors consider the permeability characteristics of a cell as a property of the cytoplasm rather than of the membranes. Such approaches are represented by "the sorptional theory of cell permeability" (Troshin 1966), referred to above and Ling's "association-induction hypothesis" discussed for smooth muscle by Jones (1970). According to the latter approach, cellular ions are either associated with polarized groups of the proteins (fixed charges, mainly negative) or dissolved in the *interstitial* water. The association of ions to the fixed charges is selective and metabolically dependent. The exchange kinetics of the dissolved ions are those of bulk diffusion, exhibiting little temperature dependence in contrast to the "adsorption-desorption" mechanism governing the exchange of the "associated" ions. The efflux of Na from the cells is considered to be governed mainly by bulk diffusion processes and that of K by the adsorption-desorption kinetics. In accordance with this hypothesis, Brading and Jones (1969) reported that 98—99 per cent of the ^{24}Na efflux from taenia coli can be described by bulk diffusion, thus indicating that the cell membranes do not exert a barrier function with respect to this ion.

However other authors have found that the component in the ^{24}Na washout curve considered to represent transmembrane efflux in taenia coli (Buck and Goodford 1966) and in arterial smooth muscle (Garrahan, Villamil and Zadunaisky 1965, Hagemeijer, Ronive and Schoffeniels 1965 b) is, in fact, quite sensitive to alterations in temperature and to ouabain. With regard to the washout curves of ^{14}C urea and ^{14}C erythritol from the portal vein (VI) the data could after some min be fitted by simple exponentials whose intercepts with the ordinate corresponded to spaces which agreed fairly well with the volume of intracellular water as calculated from determinations of total water and extracellular (^{14}C sucrose) space. These different results, obtained with various kinds of smooth muscle seem to support the concept of cell membranes as rate-limiting barriers and to justify the application of the membrane model in the interpretation of the results in VI and VII.

The results obtained in the experiments where the efflux of ^{14}C urea and ^{14}C erythritol were studied did not indicate any change in the permeability constants for these non-electrolytes in connection with increases or moderate decreases in extracellular tonicity. However at more pronounced reductions (—109 mOsm/kg) in osmolality a clear-cut increase in the permeability for both substances was observed. The fact that the P value for the smallest and most lipid soluble molecule of the two, i.e.

urea, increased more than that for erythritol, suggests that the reduction in the barrier function of the cell membranes was not due to widening of water filled pores since such an alteration would probably favour the larger and more water-soluble molecule. Some other mechanism, for instance thinning of the lipoid membrane, may therefore be considered.

The question as to whether the permeability coefficients for sodium and potassium (P_{Na} and P_K, respectively) are differently influenced by anisosmotic media, was elucidated by studying the fluxes of ^{24}Na and ^{42}K (VII) The washout of ^{42}K in normal Krebs solution at 37°C could, after the first few min, be described by a simple exponential, the ordinate intercept of which corresponded to a value for $[K^+]_i$ that agreed satisfactorily with that calculated by the "analytical" method in V Since the exchange of ^{24}Na at 37°C was too rapid to permit detailed compartmental analysis, the comparative study concerning tonicity effects on P_K and P_{Na} was performed at 15 C. At this low temperature the decline in tissue ^{42}K could not be strictly fitted by a single exponential term until 40—60 min had elapsed, probably due to a reduction in P_K at prolonged exposure to 15 C. However the earlier part of the washout curve must also to a great extent represent efflux of cellular potassium Further the decline in ^{42}K activity over the 7—30 min washout interval was essentially monoexponential and since this particular time interval represented transmembrane efflux of ^{24}Na in the sodium experiments, it was considered most appropriate to use this period for calculating cellular efflux of potassium as well With this approach the P_K and P_{Na} values would be estimated under quite comparable conditions as regards time of exposure to the anisosmotic media and to 15°C. With the assumption that the membrane potential under these circumstances averages 40 mV in normal Krebs solution, the calculated value for P_K amounts to 5.3 10^{-8} cm/sec, which is in fairly good agreement with that reported by Casteels (1969) for the taenia coli.

Since a considerable fraction of the Na content in the portal vein prevails in a bound, osmotically inactive form (V), ^{24}Na washout experiments were not only performed with intact portal veins but also with the damaged "membrane-deprived" tissues, described above. This approach made it possible to distinguish that component of the ^{24}Na washout curve of normal tissues which represented exchange of $[Na^+]_i$ from that representing washout of sequestered Na. This method gave a value for the transmembrane Na efflux at 15 C of 1.2 10^{-11} M/cm² sec. However due to the action of the postulated Na K pump the passive permeability for sodium should be investigated by studying the kinetics of the

uptake which is considered to be a solely passive process. Yet, since the total exchangeable Na amount remained essentially constant during the washout period, influx and efflux of Na^+ should equal each other in the experimental situation. The value given above for the transmembrane sodium efflux may therefore be used to estimate P_x and a figure of 4.3 10^{-8} cm/sec is then obtained. A P_{x_a}/P_k ratio of 0.081 would then prevail in portal vein, assuming a membrane potential of 40 mV at 15°C.

Similar determinations were made in hyper- and hypo-osmotic media, but since the change in membrane potential induced by these alterations in the environment was not known, no definite values for the actual permeability coefficients could be calculated. Instead, a set of P_K and P_x values were deduced for different possible levels of membrane potential. On the basis of these data it was concluded that the ratio P_{x_a}/P_K increases in connection with osmotically induced swelling of the smooth muscle cells. This effect can, according to the discussion above, contribute to the depolarization caused by hypo-osmolality and thus help to explain the strong excitation seen under such conditions. Concerning the effects of raised osmolality no evidence for changes in either P_K or P_x was obtained. It should, however, in this context be stressed that determination of permeability constants in smooth muscles in general is technically exceedingly difficult for several reasons, implying that given values must always be judged with caution.

The hypothesis that an increase in the P_{x_a}/P_K ratio contributes to the excitation induced by exposure to hypotonicity is supported by some observations made in III. The marked increase in activity evoked by a reduction in osmolality by approximately 60 mOsm/kg was almost completely abolished when the NaCl concentration of the hypo-osmotic solution was reduced from 92 to 32 mmoles/l. This inability of hypotonicity to cause excitation in NaCl-deficient medium was shown to be due to the low $[Na^+]$ and not to the reduced $[Cl^-]_o$. Moreover, no similar "anti-hypo-osmolality" effect of reduced $[K^+]$ could be demonstrated. These results suggest that the sodium ion is of particular importance for the response elicited by reduced tonicity, just as would be expected on the basis of the above hypothesis for its underlying mechanism.

Since no convincing evidence could be obtained for any alterations in the P_x to P_k ratio upon cell shrinkage and since the subsequent changes in the $[K^+]_i$ to $[K^+]_o$ ratio apparently cannot alone explain the inhibition of activity, some additional mechanism must be sought. In this context the observation made by Sperelakis and Schneider (1968) that the Cl^- conductance/K conductance ratio of the frog sartorius muscle

decreases on exposure to hyperosmotic media is of interest. If this also *holds true for the portal vein it offers a possible explanation for the* hyperpolarization caused by raised tonicity since the equilibrium potential for chloride seems to be much more positive than the membrane potential (V) Another possibility might be tonicity effects on an electrogenic sodium pump.

General Discussion

Since vascular smooth muscle presents marked individualities with regard to its physiological characteristics depending on its localization in the vascular tree (*e g* Bohr 1965) it is important to consider to what extent the present results with the portal vein are relevant for other types of vascular smooth muscle. Unfortunately there seems to be very little information concerning the effects of osmolality on preparations from other vessels. However in a study on strips of canine aorta, Yamabayashi and Hamilton (1959) reported the occurrence of phasic spontaneous contractions in this normally quiescent preparation when the tonicity of the incubation medium was increased by adding NaCl or sucrose. Furthermore, the amplitude of these contractions rose with the degree of hypertonicity In accordance with these observations, Somlyo and Somlyo (1970) found that rabbit and canine pulmonary arteries are contracted by hyperosmolality They conclude that these findings on different types of "Windkessel" vessels, where the smooth muscle exhibits essentially "multi-unit" behaviour indicate that the portal vein responses to tonicity variations may not be representative for the osmometric properties of *all* types of vascular *smooth muscle*

However there is much experimental evidence indicating that the functionally more important resistance vessels in many systemic circuits behave like the portal vein with respect to artificially induced osmolality variations. For instance, close intra arterial injections or infusions of hypertonic solutions of NaCl or of different nonelectrolytes, cause increased regional blood flow in dog limb (Marshall and Shepherd 1959 Read *et al* 1960 Overbeck, Molnar and Haddy 1961 Haddy and Scott 1965) cat skeletal muscle (Mellander *et al* 1967) dog skeletal muscle (Stainsby and Fregly 1968) dog myocardium (Read *et al* 1960) dog brain (Buyniski and Rapela 1968) dog kidney (Lucas and Read 1966, Gazitua *et al* 1969) and human forearm (Lundvall, Mellander and White 1969) Analysis of the underlying mechanisms indicate that the hyperemia caused by hyperosmolality is neither due to any passive widening of the vessels as a result of dehydration of the vascular walls, nor due to an altered blood viscosity but is caused by a locally elicited inhibition of vascular smooth muscle activity (Mellander *et al.* 1967)

Furthermore, arterial infusions of hypotonic solutions lead to *increases* of flow resistance in the dog forelimb (Overbeck, Molnar and Haddy 1961), dog kidney (Gazitua *et al.* 1969), dog skeletal muscle (Stainsby and Fregly 1968) as well as the human forearm (Overbeck, Daugherty and Haddy 1966) The mechanism behind these latter effects has not been studied as extensively as in the case of hyperosmolality

The present *in vitro* results concerning osmotic effects on myogenic activity in single unit vascular smooth muscle have quite recently been supplemented by an interesting *in vivo* study concerning the effects of close arterial infusions of hypo- iso- and hyperosmotic solutions of NaCl, urea or sucrose on the vascular resistance of the dog kidney (Gazitua *et al* 1969) These investigators found that hypertonic sucrose solutions elicited sustained vasodilatation whereas urea and NaCl only brought about a transient blood flow increase. When the infusion of urea and NaCl was stopped, a shortlasting pronounced rise in vascular resistance was obtained Similar characteristics in the vascular responses to hyperosmotic urea were found also in the dog forelimb. Furthermore, infusions of hypo-osmotic NaCl, sucrose and urea or of iso-osmotic urea caused an increase in renal vascular resistance while no such reaction was induced by iso-osmotic sucrose solutions. These results obtained with the blood perfused dog kidney can be fully explained, as pointed out by the authors, if it is assumed that the vascular smooth muscle of the renal resistance vessels exhibit osmometric properties similar to those shown by the isolated rat portal vein.

However this pattern of response to osmolality variations is apparently not typical for *all* kinds of vascular smooth muscles or vascular regions as pointed out earlier in this chapter For example, in the pulmonary circuit, blood flow *decreases* as a response to strongly hypertonic solutions (Binet and Burstein 1951 Eliakim, Rosenberg and Braun 1958 Semler Shepherd and Swan 1959 Read *et al* 1960 Eliakim, Stern and Nathan 1961 Braun 1966) by many of the investigators proposed to be due to an osmotically induced *vasoconstriction*. Semler Shepherd and Swan (1959) and Read *et al* (1960) on the other hand, suggested that it is caused by a transient red cell agglutination, because hypertonic injections did not increase pulmonary flow resistance when the isolated dog lung was perfused with dextran instead of blood. Further evidence for the occurrence of erythrocyte agglutination as a result of hyperosmolality was obtained in studies using vital microscopy (Read *et al* 1960). Different opinions prevail concerning the responses to hypertonicity of the pulmonary vascular bed when the role played by sludging of the blood is

eliminated. According to some early reports (Semler Shepherd and Swan 1959 Read *et al.* 1960 Haddy and Scott 1965) no vasodilatation ensues while later studies have indicated a pattern of response that closely resembles that exhibited by the systemic circuits (Bo and Hauge 1969) It should in this context be stressed that the pulmonary precapillary vessels react in the *opposite* direction to the systemic ones to a whole series of vasoactive agents (*e g* Hauge, Lunde and Waaler 1966)

The importance of osmolality variations as a factor in the physiological regulation of vascular tone in skeletal muscle was suggested by Mellander in 1966 (see Mellander 1968) and has been extensively studied by his group (Mellander *et al.* 1967 Gray Lundvall and Mellander 1968 Lundvall 1969 Lundvall Mellander and White 1969 Mellander and Lundvall 1970) They have demonstrated that the osmolality of the regional venous blood increases in direct proportion to the intensity of the work performed and can reach a value of 40 mOsm/kg above control during heavy exercise. When comparable degrees of hyperosmolality are induced by intra arterial infusions of concentrated solutions, a pattern of response within the various series-coupled sections of the vascular bed is elicited which in all respects, resembles that observed during muscle exercise. Furthermore, interstitial deposits of ^{133}Xe in resting muscle are cleared at faster rates when the tracer is dissolved in a hypertonic instead of an iso-tonic medium These results indicate that experimental hyperosmolality which primarily involves the extravascular space is also able to elicit vasodilatation It appears clear from these studies by Mellander *et al* that the exercise hyperemia in skeletal muscle in cat as well as in man is, at least partly caused by an increased release of osmotically active particles. It is, of course, possible that a similar blood flow regulating mechanism exists also in other metabolically active tissues.

It is conceivable that increased tissue osmolality and hence local vasodilatation, can result also from other processes than release of metabolites. For instance, events like resorption and secretion in an organ may obviously be accompanied by alterations in the regional osmolality Such a mechanism is indeed suggested by the results of van Heerden Wagner and Kaihara (1968) upon studying the effects on jejunal blood flow of intraintestinal administrations of concentrated glucose solutions. They demonstrated that perfusion of one part of the jejunum with a hypertonic solution caused vasodilatation in that particular intestinal section while blood flow in adjacent unperfused segments was unaffected. Furthermore, it has been suggested that the systemic vasodilatation seen in the dumping syndrome of patients after gastric resection is due to a raised osmotic

pressure of the blood following absorption of materials that are more concentrated than when a normal pyloric function is present (Lucas and Read 1966) These authors provoked a typical dumping syndrome in dog and man by intraduodenal administration of 50 per cent glucose as previously described by Machella (1949) The time course of the general vasodilatation elicited in this way turned out to be strictly correlated to the concomitant increase in blood osmolality Moreover intravenous administration of hypertonic glucose elicited a similar type of vascular response, indicating that the vasodilatory stimulus is not of intestinal origin but the result of blood hypertonicity It is further interesting to consider what happen to the intestinal circulation on drinking large amounts of water To the knowledge of the author this interesting topic has not yet been subjected to experimental study

Angiography in clinical practice often implies infusion of strongly hypertonic solutions. Giammona, Lurie and Segar (1963) reported that plasma osmolality could rise as much as 10 per cent in children with a variety of cardiac abnormalities undergoing selective angiocardiography The sensation of warmth that patients often feel at angiographic examination has been ascribed to a peripheral vasodilatation (Deterling 1952) which apparently might be due to the subsequent raise in blood tonicity In this context it may be of interest to note that repeated intravenous injections of hypertonic solutions have been reported to give successful results in the treatment of *e g* thromboangiitis obliterans (Demel and Sgalitzer 1933 Silbert 1935)

Another aspect of the present results that might have clinical connection concerns the effects of lowered osmolality on the portal vein. It has been claimed that, in hypertensive disease, the arterial walls contain more water than under normal conditions. These observations were originally made by Tobian and Binion (1952) on renal arteries from patients with essential hypertension Such waterlogging of the arterial wall would, as these authors pointed out, lead to a passive increase in the peripheral resistance. Furthermore, if the extra water was located intracellularly and thus the vascular smooth muscle cells were swelled, the active tone might also be increased according to the results presented in I and III Since these original findings of Tobian and Binion were published, several studies have been performed on water content and ionic distribution in arteries from animals with experimental hypertension (for ref see Schoffenels 1969) Most authors seem to agree that hypertension is accompanied by a rise in the sodium content of the arterial wall However a great discrepancy prevails in the opinions concerning the exact localization of

these extra amounts of sodium in the tissue. Redleaf and Tobian (1958) concluded that $[Na^+]_i$ is increased in the hypertensive state. They based this conclusion on the fact that the ratio of Na to Cl was above normal and on the assumption that Cl^- is mainly located extracellularly. Such a shift in the Na distribution might lead to accumulation of water inside the cell which, in turn, should stimulate the spontaneous activity as outlined above. In contrast to this, some authors claim that the excess sodium found in arteries from hypertensive animals is bound extracellularly and then the muscle cells would not swell (Friedman and Friedman 1967, Schoffeniels 1969). This hypothesis is supported by the observation made by the former authors that even in the absence of functional cellular membranes, the contents of cations is higher in aortae isolated from hypertensive animals than in normal aortae. Thus, the question concerning the relations that may exist between the excess of vascular sodium and the hypertensive condition are, at present, far from settled.

In summary, the activity responses of the portal vein on variations in the osmolality studied in I—III are similar to those of the resistance vessels in many different vascular regions. It therefore seems reasonable that the results of the examinations concerning the underlying mechanisms, summarized in the preceding sections, are relevant also for the latter kinds of vessels. Since alterations in the regional tonicity, as discussed above, occur under physiological conditions it is conceivable that the demonstrated relation between volume and degree of activity in "single unit" vascular smooth muscle cells constitutes an important local blood flow regulating mechanism, also in other situations than muscle exercise.

Summary

A study has been performed concerning the effects of altered extracellular osmolality on the spontaneously active, isolated rat portal vein. This vascular smooth muscle preparation has functional characteristics that, in many aspects, resemble those of the systemic resistance vessels. The results and conclusions can be summarized as follows

1 Evidence has been obtained for a correlation between muscle cell volume and degree of activity swelling being associated with muscle excitation and shrinkage with inhibition of the spontaneous electrical and mechanical activity Thus, incubation of the portal vein in hypo-osmotic media greatly enhances the spontaneous activity In contrast, exposure to a hyperosmotic environment, induced by supplementing the normal Krebs solution with sucrose, which does not penetrate the cell membranes, leads to a *sustained* inhibition of the spontaneous activity When, on the other hand, hyperosmolality is created by addition of urea, which penetrates the cell membranes at a moderate rate and hence equilibrates in the total tissue water only a *transient* inhibition is obtained with rapid return to control activity despite the continued presence of urea. Normalization of the osmolality after urea exposure is associated with a transient excitation whose intensity is closely related to the duration of the previous period of urea hyperosmolality up to the point when ^{14}C urea reaches its plateau value in the uptake curve.

Determinations of the cell water content at different tonicities indicate that the muscle cells are, in fact, continuously shrunken in hyperosmotic sucrose solutions and swelled in hypo-osmotic media. In contrast, exposure to a membrane penetrating substance like urea, apparently leads to only a transient shrinkage and, on return to the control solution to a shortlasting swelling

An analysis of the mechanisms responsible for this correlation between cell olume and degree of cell activity requires quantitative information concerning the osmometric behaviour of the cells and the ionic distribution in the portal vein.

2. When the osmolality is raised by addition of sucrose to the incubation medium, the muscle cells shrink to an extent expected for perfect osmo-

meters. The alterations in cell water content upon exposure to hypo-osmolality are, however more complex since the cell swelling is to some extent hampered by the concomitantly enhanced active tension development of the muscle cells. If this activity is suppressed by cooling the cells behave like perfect osmometers up to a 20 per cent reduction in osmolality but not at still more drastic levels of hypo-osmolality It is, however even in this latter situation possible that the muscle cells approach an osmotic equilibrium with the medium, since a loss of intracellular ions occurs under these circumstances.

3 Concerning the ionic distribution in the portal vein, a simple two compartment model cannot be applied for either sodium, potassium or chloride, since there exists bound osmotically inactive fractions of the electrolytes. As in other types of excitable tissues, $[K^+]_i$ is higher than $[Na^+]_i$ The membrane potential is predominantly determined by E_{K^+} but also influenced to an appreciable extent by E_{X^+} The distribution of Cl^- does not seem to conform to a passive Donnan equilibrium.

4 The possibility that the relation between muscle cell volume and degree of activity is mediated by variations in the transmembrane ionic concentration gradients has been elucidated by making simultaneous alterations in tonicity and in the extracellular electrolyte concentrations. The results indicate that, in the *normal* range of $[K^+]_o$, a restoration of the original ionic concentration gradients is not alone sufficient to cancel the osmolality effects on the spontaneous muscle activity However at supranormal levels of $[K^+]_o$, alterations in tonicity and thus in the intracellular electrolyte concentrations, seem to be quantitatively more comparable to changes in the extracellular ionic composition.

5 Studies of the exchange kinetics of ^{22}Na and ^{42}K across the cell membranes at different osmolalities suggest that the permeability constant for sodium increases more than that for potassium during hypo-osmolality Such an effect of swelling on the membrane permeability may help to explain the subsequent depolarization and increase of phasic activity During cell shrinkage, on the other hand, there was no evidence of any change in the ratio P_X to P_K and alternative mechanisms must therefore be considered to explain the inhibitory responses.

6. The application of the present *in vitro* results, concerning osmotic effects on the active tension development of isolated vascular smooth muscle of the "single unit" type to the *in vivo* situation is discussed from physiological and pathophysiological points of view

Acknowledgements

I am deeply grateful to my teacher in research, Professor Börje Johansson, for his inspiring guidance and co-operation. Without the benefit of his support, great knowledge and encouragement this investigation would not have been possible. I am also very grateful to Professor Björn Folkow for his encouraging interest, support and valuable criticism throughout the work.

My sincere thanks are due to Civ Ing. Lars Stage for professional help with problems concerning the mathematical treatment of the present data. I wish to thank the co-authors for stimulating collaboration and Docent Bengt Ljung, Docent Ove Lundgren Docent Bengt Öberg and Fil.lic. Bo Wahlström for valuable discussions.

For skilled technical assistance and pleasant collaboration I thank Mrs Eva Bengtsson, Mrs Siv Samuelsson, Mrs Gun Jidesten and Miss Christine Lind. Thanks are due to Miss Helen Brogren for revising the English text and to Mrs Kerstin Andréasson for skilled typing of the manuscripts.

I also wish to express my gratitude to my wife, Marianne, for constant encouragement and support.

This research program was supported by grants from the Faculty of Medicine, University of Göteborg, from the Swedish Medical Research Council, from Magnus Bergvalls stiftelse, from AB Hässle, from US Public Health Service (HE-05675-09) and from the Air Force Office of Scientific Research through the European Office of Aerospace Research, OAR United States Air Force under Contract F61052-68-C-0044

uptake which is considered to be a solely passive process. Yet, since the total exchangeable Na amount remained essentially constant during the washout period, influx and efflux of Na^+ should equal each other in the experimental situation. The value given above for the transmembrane sodium efflux may therefore be used to estimate P_X and a figure of 4.3 10^{-9} cm/sec is then obtained. A P_{X_a}/P_K ratio of 0.081 would then prevail in portal vein, assuming a membrane potential of 40 mV at 15°C.

Similar determinations were made in hyper- and hypo-osmotic media, but since the change in membrane potential induced by these alterations in the environment was not known, no definite values for the actual permeability coefficients could be calculated. Instead, a set of P_K and P_X values were deduced for different possible levels of membrane potential. On the basis of these data it was concluded that the ratio P_{X_a}/P_K increases in connection with osmotically induced swelling of the smooth muscle cells. This effect can according to the discussion above, contribute to the depolarization caused by hypo-osmolality and thus help to explain the strong excitation seen under such conditions. Concerning the effects of raised osmolality no evidence for changes in either P_K or P_X was obtained. It should however in this context be stressed that determination of permeability constants in smooth muscles in general is technically exceedingly difficult for several reasons, implying that given values must always be judged with caution.

The hypothesis that an increase in the P_{X_a}/P_K ratio contributes to the excitation induced by exposure to hypotonicity is supported by some observations made in III. The marked increase in activity evoked by a reduction in osmolality by approximately 60 mOsm/kg was almost completely abolished when the NaCl concentration of the hypo-osmotic solution was reduced from 92 to 32 mmoles/l. This inability of hypotonicity to cause excitation in NaCl-deficient medium was shown to be due to the low $[Na^+]$ and not to the reduced $[Cl^-]_o$. Moreover no similar anti-hypo-osmolality" effect of reduced $[K^+]$ could be demonstrated. These results suggest that the sodium ion is of particular importance for the response elicited by reduced tonicity just as would be expected on the basis of the above hypothesis for its underlying mechanism.

Since no convincing evidence could be obtained for any alterations in the P_{X_a} to P_K ratio upon cell shrinkage and since the subsequent changes in the $[K^+]_i$ to $[K^+]_o$ ratio apparently cannot alone explain the inhibition of activity some additional mechanism must be sought. In this context the observation made by Sperelakis and Schneider (1968) that the Cl^- conductance/K^+ conductance ratio of the frog sartorius muscle

decreases on exposure to hyperosmotic media is of interest. If this also holds true for the portal vein, it offers a possible explanation for the hyperpolarization caused by raised tonicity since the equilibrium potential for chloride seems to be much more positive than the membrane potential (V). Another possibility might be tonicity effects on an electrogenic sodium pump.

sites. They concluded that these sites were equilibrated with the extracellular sodium-rich medium and that therefore, in the normal state, only Na binding occurred. It was proposed that this binding occurred in the mucopolysaccharides of the ground substance.

The assumption that the sequestered Na was located extracellularly was supported by the results of Garrahan Villamil and Zadunaisky (1965) who studied washout of ^{22}Na from dog carotid artery They found that the first, rapid component in the curve representing the decline in remaining activity contained considerably more Na than could be extracellularly dissolved and concluded that the excess represented bound Na. Analyses performed later have indicated the occurrence of four or five different Na compartments in arterial wall (Friedman and Friedman 1967 Friedman *et al* 1968 Friedman, Gustafson and Friedman 1968 Rorive 1969) of which two to three represent sequestered Na. The opinions concerning their magnitude and characteristics do however vary considerably as reflected in the scatter of the values for $[Na^+]_i$ reported by different authors 7 mmoles/l (Keatinge 1968) 20—30 mmoles/l (calculated from Friedman *et al* 1968) 44 mmoles/l (Schoffeniels 1969) 50 mmoles/l (Garrahan, Villamil and Zadunaisky 1965) 84 mmoles/l (Hagemeijer Rorive and Schoffeniels 1965 a) Binding of Cl and of smaller K components have also been reported (Friedman and Friedman 1967 Villamil *et al* 1968 Surprisingly high $[Cl^-]_i$ values have been given suggesting again that this ion is not passively distributed according to a Donnan equilibrium in vascular smooth muscle (Villamil *et al.* 1968) The $[K^+]_i$ estimates are somewhat more uniform than in the case of sodium 125 meq/l (Headings, Rondell and Bohr 1960) 114 meq/l (Hagemeijer Rorive and Schoffeniels 1965 a) 151 meq/l (Villamil *et al.* 1968) 99 meq/l (Schoffeniels 1969)

Also for intestinal smooth muscle the ionic content does not seem to be distributed according to a simple two compartment model (Durbin and Jenkinson 1961 Durbin and Monson 1961 Goodford and Hermansen 1961 Freeman Narrod and Goodford 1962, Goodford 1962, 1964 1965 1966 1970 Buck and Goodford 1966 Brading, Bülbring and Tomita 1969 Brading and Jones 1969) The occurrence of bound fractions of both cations and anions have been established For instance, Goodford has demonstrated a competition between Na^+ K^+ Mg^{++} and Ca for superficial anionic charges, probably located at the cell membranes (Goodford 1965 1966 1970) Besides these rapidly exchanging fractions of "counter cations" the occurrence of more firmly bound ions in the intestinal smooth muscle has been established (*e g* Goodford and

Hermansen 1961 Buck and Goodford 1966) As for vascular smooth muscle, the values reported by different authors for $[Na^+]_i$ and $[K^+]_i$ vary due to divergent interpretations of the magnitude of the sequestered fractions and of the amounts of the cellular fluid (Goodford and Hermansen 1961 Casteels 1969) Casteels and Kuriyama (1966) reported rather high values for $[Cl^-]_i$ in the taenia coli and concluded that Cl^- is not passively distributed according to a Donnan equilibrium in the smooth muscle. However in taenia coli preparations made quiescent by cooling, the distribution of chloride may be represented by such a passive equilibrium as pointed out by Buck and Goodford (1966) These observations indicate that the equilibrium potential for Cl^- ought to be compared to a mean potential during a period of spontaneous activity rather than to the highest polarization observed. Although such an analysis no doubt would cause the Cl^- distribution in smooth muscle to deviate less from a Donnan equilibrium, the findings made by Casteels and Kuriyama (1966) that $[Cl^-]_i$ is not increased on exposure of the tissue to high potassium concentrations until E_{Cl^-} is less positive than the membrane potential suggest a more complex mechanism For instance, an active inward movement of Cl^- was proposed by Casteels and Kuriyama (1966) to explain the high values of $[Cl^-]_i$ in the normal state. The question whether Cl^- is passively distributed in smooth muscle is intimately connected to the estimate of $[Cl^-]_i$ which in turn is dependent on the evaluation of the magnitude of the bound chloride fraction. Since the latter has not been as extensively studied as is the case for the cations, more information is required before it can be definitely decided whether a Donnan equilibrium prevails for Cl^-

It may thus be concluded that the ionic distribution in vascular as well as intestinal smooth muscle is best represented by a multicompartment model When due attention is paid to the sequestered amounts of electrolytes the calculated values for the intracellular ionic concentrations seem to conform to the concept of an osmotic equilibrium across the cell membranes.

The importance of altered ionic concentration gradients for the muscle responses induced by osmolality variations.

Evidence has been presented above for a correlation between cell volume and degree of activity in vascular smooth muscle. The alterations of spontaneous contractile activity caused by variations in extracellular tonicity could be ascribed essentially to changes in the pattern of electrical

activity (I and III) Therefore, in looking for the underlying mechanisms behind these effects, attention should be paid to factors which regulate the electrical behaviour of the cell membranes.

As pointed out above the membrane potential of the portal vein is, in regard to ionic distribution principally influenced by the equilibrium potential for potassium. However due to the relatively high permeability of smooth muscle to sodium, (Kuriyama 1963) this ion will also influence the membrane potential Furthermore, since the chloride distribution may not be passive in smooth muscle (Casteels 1965 1969 Casteels and Kuriyama 1966 V) this ion must be taken into account as well.

In a system where ions move across a membrane only under the influence of potential and concentration gradients, and where the voltage gradient through the membrane is constant, the "net" potential (E), caused by the combined influence of K^+ Na^+ and Cl^- is given by the "constant field equation" (Goldman 1943 Hodgkin and Katz 1949)

$$E = \frac{RT}{F} \ln \frac{[K^+]_i + \alpha[Na^+]_i + \beta[Cl^-]}{[K^+] + \alpha[Na^+] + \beta[Cl^-]_i}$$

α and β denote the relative permeabilities for Na^+ and Cl^- compared to that for K taken as unity Thus, if the sodium pump of smooth muscle cells was electrically neutral, *i e* if it transferred Na^+ outwards and K inwards in a one to one fashion, the membrane potential of the portal vein would be given by this formula. However evidence has been presented for an electrogenic function of the Na pump in smooth muscle at least under some circumstances, implying that it extrudes a net amount of positive charges and thus contributes to the membrane potential directly (Casteels, Hendrickx and Droogmans 1969 Taylor Paton and Daniel 1969) Furthermore increased activity of such an electrogenic pump has been proposed to explain the hyperpolarization of intestinal smooth muscle induced by adrenaline (Burnstock 1958) If so the actual membrane potential would be determined by some combination of "passive" diffusion potential and the rate of "active net transfer of positive charges out from the cells.

Casteels (1969) obtained a value for the membrane potential of —37 mV in the taenia coli by inserting into the constant field equation the ionic concentrations and the permeability constants for the ions deduced from estimated fluxes of ^{42}K, ^{24}Na and ^{36}Cl This value is approximately 20 mV lower than that measured by the microelectrode technique. The difference was ascribed either to the presence of a partly electrogenic sodium pump or to "single file diffusion" of K^+ as was suggested to occur in giant axons from *Sepia officinalis* by Hodgkin and Keynes (1955)

Such single file diffusion of K^+ would lead to an underestimation of the permeability constant for this ion.

In spite of the possibility of an electrogenic Na pump and of the lack of information concerning the voltage profile in the cell membranes of smooth muscle, the "constant field" equation might still be useful as a starting point for the discussion of osmolality induced effects on the electrical activity

A shrinkage of the muscle cells caused by increased extracellular tonicity should result in raised intracellular ionic concentrations. The question arises whether the changed transmembrane ionic gradients are the cause of the inhibited spontaneous activity According to the constant field equation, an increase of $[K^+]_i$ and $[Na^+]_i$ should lead to hyperpolarization, and an increase of $[Cl^-]_i$ to depolarization. Since the electrical activity of the portal vein is relatively slightly influenced by changes in the $[Na^+]_i$ to $[Na^+]$ ratio when induced by changes in $[Na^+]$ (Axelsson *et al.* 1967 I and III) and since a raised $[Cl^-]_i$ would tend to cause excitation, it is probably sufficient to consider the potassium ion alone in this particular context. The question can then be simplified as to whether the increased $[K^+]_i$ to $[K^+]$ ratio can entirely explain the suppressed spontaneous activity in hypertonic media. Brading and Setekleiv (1968) measured the changes in the ionic content of taenia coli on alterations in osmolality and concluded that the hyperpolarization of 10—15 mV recorded by Tomita (1966) on exposure to two times the normal tonicity could be fully explained by the concomitant increase in $[K^+]_i$. Furthermore, for striated muscle, Adrian (1956) reported that the membrane potential was altered to an extent that could be expected for a potassium electrode when the extracellular tonicity was raised Direct measurements of the resting membrane potential have not been carried out in the present series of studies and the following discussion of the importance of the potassium gradient is therefore based on observations concerning the pattern of phasic electrical activity The discussion thus rests on the assumption that the relationship between the level of the membrane potential and the spontaneous burst activity is not materially affected by osmolality

In I III and in a preceding article (Mellander *et al.* 1967) the role played by an altered $[K^+]_i$ to $[K^+]$ ratio in the activity responses of portal veins as a result of variations in osmolality was elucidated by making combined changes in $[K^+]_o$ and in tonicity The purpose of this procedure was to investigate whether a normalization of the $[K^+]_i$ to $[K^+]_o$ ratio could outbalance the effects of the anisosmotic media on the spontaneous activity If so, the K^+ concentration gradient would

adequately and completely account for the relationship between cell volume and degree of activity It could be clearly demonstrated, however that such a simple relationship does not prevail at least not at the normal $[K^+]$ level For instance, $[K^+]$ had to be raised from the normal value 5 9 meq/l by two to three times to compensate for the inhibitory effect exerted by a 30 per cent tonicity increase (I) In this case a $[K^+]$ rise to about 8 meq/l would have been sufficient to normalize the transmembrane concentration gradient. Since a far more pronounced increment was required to restore normal activity this strongly suggests the involvement of additional mechanisms. A similar conclusion was drawn in III concerning the excitation induced by hypo-osmolality at the normal range of potassium concentrations. In fact, here it was even more obvious that the excitation could not be solely ascribed to an altered $[K^+]_i$ to $[K^+]$ ratio For instance, the response to a tonicity reduction of 55 mOsm/kg was stronger than that caused by a fourfold $[K^+]$ increment. *As judged by the changed amount of cell water* obtained on exposure to such a lowered tonicity the $[K^+]_i$ to $[K^+]$ ratio would decrease only some 10—20 per cent (IV VI)

However at higher levels of extracellular potassium ion concentrations, the effects of anisosmotic media are cancelled by roughly proportional alterations in $[K^+]$ (I III) The inhibitory effect induced by the addition of 100 mmoles sucrose/l to a medium containing 24 meq K^+/l could then be completely eliminated by an increment of the latter constituent to 30—36 meq/l Thus, in this case, a tonicity rise of 30 per cent could be completely compensated by a corresponding increase of $[K^+]_e$, just as would be expected for a potassium electrode exhibiting a perfect osmotic behaviour

A similar increase in the importance of the potassium concentration gradient for the responses to lowered osmolality was demonstrated in III The reason for this shift in the relation between the effects of altered $[K^+]$ and changed osmolality when the potassium concentration in the control situations is high, may be the fact that the membrane potential of smooth muscle cells is more influenced by the $[K^+]_i$ to $[K^+]$ ratio at higher levels of $[K^+]$ (Holman 1958 Marshall 1962, Axelsson *et al.* 1967) It has been proposed that this potassium electrode — like behaviour of smooth muscle in K rich media is due to a relatively higher membrane permeability for K under these circumstances.

It can thus be concluded that the concomitant changes in the ratio of $[K^+]_i$ to $[K^+]$ on alterations in cell volume, can fully explain the activity responses when $[K^+]$ is initially supranormal but that some

additional mechanism must contribute to the events at the normal range of $[K^+]$ which, of course, is most relevant for the *in vivo* situation. According to the constant field equation, not only changes in the ionic concentration gradients but also alterations in ionic membrane permeability can influence the membrane potential. The question now arises as to whether such alterations occur upon osmotically induced shrinkage or swelling of the smooth muscle cells. These problems were investigated in VI and VII and are discussed below.

Permeability properties of smooth muscle cell membranes at different osmolalities

As discussed above the changes in portal vein activity produced by alterations in osmolality could not be solely ascribed to the concomitant variations in transmembrane ionic concentration gradients. An additional factor might be variations in the passive permeability properties of the cell membranes associated with alterations in the cell volume. For instance, it seems possible that stretching of the cell membranes in connection with osmotic swelling, might lead to a thinning of the lipoid membrane structures, or to widening of the aqueous pathways ("the pores"). Furthermore, it is conceivable that such modifications in the membrane structures might facilitate the passage of a larger penetrating ion (*e g* the hydrated Na^+) relatively more than that of a smaller one (*e g* K^+). If so the ratio P_{Na}/P_K would increase during osmotically induced swelling of the muscle cells, an adjustment which would lead to depolarization according to the "constant field equation". The hyperpolarization caused by raised tonicity may also be explained along these lines.

The possibility of such alterations in permeability upon swelling and shrinkage of the smooth muscle cells was examined in VI and VII. In VI some general aspects of membrane permeability were considered by investigating the effects of tonicity on the exchange kinetics of two non electrolytes, urea and erythritol. In VII the specific permeabilities for Na^+ and K^+ under different environmental conditions were examined. The methods used involved "loading" of the portal veins in radioactive medium until the actual tracer substance had equilibrated in the tissue, followed by examination of the decay in tissue radioactivity during exposure to a non-active medium. The washout curves were analysed with the purpose of identifying a monoexponential term that could be considered to represent the transmembrane exchange. It was then assumed that the cell membranes exert a rate-limiting barrier function which

predominantly determines the permeability for the different penetrating substances. This view is the most widely accepted one although some authors consider the permeability characteristics of a cell as a property of the cytoplasm rather than of the membranes. Such approaches are represented by the sorptional theory of cell permeability (Troshin 1966) referred to above and Ling's "association induction hypothesis" discussed for smooth muscle by Jones (1970). According to the latter approach, cellular ions are either associated with polarized groups of the proteins (fixed charges, mainly negative) or dissolved in the *interstitial* water. The association of ions to the fixed charges is selective and metabolically dependent. The exchange kinetics of the dissolved ions are those of bulk diffusion, exhibiting little temperature dependence in contrast to the "adsorption-desorption" mechanism governing the exchange of the "associated" ions. The efflux of Na from the cells is considered to be governed mainly by bulk diffusion processes and that of K by the adsorption desorption kinetics. In accordance with this hypothesis, Brading and Jones (1969) reported that 98—99 per cent of the ^{24}Na efflux from taenia coli can be described by bulk diffusion, thus indicating that the cell membranes do not exert a barrier function with respect to this ion.

However other authors have found that the component in the ^{24}Na washout curve considered to represent transmembrane efflux in taenia coli (Buck and Goodford 1966) and in arterial smooth muscle (Garrahan, Villamil and Zadunaisky 1965 Hagemeijer Ronve and Schoffeniels 1965 b) is, in fact, quite sensitive to alterations in temperature and to ouabain. With regard to the washout curves of ^{14}C urea and ^{14}C erythritol from the portal vein (VI) the data could after some min be fitted by simple exponentials whose intercepts with the ordinate corresponded to spaces which agreed fairly well with the volume of intracellular water as calculated from determinations of total water and extracellular (^{14}C sucrose) space. These different results, obtained with various kinds of smooth muscle seem to support the concept of cell membranes as rate-limiting barriers and to justify the application of the membrane model in the interpretation of the results in VI and VII.

The results obtained in the experiments where the efflux of ^{14}C urea and ^{14}C erythritol were studied did not indicate any change in the permeability constants for these non-electrolytes in connection with increases or moderate decreases in extracellular tonicity. However at more pronounced reductions (—109 mOsm/kg) in osmolality a clear-cut increase in the permeability for both substances was observed. The fact that the P value for the smallest and most lipid soluble molecule of the two i.e.

urea, increased more than that for erythritol suggests that the reduction in the barrier function of the cell membranes was not due to widening of water filled pores since such an alteration would probably favour the larger and more water-soluble molecule. Some other mechanism, for instance thinning of the lipoid membrane, may therefore be considered.

The question as to whether the permeability coefficients for sodium and potassium (P_{Na} and P_K, respectively) are differently influenced by anisosmotic media, was elucidated by studying the fluxes of ^{24}Na and ^{42}K (VII) The washout of ^{42}K in normal Krebs solution at 37°C could, after the first few min, be described by a simple exponential, the ordinate intercept of which corresponded to a value for $[K^+]_i$ that agreed satisfactorily with that calculated by the "analytical" method in V Since the exchange of ^{24}Na at 37°C was too rapid to permit detailed compartmental analysis, the comparative study concerning tonicity effects on P_K and P_{Na} was performed at 15 C. At this low temperature the decline in tissue ^{42}K could not be strictly fitted by a single exponential term until 40—60 min had elapsed, probably due to a reduction in P_K at prolonged exposure to 15°C. However the "earlier" part of the washout *curve must also to a great extent represent efflux of cellular potassium* Further the decline in ^{42}K activity over the 7—30 min washout interval was essentially monoexponential and since this particular time interval represented transmembrane efflux of ^{24}Na in the sodium experiments, it was considered most appropriate to use this period for calculating cellular efflux of potassium as well. With this approach the P_K and P_{Na} values would be estimated under quite comparable conditions as regards time of exposure to the anisosmotic media and to 15 C. With the assumption *that the membrane potential under these circumstances averages 40 mV* in normal Krebs solution, the calculated value for P_K amounts to $5.3 \cdot 10^{-8}$ cm/sec, which is in fairly good agreement with that reported by Casteels (1969) for the taenia coli.

Since a considerable fraction of the Na content in the portal vein prevails in a bound, osmotically inactive form (V) ^{24}Na washout experiments were not only performed with intact portal veins but also with the damaged "membrane-deprived" tissues, described above. This approach made it possible to distinguish that *component of the* ^{24}Na washout curve of normal tissues which represented exchange of $[Na^+]_i$ from that representing washout of sequestered Na. This method gave a value for the transmembrane Na efflux at 15 C of $1.2 \cdot 10^{-11}$ M/cm² sec. However due to the action of the postulated Na K pump the passive permeability for sodium should be investigated by studying the kinetics of the ^{24}Na

uptake which is considered to be a solely passive process. Yet, since the total exchangeable Na amount remained essentially constant during the washout period, influx and efflux of Na^+ should equal each other in the experimental situation. The value given above for the transmembrane sodium efflux may therefore be used to estimate P_{Na} and a figure of 4.3 10^{-9} cm/sec is then obtained. A P_{Na}/P_K ratio of 0.081 would then prevail in portal vein, assuming a membrane potential of 40 mV at 15°C.

Similar determinations were made in hyper and hypo-osmotic media, but since the change in membrane potential induced by these alterations in the environment was not known, no definite values for the actual permeability coefficients could be calculated. Instead, a set of P_K and P_{Na} values were deduced for different possible levels of membrane potential. On the basis of these data it was concluded that the ratio P_{Na}/P_K increases in connection with osmotically induced swelling of the smooth muscle cells. This effect can according to the discussion above, contribute to the depolarization caused by hypo-osmolality and thus help to explain the strong excitation seen under such conditions. Concerning the effects of raised osmolality no evidence for changes in either P_K or P_{Na} was obtained. It should, however in this context be stressed that determination of permeability constants in smooth muscles in general is technically exceedingly difficult for several reasons, implying that given values must always be judged with caution.

The hypothesis that an increase in the P_{Na}/P_K ratio contributes to the excitation induced by exposure to hypotonicity is supported by some observations made in III The marked increase in activity evoked by a reduction in osmolality by approximately 60 mOsm/kg was almost completely abolished when the NaCl concentration of the hypo-osmotic solution was reduced from 92 to 32 mmoles/l This inability of hypotonicity to cause excitation in NaCl-deficient medium was shown to be due to the low $[Na^+]$ and not to the reduced $[Cl^-]_o$. Moreover no similar anti hypo-osmolality" effect of reduced $[K^+]$ could be demonstrated. These results suggest that the sodium ion is of particular importance for the response elicited by reduced tonicity just as would be expected on the basis of the above hypothesis for its underlying mechanism

Since no convincing evidence could be obtained for any alterations in the P_{Na} to P_K ratio upon cell shrinkage and since the subsequent changes in the $[K^+]_i$ to $[K^+]$ ratio apparently cannot alone explain the inhibition of activity some additional mechanism must be sought. In this context the observation made by Sperelakis and Schneider (1968) that the Cl^- conductance/K^+ conductance ratio of the frog sartorius muscle

decreases on exposure to hyperosmotic media is of interest. If this also holds true for the portal vein, it offers a possible explanation for the hyperpolarization caused by raised tonicity since the equilibrium potential for chloride seems to be much more positive than the membrane potential (V) Another possibility might be tonicity effects on an electrogenic sodium pump

General Discussion

Since vascular smooth muscle presents marked individualities with regard to its physiological characteristics depending on its localization in the vascular tree (*e g* Bohr 1965) it is important to consider to what extent the present results with the portal vein are relevant for other types of vascular smooth muscle. Unfortunately there seems to be very little information concerning the effects of osmolality on preparations from other vessels. However in a study on strips of canine aorta, Yamabayashi and Hamilton (1959) reported the occurrence of phasic spontaneous contractions in this normally quiescent preparation when the tonicity of the incubation medium was increased by adding NaCl or sucrose Furthermore, the amplitude of these contractions rose with the degree of hypertonicity In accordance with these observations, Somlyo and Somlyo (1970) found that rabbit and canine pulmonary arteries are contracted by hyperosmolality They conclude that these findings on different types of "Windkessel" vessels, where the smooth muscle exhibits essentially "multi-unit" behaviour indicate that the portal vein responses to tonicity variations may not be representative for the osmometric properties of *all* types of vascular smooth muscle.

However there is much experimental evidence indicating that the functionally more important resistance vessels in many systemic circuits behave like the portal vein with respect to artificially induced osmolality variations. For instance, close intra arterial injections or infusions of hypertonic solutions of NaCl or of different nonelectrolytes, cause increased regional blood flow in dog limb (Marshall and Shepherd 1959 Read *et al* 1960, Overbeck, Molnar and Haddy 1961 Haddy and Scott 1965), cat skeletal muscle (Mellander *et al* 1967) dog skeletal muscle (Staunsby and Fregly 1968) dog myocardium (Read *et al.* 1960) dog brain (Buyniski and Rapela 1968) dog kidney (Lucas and Read 1966 Gazitua *et al* 1969) and human forearm (Lundvall Mellander and White 1969) Analysis of the underlying mechanisms indicate that the hyperemia caused by hyperosmolality is neither due to any passive widening of the vessels as a result of dehydration of the vascular walls, nor due to an altered blood *viscosity but is caused by a locally elicited inhibition of* vascular smooth muscle activity (Mellander *et al* 1967)

Furthermore, arterial infusions of hypotonic solutions lead to *increases* of flow resistance in the dog forelimb (Overbeck, Molnar and Haddy 1961) dog kidney (Gazitua *et al* 1969) dog skeletal muscle (Staunby and Fregly 1968) as well as the human forearm (Overbeck, Daugherty and Haddy 1966) The mechanism behind these latter effects has not been studied as extensively as in the case of hyperosmolality

The present *in vitro* results concerning osmotic effects on myogenic activity in single unit vascular smooth muscle have quite recently been supplemented by an interesting *in vivo* study concerning the effects of close arterial infusions of hypo- iso- and hyperosmotic solutions of NaCl, urea or sucrose on the vascular resistance of the dog kidney (Gazitua *et al* 1969) These investigators found that hypertonic sucrose solutions elicited sustained vasodilatation whereas urea and NaCl only brought about a transient blood flow increase. When the infusion of urea and NaCl was stopped, a shortlasting pronounced rise in vascular resistance was obtained. Similar characteristics in the vascular responses to hyperosmotic urea were found also in the dog forelimb. Furthermore, infusions of hypo-osmotic NaCl, sucrose and urea or of iso-osmotic urea caused an increase in renal vascular resistance while no such reaction was induced by iso-osmotic sucrose solutions. These results obtained with the blood perfused dog kidney can be fully explained, as pointed out by the authors, if it is assumed that the vascular smooth muscle of the renal resistance vessels exhibit osmometric properties similar to those shown by the isolated rat portal vein.

However this pattern of response to osmolality variations is apparently not typical for *all* kinds of vascular smooth muscles or vascular regions as pointed out earlier in this chapter For example, in the pulmonary circuit, blood flow *decreases* as a response to strongly hypertonic solutions (Binet and Burstein 1951; Eliakim, Rosenberg and Braun 1958 Semler Shepherd and Swan 1959 Read *et al* 1960 Eliakim, Stern and Nathan 1961 Braun 1966), by many of the investigators proposed to be due to an osmotically induced *vasoconstriction* Semler Shepherd and Swan (1959) and Read *et al.* (1960) on the other hand, suggested that it is caused by a transient red cell agglutination, because hypertonic injections did not increase *pulmonary flow* resistance when the isolated dog lung was perfused with dextran instead of blood. Further evidence for the occurrence of erythrocyte agglutination as a result of hyperosmolality was obtained in studies using vital microscopy (Read *et al.* 1960). Different opinions prevail concerning the responses to hypertonicity of the pulmonary vascular bed when the role played by sludging of the blood is

General Discussion

Since vascular smooth muscle presents marked individualities with regard to its physiological characteristics depending on its localization in the vascular tree (*e g* Bohr 1965), it is important to consider to what extent the present results with the portal vein are relevant for other types of vascular smooth muscle. Unfortunately there seems to be very little information concerning the effects of osmolality on preparations from other vessels. However in a study on strips of canine aorta, Yamabayashi and Hamilton (1959) reported the occurrence of phasic spontaneous contractions in this normally quiescent preparation when the tonicity of the incubation medium was increased by adding NaCl or sucrose. Furthermore, the amplitude of these contractions rose with the degree of hypertonicity In accordance with these observations, Somlyo and Somlyo (1970) found that rabbit and canine pulmonary arteries are contracted by hyperosmolality They conclude that these findings on different types of "Windkessel" vessels, where the smooth muscle exhibits essentially "multi-unit" behaviour indicate that the portal vein responses to tonicity variations may not be representative for the osmometric properties of *all* types of vascular smooth muscle.

However there is much experimental evidence indicating that the functionally more important resistance vessels in many systemic circuits behave like the portal vein with respect to artificially induced osmolality variations. For instance, close intra arterial injections or infusions of hypertonic solutions of NaCl, or of different nonelectrolytes, cause increased regional blood flow in dog limb (Marshall and Shepherd 1959 Read *et al* 1960 Overbeck, Molnar and Haddy 1961 Haddy and Scott 1965) cat skeletal muscle (Mellander *et al* 1967) dog skeletal muscle (Stainsby and Fregly 1968) dog myocardium (Read *et al* 1960) dog brain (Buyniski and Rapela 1968) dog kidney (Lucas and Read 1966 Gazitua *et al* 1969) and human forearm (Lundvall Mellander and White 1969) Analysis of the underlying mechanisms indicate that the hyperemia caused by hyperosmolality is neither due to any passive widening of the vessels as a result of dehydration of the vascular walls, nor due to an altered blood viscosity but is caused by a locally elicited inhibition of vascular smooth muscle activity (Mellander *et al* 1967)

Furthermore, arterial infusions of hypotonic solutions lead to *increases* of flow resistance in the dog forelimb (Overbeck, Molnar and Haddy 1961) dog kidney (Gazitua *et al.* 1969) dog skeletal muscle (Stainsby and Fregly 1968) as well as the human forearm (Overbeck, Daugherty and Haddy 1966) The mechanism behind these latter effects has not been studied as extensively as in the case of hyperosmolality

The present *in vitro* results concerning osmotic effects on myogenic activity in single unit vascular smooth muscle have quite recently been supplemented by an interesting *in vivo* study concerning the effects of close arterial infusions of hypo- iso- and hyperosmotic solutions of NaCl, urea or sucrose on the vascular resistance of the dog kidney (Gazitúa *et al* 1969) These investigators found that hypertonic sucrose solutions elicited sustained vasodilatation whereas urea and NaCl only brought about a transient blood flow increase. When the infusion of urea and NaCl was stopped, a shortlasting pronounced rise in vascular resistance was obtained. Similar characteristics in the vascular responses to hyperosmotic urea were found also in the dog forelimb Furthermore, infusions of hypo-osmotic NaCl, sucrose and urea or of iso-osmotic urea caused an increase in renal vascular resistance while no such reaction was induced by iso-osmotic sucrose solutions. These results obtained with the blood perfused dog kidney can be fully explained as pointed out by the authors, if it is assumed that the vascular smooth muscle of the renal resistance vessels exhibit osmometric properties similar to those shown by the isolated rat portal vein.

However this pattern of response to osmolality variations is apparently not typical for *all* kinds of vascular smooth muscles or vascular regions as pointed out earlier in this chapter For example, in the pulmonary circuit, blood flow *decreases* as a response to strongly hypertonic solutions (Banet and Burstein 1951 Eliakim, Rosenberg and Braun 1958 Semler Shepherd and Swan 1959 Read *et al* 1960 Eliakim, Stern and Nathan 1961 Braun 1966) by many of the investigators proposed to be due to an osmotically induced *vasoconstriction*. Semler Shepherd and Swan (1959) and Read *et al* (1960) on the other hand, suggested that it is caused by a transient red cell agglutination, because hypertonic injections did not increase pulmonary flow resistance when the isolated dog lung was perfused with dextran instead of blood. Further evidence for the occurrence of erythrocyte agglutination as a result of hyperosmolality was obtained in studies using vital microscopy (Read *et al* 1960) Different opinions prevail concerning the responses to hypertonicity of the pulmonary vascular bed when the role played by sludging of the blood is

eliminated. According to some early reports (Semler Shepherd and Swan 1959 Read *et al.* 1960 Haddy and Scott 1965) no vasodilatation ensues while later studies have indicated a pattern of response that closely resembles that exhibited by the systemic circuits (Bo and Hauge 1969) It should in this context be stressed that the pulmonary precapillary vessels react in the *opposite* direction to the systemic ones to a whole series of vasoactive agents (*e g* Hauge, Lunde and Waaler 1966)

The importance of osmolality variations as a factor in the physiological regulation of vascular tone in skeletal muscle was suggested by Mellander in 1966 (see Mellander 1968) and has been extensively studied by his group (Mellander *et al* 1967 Gray Lundvall and Mellander 1968 Lundvall 1969 *Lundvall, Mellander and White 1969 Mellander and Lundvall* 1970) They have demonstrated that the osmolality of the regional venous blood increases in direct proportion to the intensity of the work performed and can reach a value of 40 mOsm/kg above control during heavy exercise. When comparable degrees of hyperosmolality are induced by intra-arterial infusions of concentrated solutions, a pattern of response within the various series-coupled sections of the vascular bed is elicited which, in all respects, resembles that observed during muscle exercise. Furthermore, interstitial deposits of ^{133}Xe in resting muscle are cleared at faster rates when the tracer is dissolved in a hypertonic instead of an iso-tonic medium. These results indicate that experimental hyperosmolality which primarily involves the extravascular space is also able to elicit vasodilatation. It appears clear from these studies by Mellander *et al* that the exercise hyperemia in skeletal muscle in cat as well as in man is, at least partly caused by an increased release of osmotically active particles. It is, of course, possible that a similar blood flow regulating mechanism exists also in other metabolically active tissues.

It is conceivable that increased tissue osmolality and hence local vasodilatation, can result also from other processes than release of metabolites. For instance events like resorption and secretion in an organ may obviously be accompanied by alterations in the regional osmolality Such a mechanism is indeed suggested by the results of van Heerden, Wagner and Kaihara (1968) upon studying the effects on jejunal blood flow of intraintestinal administrations of concentrated glucose solutions. They demonstrated that perfusion of one part of the jejunum with a hypertonic solution caused vasodilatation in that particular intestinal section while blood flow in adjacent unperfused segments was unaffected. Furthermore, it has been suggested that the systemic vasodilatation seen in the dumping syndrome of patients after gastric resection is due to a raised osmotic

pressure of the blood following absorption of materials that are more concentrated than when a normal pyloric function is present (Lucas and Read 1966) These authors provoked a typical dumping syndrome in dog and man by intraduodenal administration of 50 per cent glucose as previously described by Machella (1949) The time course of the general vasodilatation elicited in this way turned out to be strictly correlated to the concomitant increase in blood osmolality Moreover intravenous administration of hypertonic glucose elicited a similar type of vascular response, indicating that the vasodilatory stimulus is not of intestinal origin but the result of blood hypertonicity It is further interesting to consider what happen to the intestinal circulation on drinking large amounts of water To the knowledge of the author this interesting topic has not yet been subjected to experimental study

Angiography in clinical practice often implies infusion of strongly hypertonic solutions. Giammona, Lurie and Segar (1963) reported that plasma osmolality could rise as much as 10 per cent in children with a variety of cardiac abnormalities undergoing selective angiocardiography The sensation of warmth that patients often feel at angiographic examination has been ascribed to a peripheral vasodilatation (Deterling 1952) which apparently might be due to the subsequent raise in blood tonicity In this context it may be of interest to note that repeated intravenous injections of hypertonic solutions have been reported to give successful results in the treatment of *e g* thromboangiitis obliterans (Deibel and Sgalitzer 1933 Silbert 1935)

Another aspect of the present results that might have clinical connection concerns the effects of lowered osmolality on the portal vein. It has been claimed that, in hypertensive disease, the arterial walls contain more water than under normal conditions. These observations were originally made by Tobian and Binion (1952) on renal arteries from patients with essential hypertension. Such waterlogging of the arterial wall would, as these authors pointed out, lead to a passive increase in the peripheral resistance. Furthermore, if the extra water was located intracellularly and thus the vascular smooth muscle cells were swelled, the active tone might also be increased according to the results presented in I and III Since these original findings of Tobian and Binion were published, several studies have been performed on water content and ionic distribution in arteries from animals with experimental hypertension (for ref see Schofenels 1969) Most authors seem to agree that hypertension is accompanied by a rise in the sodium content of the arterial wall. However a great discrepancy prevails in the opinions concerning the exact localization of

these extra amounts of sodium in the tissue Redleaf and Tobian (1958) concluded that $[Na^+]_i$ is increased in the hypertensive state. They based this conclusion on the fact that the ratio of Na to Cl was above normal and on the assumption that Cl^- is mainly located extracellularly Such a shift in the Na distribution might lead to accumulation of water inside the cell which in turn, should stimulate the spontaneous activity as outlined above. In contrast to this, some authors claim that the excess sodium found in arteries from hypertensive animals is bound extracellularly and then the muscle cells would not swell (Friedman and Friedman 1967 Schoffeniels 1969) This hypothesis is supported by the observation made by the former authors that even in the absence of functional cellular membranes, the contents of cations is higher in aortae isolated from hypertensive animals than in normal aortae. Thus, the question concerning the relations that may exist between the excess of vascular sodium and the hypertensive condition are, at present, far from settled.

In summary the activity responses of the portal vein on variations in the osmolality studied in I—III are similar to those of the resistance vessels in many different vascular regions. It therefore seems reasonable that the results of the examinations concerning the underlying mechanisms, summarized in the preceding sections, are relevant also for the latter kinds of vessels. Since alterations in the regional tonicity as discussed above, occur under physiological conditions it is conceivable that the demonstrated relation between volume and degree of activity in "single unit vascular smooth muscle cells constitutes an important local blood flow regulating mechanism also in other situations than muscle exercise.

Summary

A study has been performed concerning the effects of altered extracellular osmolality on the spontaneously active, isolated rat portal vein. This vascular smooth muscle preparation has functional characteristics that, in many aspects, resemble those of the systemic resistance vessels. The results and conclusions can be summarized as follows.

1. Evidence has been obtained for a correlation between muscle cell volume and degree of activity, swelling being associated with muscle excitation and shrinkage with inhibition of the spontaneous electrical and mechanical activity. Thus, incubation of the portal vein in hypo-osmotic media greatly enhances the spontaneous activity. In contrast, exposure to a hyperosmotic environment, induced by supplementing the normal Krebs solution with sucrose, which does not penetrate the cell membranes, leads to a *sustained* inhibition of the spontaneous activity. When, on the other hand, hyperosmolality is created by addition of urea, which penetrates the cell membranes at a moderate rate and hence equilibrates in the total tissue water, only a *transient* inhibition is obtained with rapid return to control activity despite the continued presence of urea. Normalization of the osmolality after urea exposure is associated with a transient excitation whose intensity is closely related to the duration of the previous period of urea hyperosmolality, up to the point when ^{14}C urea reaches its plateau value in the uptake curve.

Determinations of the cell water content at different tonicities indicate that the muscle cells are, in fact, continuously shrunken in hyperosmotic sucrose solutions and swelled in hypo-osmotic media. In contrast, exposure to a membrane penetrating substance like urea, apparently leads to only a transient shrinkage and, on return to the control solution, to a shortlasting swelling.

An analysis of the mechanisms responsible for this correlation between cell volume and degree of cell activity requires quantitative information concerning the osmometric behaviour of the cells and the ionic distribution in the portal vein.

2. When the osmolality is raised by addition of sucrose to the incubation medium, the muscle cells shrink to an extent expected for perfect osmo-

meters. The alterations in cell water content upon exposure to hypo-osmolality are, however more complex since the cell swelling is to some extent hampered by the concomitantly enhanced active tension development of the muscle cells. If this activity is suppressed by cooling, the cells behave like perfect osmometers up to a 20 per cent reduction in osmolality but not at still more drastic levels of hypo-osmolality It is, however even in this latter situation possible that the muscle cells approach an osmotic equilibrium with the medium since a loss of intracellular ions occurs under these circumstances.

3 Concerning the ionic distribution in the portal vein, a simple two compartment model cannot be applied for either sodium, potassium or chloride, since there exists bound osmotically inactive fractions of the electrolytes. As in other types of excitable tissues, $[K^+]_i$ is higher than $[Na^+]_i$. The membrane potential is predominantly determined by E_{K^+} but also influenced to an appreciable extent by E_{X^+} The distribution of Cl^- does not seem to conform to a passive Donnan equilibrium.

4 The possibility that the relation between muscle cell volume and degree of activity is mediated by variations in the transmembrane ionic concentration gradients has been elucidated by making simultaneous alterations in tonicity and in the extracellular electrolyte concentrations. The results indicate that, in the *normal* range of $[K^+]_o$, a restoration of the original ionic concentration gradients is not alone sufficient to cancel the osmolality effects on the spontaneous muscle activity However at supranormal levels of $[K^+]_o$, alterations in tonicity and thus in the intracellular electrolyte concentrations, seem to be quantitatively more comparable to changes in the extracellular ionic composition

5 Studies of the exchange kinetics of ^{24}Na and ^{42}K across the cell membranes at different osmolalities suggest that the permeability constant for sodium increases more than that for potassium during hypo-osmolality Such an effect of swelling on the membrane permeability may help to explain the subsequent depolarization and increase of phasic activity *During cell shrinkage on the other hand, there was no evidence of any* change in the ratio P_{X_o} to P_K and alternative mechanisms must therefore be considered to explain the inhibitory responses.

6 The application of the present *in vitro* results, concerning osmotic effects on the active tension development of isolated vascular smooth muscle of the "single unit" type to the *in vivo* situation is discussed from physiological and pathophysiological points of view

Acknowledgements

I am deeply grateful to my teacher in research, Professor Börje Johansson, for his inspiring guidance and co-operation. Without the benefit of his support, great knowledge and encouragement this investigation would not have been possible. I am also very grateful to Professor Björn Folkow for his encouraging interest, support and valuable criticism throughout the work.

My sincere thanks are due to Civ Ing. Lars Stage for professional help with problems concerning the mathematical treatment of the present data. I wish to thank the co-authors for stimulating collaboration and Docent Bengt Ljung, Docent Ove Lundgren, Docent Bengt Öberg and Fil.lic. Bo Wahlström for valuable discussions.

For skilled technical assistance and pleasant collaboration I thank Mrs Eva Bengtsson, Mrs Siv Samuelsson, Mrs Gun Jidesten and Miss Christine Lind. Thanks are due to Miss Helen Brogren for revising the English text and to Mrs Kerstin Andréasson for skilled typing of the manuscripts.

I also wish to express my gratitude to my wife, Marianne, for constant encouragement and support.

This research program was supported by grants from the Faculty of Medicine, University of Göteborg, from the Swedish Medical Research Council, from Magnus Bergvalls stiftelse, from AB Hässle, from US Public Health Service (HE-05675-09) and from the Air Force Office of Scientific Research through the European Office of Aerospace Research, OAR United States Air Force under Contract F61052-68-C-0044

Introduction

The physiological importance of the biogenic amines was early linked with neuronal transmittor functions (*cf* Guggenheim 1951) The occurrence of catecholamines in the adrenal medulla was also observed at an early stage (Meulon 1905) In recent years special interest has been focused on other extraneuronal localizations and functions of the biogenic amines. The discovery of biogenic amines as occurring in several non-neuronal tissues has been contributory to this development. This has been possible due to the introduction of sensitive histochemical and autoradiographical methods, which permit the demonstration of small amounts of biogenic amines in the tissues (see Ritzén 1967)

With the help of these methods it has been possible to demonstrate a localization of catechol- and indolamines in some endocrine cell systems such as the pancreatic islets, the parafollicular cells of the thyroid and the enterochromaffin cells of the gastrointestinal tract (*cf* Falck and Owman 1968) In species where catechol- and indolamines have not been demonstrated in the pancreatic islets and the parafollicular cells, a formation of amines has been shown to occur after the administration of the precursors in the biosynthesis of the amines dihydroxyphenylalanine (DOPA) and 5-hydroxytryptophan (5-HTP) (see Ritzén *et al.* 1965, Larsson *et al.* 1966, Cegrell 1968) In the gastrointestinal tract, where the presence of serotonin has long been known (Erspamer and Asero 195) precursor injections have been found to give an amine formation in cells, which lack endogenous storage of serotonin (Hâkanson *et al.* 1967 a)

The capability of these cell systems to store and form catechol and indolamines have led to assumptions that they are of importance for the synthesis and/or release of the polypeptide hormones, which are known to be produced by these cell systems (see Falck and Owman 1968 Pearse 1968, Ullberg and Hammarström 1969) The monoamine forming capability of the enterochromaffin cells has been taken as an indication of the possibility that they might be the producers of the gastrointestinal hormones (see Aures *et al.* 1970)

The development of radioimmunological techniques for the measurement of hormones has made it possible to show that monoamines really have an effect on the release of insulin (see Malaisse *et al* 1967 Porte 1969 Feldman and Lebovitz 1970 and Chapter 8) An effect on the release of calcitonin, which is produced by the parafollicular cells has also been shown (Bates *et al* 1969 Phillippo *et al* 1969)

Connected with the localization and function of the biogenic amines are the enzymes, which are respon ible for their formation and metabolism. The same enzyme namely L-amino acid decarboxylase is responsible for the decarboxyla tion of DOPA to dopamine and of 5-HTP to 5-hydroxytryptamine (Lovenberg *et al* 1962 a) The catabolism of catecholamines takes place through the action of the enzymes monoamine oxidase (MAO) and catechol O-methyl transferase (COMT) (see Kopin 1964) Serotonin is mainly metabolized through the action of MAO (see Erspamer 1961) While the enzymes L-amino acid decarboxylase MAO and COMT have a widespread distribution in the body both in neuronal and extraneuronal tissues, the enzymes which convert dopamine to noradrenaline (dopamine β-hydroxylase) and noradrena line to adrenaline (phenylethanolamine N methyl transferase) seem to be restricted in their localization to neuronal tissues, blood vessel walls and the adrenal medulla (see Axelrod 1966, Hartman and Udenfriend 1970)

The aim of the present investigation has been to elucidate some of the extraneuronal localizations and functions of catechol and indolamines. Special attention has been paid to the localization and function in the mentioned endocrine cell systems. Mice and rabbits ha e been used as experimental animals.

Autoradiographical and fl orescence microscopical methods ha e been used to study the localization of catechol and indolamines formed after the administration of DOPA and 5-HTP and the combination of autoradiography and fluorescence microscopy has allowed a concon itant demonstration of catechol- and indolamines in a/ the pancreatic islets, b/ the parafollicular cells of the thyroid and c/ the mucosa of the stomach in mice (Chapter 1—3) Electron microscope autoradiography has been applied to study the formation of catecholamines in the enterochromaffin cell types of the fundic part of the stomach after the administration of ^{3}H DOPA into mice (Chapter 4) Whole body autoradiography has been used to compare the distribution patterns obtained after the administration of DOPA 1 ^{14}C and DOPA 2 ^{14}C to mice (Chapter 5) The localization of MAO has been studied with a histochemical method in whole-body sections of mice (Chapter 6) The uptake and metabolism of DOPA in the rabbit pancreas has been studied by fluorescence microscopy and chromatography (Chapter 7) The effect of catechol and indol-

amines and of their precursors on the insulin secretion from rabbit pancreas *in vitro* has been studied by radioimmunological methods (Chapter 8)

Parts of Chapter 1 and Chapter 2 have been performed in co-operation with dr Premysl Slanina and Chapter 5 in co-operation with prof Sven Ullberg (Tjalve and Slanina 1971 Tjälve and Ullberg in preparation)

CHAPTER 1

Uptake of DOPA and 5-HTP in the pancreatic islets of the mouse studied by autoradiography, fluorescence microscopy and combined autoradiography — fluorescence microscopy

In the pancreatic islets of the pig, dog, cat, guinea-pig and horse an endogenous storage of dopamine and/or serotonin has been demonstrated (see Falck and Hellman 1963 Cegrell 1968) The cell types, which store the monoamines show variations between the species, as does the type of monoamine which is stored in the cells. It also seems as if dopamine and serotonin are stored together in the same islet cells in some species (see Cegrell 1968)
In other species, such as the mouse, rat, rabbit and golden hamster no endogenous occurrence of monoamines has been demonstrated in adult animals (see Cegrell 1968) Injections of DOPA or 5-HTP into mice have however been shown to result in a formation of monoamines within the islets. This has been demonstrated with fluorescence microscopy and microautoradiography (Hempel 1963 Cegrell *et al* 1964 Ritzén *et al.* 1965 Gershon and Ross 1966 a, Cegrell 1968 Ullberg and Hammarström 1969) Cegrell (1968) who studied the uptake of DOPA in the islets with fluorescence microscopy found fluorescence in all cells of the islets shortly after the injection. Later the fluorescence could be observed mainly in cells identified as α-cells.

The present investigation gives some additional data on the uptake of DOPA and 5-HTP in the pancreatic islets. The aim has been to compare the distribution patterns obtained after DOPA and 5-HTP-injections. For this purpose a combined microautoradiographic fluorescence microscopic method (Hammarström *et al.* 1966) was employed, which makes it possible to demonstrate catechol- and indolamines concomitantly in the same sections. Moreover microautoradiography was used separately to compare the distribution patterns up to 24 hours after the injections of the precursors. Some additional fluorescence microscopical data and data on the MAO-localization by means of histochemistry are also presented.

Material and methods

Animals

Albino mice of the NMRI strain of both sexes weighing about 20 g were used. The animals were kept on a complete pelleted diet (AB Ewos Sweden) at a room temperature of +23 C and were given water ad lib.

Compounds

The isotopes used were ring 2,5 6-^{3}H-labelled L-3(3 4-dihydroxyphenyl)alanine (H DOPA) specific activity 28 Ci/mM corresponding to 140 mCi/mg and generally ^{3}H-labelled 5-hydroxy DL-tryptophan (^{3}H 5-HTP) specific activity 2.56 Ci/mM corresponding to 11 6 mCi/mg. Both isotopes were obtained from The Radiochemical Centre, Amersham, England.

Non-labelled L-*β*-3 4-dihydroxyphenylalanine (L-DOPA) and 5-hydroxy-L-tryptophan (L-5-HTP) were obtained from Sigma Chemical Company USA. The monoamine oxidase inhibitor nialamide (Niamid) was obtained from Pfizer AB, Sweden. Nitro Blue tetrazolium and tryptamine hydrochloride were obtained from Sigma Chemical Company

Microautoradiography

Microautoradiography was performed essentially according to Rittén *et al.* (1965)

Three mice were injected intravenously with 0.5 mCi ^{3}H DOPA or with 0.5 mCi ^{3}H 5-HTP respectively and were killed by cervical dislocation 5 minutes, 1 hour and 24 hours after the injections (see Table 1) Specimens from the pancreas were then rapidly removed and immediately frozen in isopentane cooled with liquid nitrogen. The pieces were then freeze-dried under vacuum (10^{-4} mm Hg) at about $-40°$ C for five days in a Speedivac Pearse tissue dryer (Edwards High Vacuum Ltd., England) After the freeze drying the specimens were transferred to a glass jar containing paraformaldehyde gas at a relative humidity of about 60 % (Hamberger *et al.* 1965 a) The jar was placed in an oven at 80° C for one hour The gas fixation obtained is the same as the one used for visualization of monoamines in tissues (Falck *et al* 1962) This treatment also fixes the monoamines in the tissues and prevents their diffusion d ring the microautoradiographic and histological treatment (Rittén *et al.* 1965)

After the gas fixation the specimens were embedded in warm (60° C) paraffin (melting point 50—52° C) in vacuo and they were then subjected to conventional stripping film autoradiography (Doniach and Pelc 1950) Sections, 5 *μ* thick, were mounted on slides, deparaffinized in xylene and carried through an alcohol series to distilled water Stripping film (Kodak AR 10) was stretched on water and floated on to the sections. Exposure was carried out at $-10°$ C for 1—6 months. The films were developed for 3 minutes in Kodak D19, fixed and thereafter stained with haematoxylin and eosin and in some cases also with aldehyde-fuchsin (see Staining)

2	H DOP\, 0 5 mCi correspooding to 0 18 mg/kg + L-5-HTP 100 mg/kg	1 h, 2 h

Fluorescence nicrosc py

The fluorescence method of Falck and Hillarp (Falck *et al.* 196? Falck and Owman 1965) for demonstration of biogenic amines in tissues was used.

Mice were injected intravenously with DOPA or 5-HTP In some cases they were pre treated with the monoamine oxidase inhibitor nialamide which then was injected i p. 2 hours before the DOPA or 5-HTP injections. The

number of animals, the substances injected and the survival times are given in Table 1

The animals were killed at the stated survival times and pieces of pancreas were frozen, freeze-dried treated with paraformaldehyde gas and paraffin embedded as has been described above (see Microautoradiography) 5 μ thick sections were taken and put on warm (70 C) slides for some minutes allowing the paraffin to melt and the sections to spread. The sections were then subjected to fluorescence microscopy in a Zeiss Standard Universal microscope.

Combined microautoradiography—fluorescence microscopy

The method which has been used for the combination of microautoradiography and fluorescence microscopy is a modification of a method described by Hammarström *et al.* (1966)

A small amount of one of the precursors in labelled form was injected together with a large amount of the other precursor in non-labelled form. The specimens obtained were first treated according to the histochemical fluorescence method. Sections were then subjected to fluorescence microscopy and photographed. The same sections were then treated according to a microautoradiographic technique. A direct comparison was thus possible between the fluorescence picture, obtained through the injection of the non-labelled precursor and the autoradiogram, obtained through the injection of the labelled precursor The amount of precursor injected in labelled form was far too small to give any fluorescence of its own. This was checked by injecting the corresponding amount of precursor in non-labeled form into mice and then treat the specimens obtained for fluorescence microscopy

The isotope was injected into a tail vein with a tuberculine syringe attached to a needle with a polyethylene catheter Immediately following the isotope injection the non-labelled substance was injected in the same polyethylene catheter after replacing the first tuberculine syringe. The number of animals, the substances injected and the survival times are given in Table 1 The animals were killed at the stated survival times and pieces of pancreas were frozen, freeze-dried treated with paraformaldehyde-gas and paraffin embedded as has been described earlier (see Microautoradiography) 5 μ thick sections were then mounted on slides without cover slips and examined and photographed under a fluorescence microscope. The same sections were then passed down an alcohol series and subjected to conventional stripping film autoradiography (Doniach and Pelc 1950) as has been described earlier (see Microautoradiography) After the development comparison was possible between fluorescence pictures and autoradiograms.

Staining

A direct identification of the β-cells in the pancreatic islets on the autoradiograms with aldehyde-fuchsin staining was not possible since this staining completely removed the silver grains. This difficulty could, however be overcome if the autoradiograms were first stained with haematoxylin and eosin and passed through a series of increasing concentrations of ethanol and mounted in euparal (GBI Ltd., England) They were then examined and photographed. Thereafter the coverslips were removed and the sections were passed through absolute ethanol, 96 % ethanol and 70 % ethanol and then postfixed in 10 % formalin for 24 hours and stained with aldehydefuchsin as described by Jennings (1965) The aldehyde-fuchsin staining completely removed the haematoxylin and eosin staining as well as the silver grains.

Monoamine oxidase histochemistry

Monoamine oxidase (MAO) activity in the pancreas was determined with the method described by Glenner *et al.* (1957) 10 μ thick cryostat sections of pancreas were incubated for one hour at 37 C in a 0.1 M phosphate buffer pH 7 6 containing tryptamine hydrochloride (0 03 M) as substrate. Nitroblue tetrazolium was used as tetrazolium salt Control sections were incubated without substrate or pre incubated with nialamide (0.01 M) for 15 minutes. The technique will be described in more detail later (Chapter 6)

Fig 1 Microautoradiogram of a pancreatic islet of mouse 5 min ten after an intravenous injection of H 5-HTP A high radioactivity can be seen in all islet cells. The radioactivity in the exocrine pancreas is lower than in the islet and diffusely distributed. Hts-eosin. (×100)

Fig. 3 a. Microautoradiogram of pancreatic islet of mouse 1 hour after an intravenous injection of H DOPA. Hx-eosin.

It was not possible to stain sections subjected to monoamine oxidase histochemistry with aldehyde-fuchsin or silver staining techniques for identification of β- and α-cells in the pancreatic islets.

Results

Microauto adiography and fluorescence microscopy

The distribution of radioactivity in the pancreatic islets after the injection of ^{3}H DOPA was similar to the distribution seen after the injection of ^{3}H 5-HTP at the survival times studied.

Five minutes after the injection of ^{3}H DOPA or H 5-HTP there was a very high activity in all cells of the pancreatic islets (Fig 1) The activity in the endocrine pancreas exceeded somewhat that in the exocrine pancreas, where a diffuse distribution of the activity could be seen.

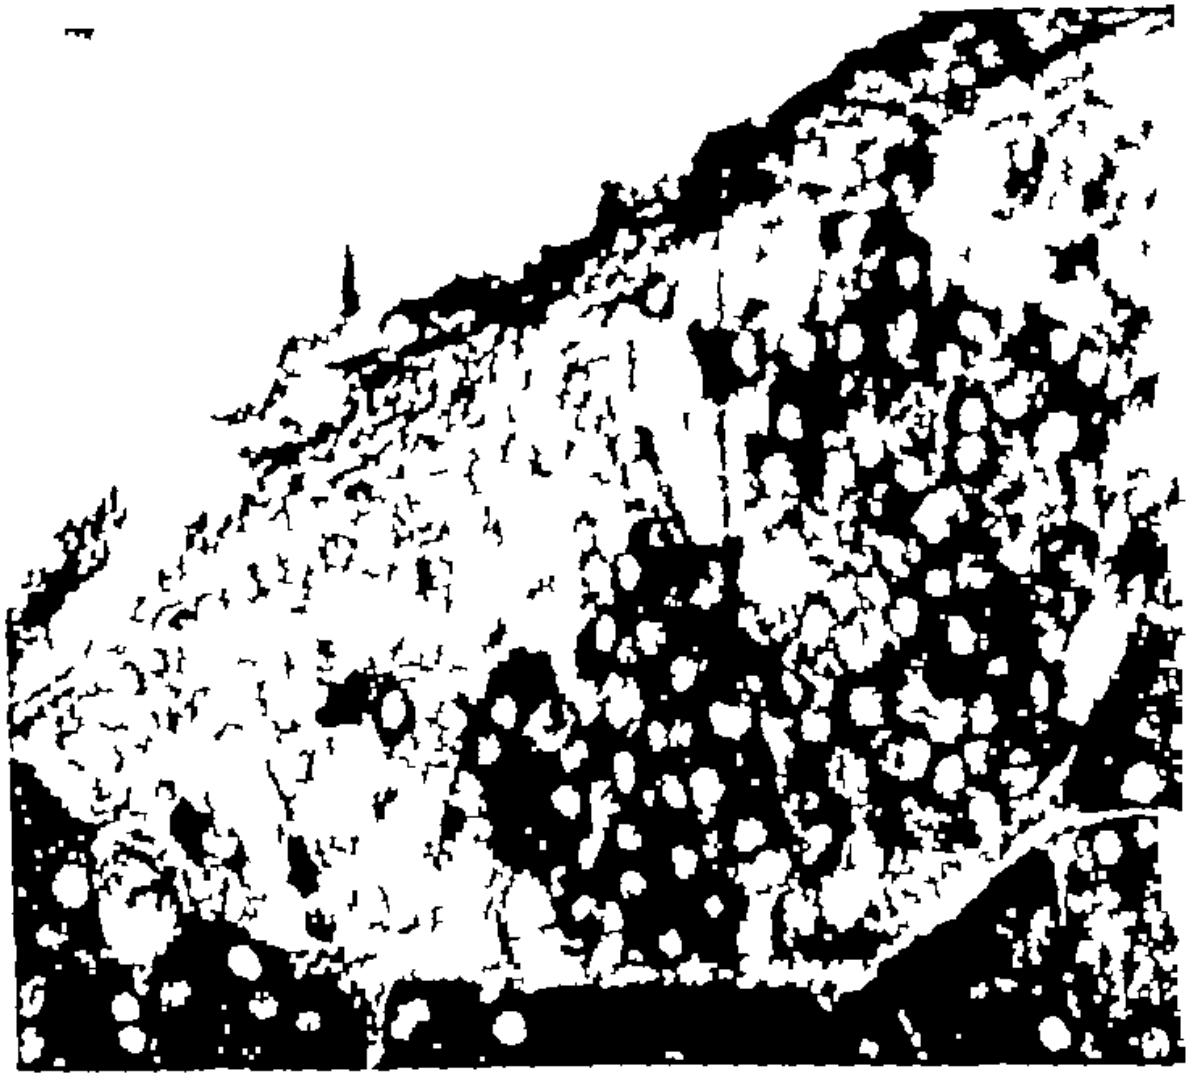

Fig. 3 b. The same islet after staining with aldehyde-fuchsin. The α-cells contain more radioactivity than the β-cells. Some α-cells are also more heavily labelled than other α-cells. (×380)

One hour after the injection of ^{3}H DOPA or ^{3}H-5-HTP some cells, mostly located at the periphery of the islets, contained a high activity (Fig. 2) The number of these cells varied between different islets. Subsequent aldehyde-fuchsin staining showed that the cells belonged to the α-cell group There were, however also α-cells with a lower amount of activity but also here the activity was considerable and seemed to exceed the activity in the β-cells to some extent (Fig. 3) In the exocrine pancreas more activity could be seen in the apical than in the basal parts of the cells. Also the excretory ducts contained a high activity

Twenty four hours after the injection of H DOPA or ^{3}H-5-HTP a high activity usually still persisted in a few scattered cells at the periphery of the islets. The number of these cells, also belonging to the α-cell group varied considerably from islet to islet and were lacking in some islets. In the exocrine

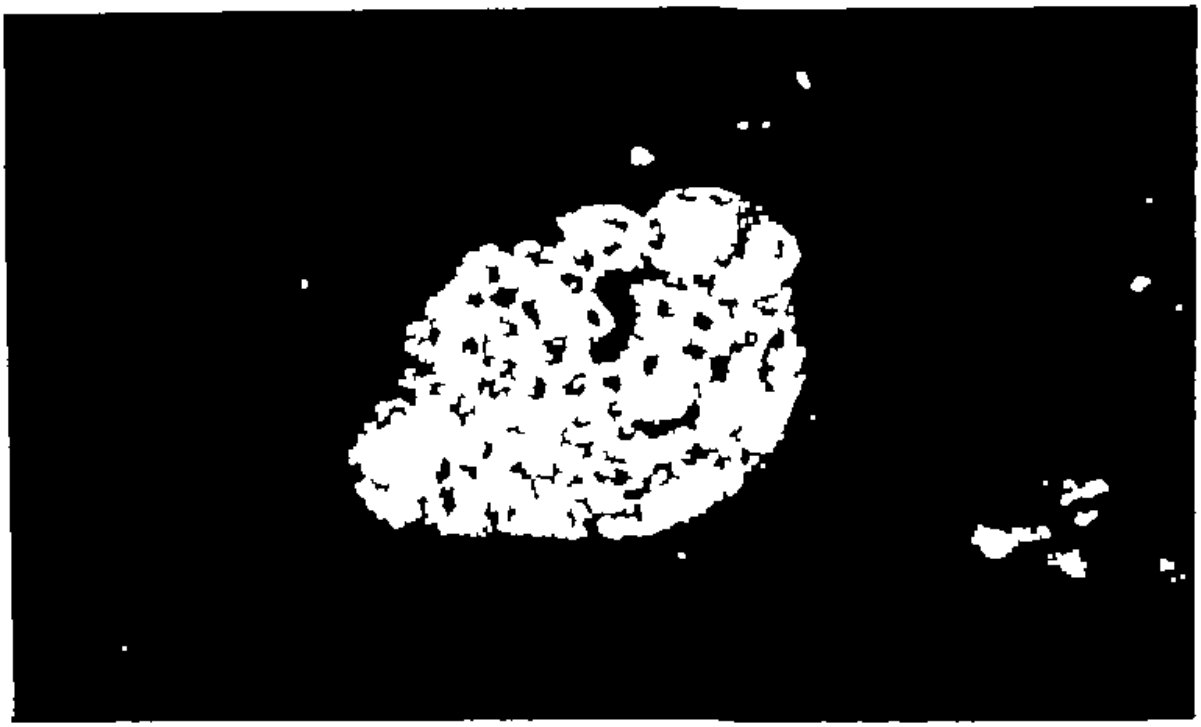

Fig. 4 Fluorescence photomicrograph of a pancreatic islet of mouse 30 minutes after an intravenous injection of DOPA. Fluorescence can be seen in all cells of the islet. Some peripherally located cells show little stronger fluorescence than the other cells. (×150)

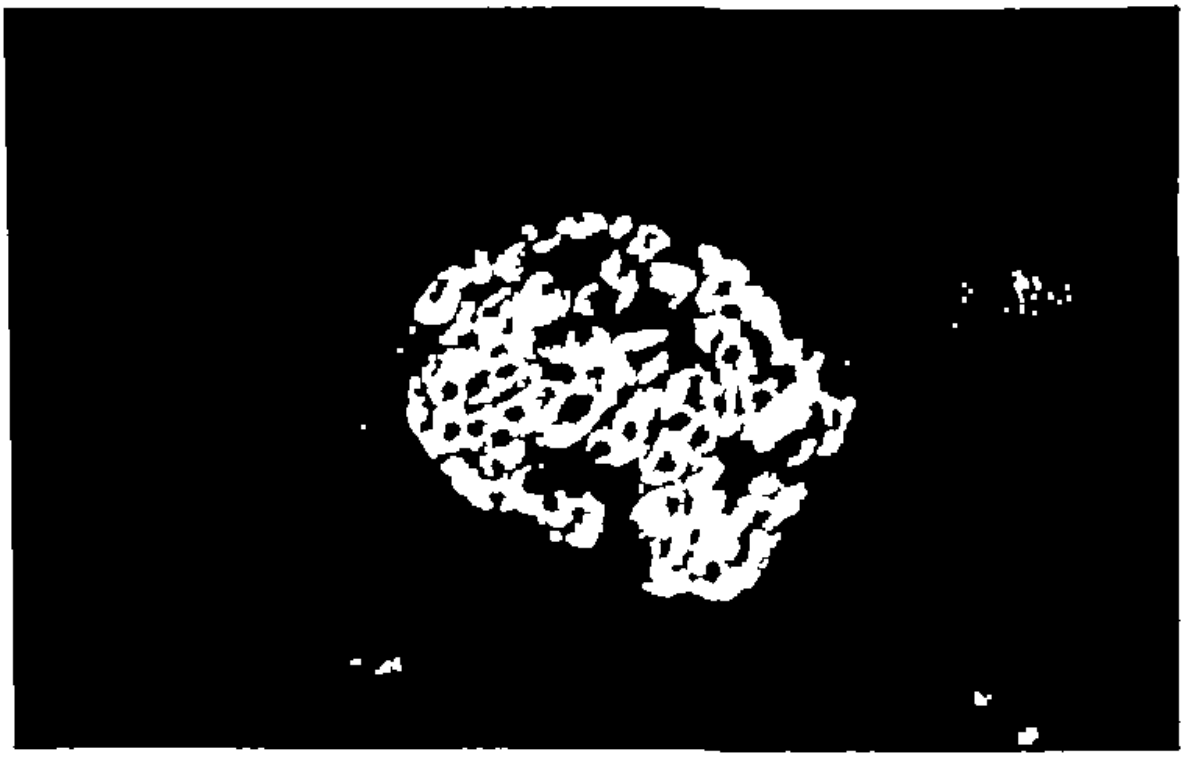

Fig. 5 Fluorescence photomicrograph of pancreatic islet of mouse 1 hou after an intravenous injection of DOPA. Some peripherally located cells show the trongest fluorescence Some cells show lower and some an even lower fluorescence. (×150)

pancreas activity could still be seen in the apical parts of acinar cells and in excretory ducts.

The fluorescence pictures obtained after injection of non-labelled DOPA and 5-HTP were also very similar to each other and showed the same general distribution patterns as seen in the autoradiograms (Fig. 4 and 5). However the lower sensitivity of the fluorescence method in comparison with the microautoradiographic method resulted in the disappearance of fluorescence 4 hours after the injection, while radioactivity could be observed in the islets 24 hours after the injection. The fluorescence pictures and the autoradiograms differed also in so far as the gradation between cells with different label was more pronounced in the fluorescent pictures, where they gave the impression of an all-or nothing effect.

If the animals were pre treated with the monoamine oxidase inhibitor nialamide there was a longer persistence of fluorescence in the islets after the injection of DOPA or 5-HTP. In addition there was no differentiation between peripherally located cells with high fluorescence and centrally located cells with lower fluorescence up to three hours after the injection (Fig. 6). Four hours after the injection the picture was similar to a picture seen after two hours without pre treatment with nialamide.

Combined microautoradiography—fluorescence microscopy

The combination of fluorescence microscopy and microautoradiography showed that the fluorescence obtained in the islets through the injection of one of the precursors (non-labelled) was in accordance with the radioactivity obtained through the injection of the other precursor (labelled) (Fig. 7). The result obtained was independent of whichever of the precursors was injected in la-

Fig. 7 b. Microautoradiogram of the same islet obtained through the simultaneous injection of ^{3}H-5-HTP. Hæ-eosin. Cells with the strongest fluorescence have also accumulated the highest radioactivity (arrows). (×350)

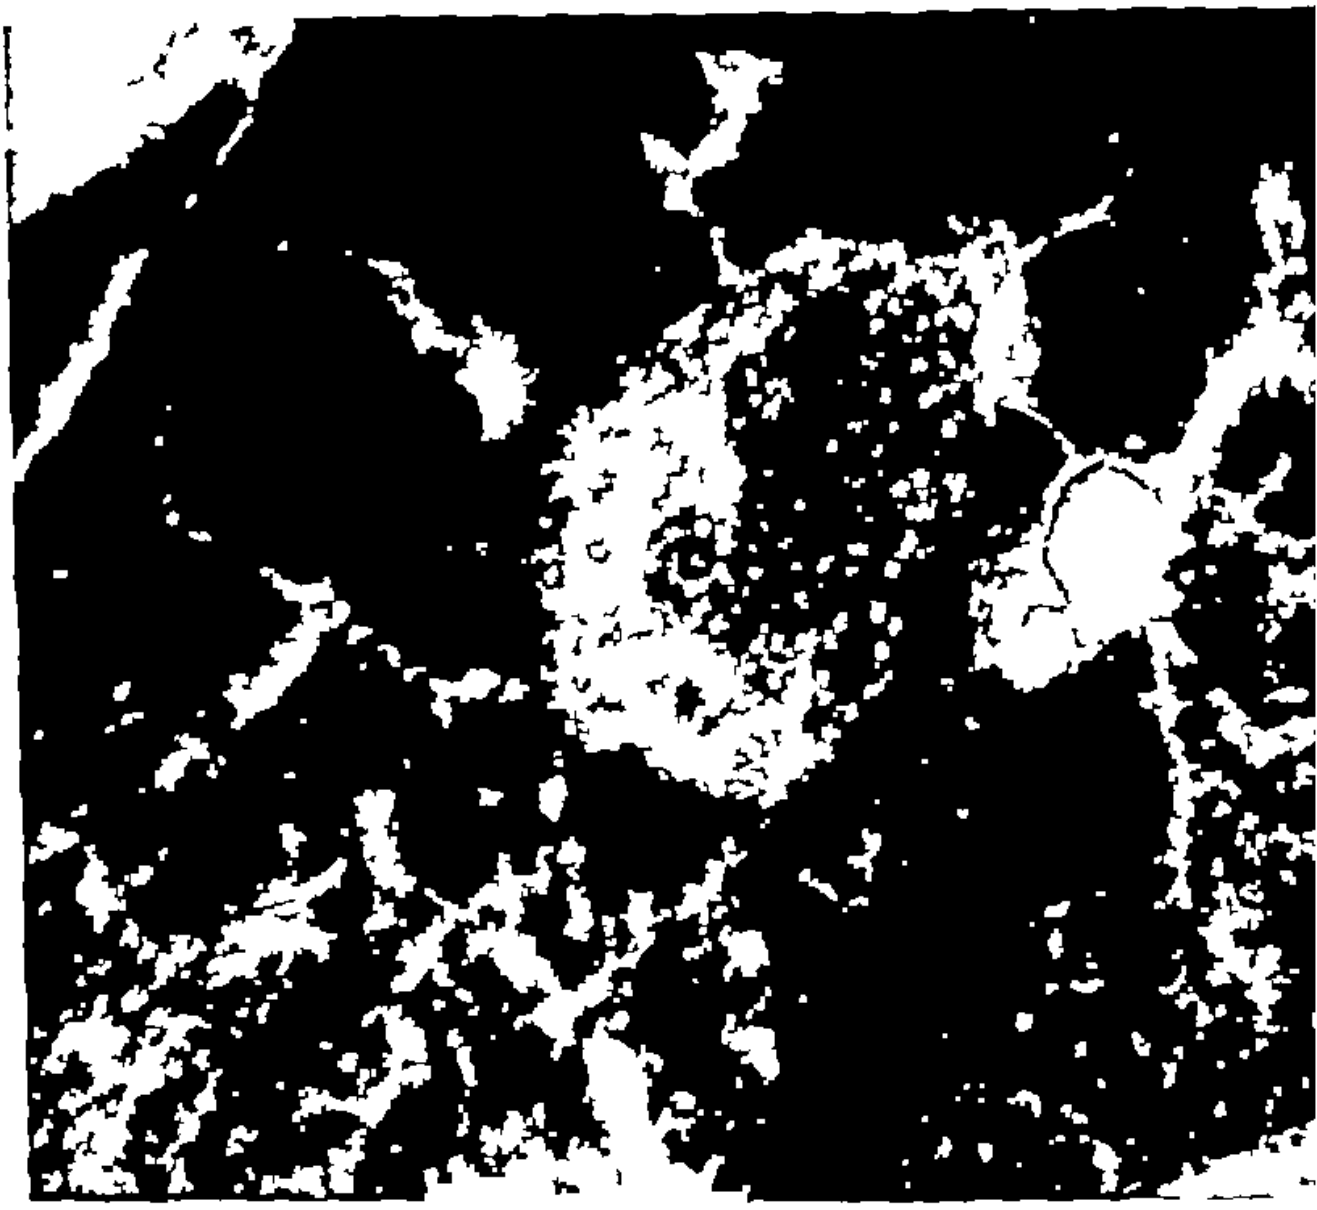

Fig. 8. MAO-activity in the pancreas of mouse. The strongest activity is seen in the exocrine pancreas. In the pancreatic islet most cells show moderate activity. Some peripherally located cells show a weak activity and some cells seem to entirely lack activity. (×140)

belled or non-labeled form. The low quantity of precursors injected the labelled form was shown to give no fluorescence of their own.

Monoamine oxidase histochemistry

The highest amount of formazan precipitate indicating the highest monoamine oxidase activity was seen in the exocrine pancreas. In the islet the majority of cells showed a moderate activity. Other cells, localized more in the periphery of the islets showed a weak activity and some cells, also peripherally localized, seemed to be entirely lacking activity (Fig. 8).

Discussion

The results obtained in the present investigation show that the localization of catechol and indolamines formed in the pancreatic islets after the injection of DOPA and 5-HTP is similar.

The accumulation of activity after the injection of the precursors is shown to appear very rapidly. This accumulation is accompanied by a decarboxylation of the precursors (Cegrell 1968). The decarboxylation is a rapid process (Udenfriend *et al.* 1957) which takes place via the action of aromatic L-amino acid decarboxylase (Lovenberg *et al.* 1962 a) an enzyme common to the two precursors. The presence of this enzyme in the pancreas has been shown (Holt *et al.* 1942, West 1958). Inhibition of the decarboxylase reduces the fluorescence induced in the islets after a DOPA injection (Cegrell 1968). This might indicate that the condition precedent for the retention of DOPA and 5-HTP in the pancreatic islets is the decarboxylation to the corresponding amine as will also be shown to be the case in the adrenal medulla (see Chapter 5). Reduced fluorescence after decarboxylase inhibition, when DOPA was injected into mice, in the parafollicular cells and in the enterochromaffin cell system has also been noted (Larsson *et al.* 1966, Hökfelt *et al.* 1967 a).

The monoamines persist in the pancreatic islets for a longer period after the inhibition of monoamine oxidase (MAO). This has been shown after the injection of DOPA (Cegrell 1968) and is now shown to be valid also for 5-HTP. The differentiation between cells with high and low monoamine content in the islets also disappears after the MAO-inhibition. As has been pointed out (Cegrell 1968) there seems to be an inverse relation between the MAO activity in and the monoamine disappearance from the islets, since the highest MAO content is present in centrally located cells, probably the β-cells, while peripherally located cells either contain a low activity or none. The low MAO activity in peripherally located cells has been observed earlier in other species (Petkov 1965). A direct identification of α- or β-cells with aldehyde fuchsin staining or silver impregnation methods on sections treated for MAO histochemistry was in the present investigation found to be impossible.

Radioactivity could in the present investigation easily be demonstrated even 24 hours after the injection. Fluorescence can be demonstrated for a much shorter time period. The inability to demonstrate an endogenous storage of monoamines in some mammals might therefore depend on the stores of monoamines being too low to be demonstrated with histochemical methods as also has been proposed (Cegrell 1968).

CHAPTER 7

Uptake of DOPA and 5-HTP in the parafollicular cells of the thyroid of the mouse studied by autoradiography and combined autoradiography fluorescence microscopy

As was the case for the pancreatic islets, the parafollicular cells of the thyroid have been shown to contain monoamines in some species, while other species lack demonstrable amounts of monoamines. Thus serotonin has been found to be endogenously occurring in the parafollicular cells of goat and sheep (Falck *et al* 1964 Falck and Owman 1968) As for the pancreatic islets, the injection of DOPA or 5-HTP leads to a formation of monoamines also in species where an endogenous monoamine storage cannot be demonstrated which has been shown with *autoradiography and fluorescence microscopy* (Falck *et al.* 1964 Rutén *et al.* 1965 Gershon and Ross 1966 a, Larsson *et al.* 1966, Pearse 1966, Owman and Sundler 1967 Ericson 1970)

In the present investigation the combined microautoradiographic—fluorescence microscopic technique has been used to investigate whether the cells which take up DOPA are identical with the cells which take up 5-HTP Some data from a separate microautoradiographic study are also presented.

Material and methods

The microautoradiographic method and the combined microautoradiographic—fluorescence microscopic method used have been described earlier (see Chapter 1) The number of animals, the substances injected and the survival times are given in Table 2.

Results

Microaut radiography

There seemed to be no difference between the microautoradiograms obtained after the ^{3}H DOPA and ^{3}H-5-HTP injections.

High activity could be seen in the parafollicular cells already five minutes after the injection (Fig 9) and was still present after 24 hours. The activity was greater than the corresponding activity in the most active cells of the pancreatic islets at the corresponding intervals.

The follicular cells contained a small amount of activity in comparison with the parafollicular cells. The activity which could be observed in them was a

TABLE II Thyroid.

Microautoradiography

No. of animals in each survival time	Treatment (substance and dose)	Survival time

in the parafollicular cells restricted to the cytoplasm of the cells. The activity in the follicle cells was a little higher than the activity in the colloid.

Combined microautoradiography—fluorescence microscopy

The combination of microautoradiography and fluorescence microscopy showed that the localization of catechol- and indolamines corresponded well (Fig. 10). The strongest fluorescing cells contained the highest radioactivity and vice versa. As can be seen in Fig. 11 fluorescence is present in the parafollicular cells 4 hours after the injection, while at this time no fluorescence is present in the pancreatic islets.

Discussion

There seems to be no principal difference between the monoaminergic mechanisms in the parafollicular cells and in the pancreatic islets.

Formation of catechol- and indolamines takes place in the same parafollicular cells. The accumulation of activity occurs rapidly. Inhibition of the decarboxylase has been shown to reduce a precursor induced fluorescence in the parafollicular cells and inhibition of MAO has been shown to produce a longer persistence of the fluorescence (Larsson *et al.* 1966). These mechanisms have been discussed in Chapter 1.

belled or non-labeled form. The low quantity of precursors injected the labelled form was shown to give no fluorescence of their own.

Monoamine oxidase histochemistry

The highest amount of formazan precipitates, indicating the highest monoamine oxidase activity was seen in the exocrine pancreas. In the islet the majority of cells showed a moderate activity. Other cells, localized more in the periphery of the islets, showed a weak activity and some cells, also peripherally localized, seemed to be entirely lacking activity (Fig. 8)

Discussion

The results obtained in the present investigation show that the localization of catechol- and indolamines formed in the pancreatic islets after the injection of DOPA and 5-HTP is similar

The accumulation of activity after the injection of the precursors is shown to appear very rapidly Thus accumulation is accompanied by a decarboxylation of the precursors (Cegrell 1968) The decarboxylation is a rapid process (Udenfriend *et al.* 1957) which takes place via the action of aromatic L-amino acid decarboxylase (Lovenberg *et al.* 1962 a) an enzyme common to the two precursors. The presence of this enzyme in the pancreas has been shown (Holz *et al* 1942, West 1958) Inhibition of the decarboxylase reduces the fluorescence induced in the islets after a DOPA injection (Cegrell 1968) This might indicate that the condition precedent for the retention of DOPA and 5-HTP in the pancreatic islets is the decarboxylation to the corresponding amine as will also be shown to be the case in the adrenal medulla (see Chapter 5) Reduced fluorescence after decarboxylase inhibition, when DOPA was injected into mice, in the parafollicular cells and in the enterochromaffin cell system has also been noted (Larsson *et al.* 1966, Håkanson *et al* 1967 a)

The monoamines persist in the pancreatic islets for a longer period after the inhibition of monoamine oxidase (MAO) This has been shown after the injection of DOPA (Cegrell 1968) and is now shown to be valid also for 5-HTP The differentiation between cells with high and low monoamine content in the islets also disappears after the MAO-inhibition. As has been pointed out (Cegrell 1968) there seems to be an inverse relation between the MAO activity in and the monoamine disappearance from the islets, since the highest MAO content is present in centrally located cells, probably the β-cells, while peripherally located cells either contain a low activity or none. The low MAO activity in peripherally located cells has been observed earlier in other species (Petkov 1965) A direct identification of α or β-cells with aldehyde fuchsin staining or silver impregnation methods on sections treated for MAO histochemistry was in the present investigation found to be impossible.

Radioactivity could in the present investigation easily be demonstrated even 24 hours after the injection. Fluorescence can be demonstrated for a much shorter time period. The inability to demonstrate an endogenous storage of monoamines in some mammals might therefore depend on the stores of monoamines being too low to be demonstrated with histochemical methods as also has been proposed (Cegrell 1968)

CHAPTER 2

Uptake of DOPA and 5-HTP in the parafollicular cells of the thyroid of the mouse studied by autoradiography and combined autoradiography fluorescence microscopy

As was the case for the pancreatic islets, the parafollicular cells of the thyroid have been shown to contain monoamines in some species, while other species lack demonstrable amounts of monoamines. Thus serotonin has been found to be endogenously occurring in the parafollicular cells of goat and sheep (Falck *et al.* 1964 Falck and Owman 1968) As for the pancreatic islets, the injection of DOPA or 5-HTP leads to a formation of monoamines also in species where an endogenous monoamine storage cannot be demonstrated, which has been shown with autoradiography and fluorescence microscopy (Falck *et al.* 1964 Ritzén *et al.* 1965 Gershon and Ross 1966 a, Larsson *et al.* 1966, Pearse 1966 Owman and Sundler 1967 Ericson 1970)

In the present investigation the combined microautoradiographic—fluorescence microscopic technique has been used to investigate whether the cells which take up DOPA are identical with the cells which take up 5-HTP Some data from a separate microautoradiographic study are also presented.

Material and methods

The microautoradiographic method and the combined microautoradiographic—fluorescence microscopic method used have been described earlier (see Chapter 1) The number of animals, the substances injected and the survival times are given in Table 2.

Results

Microautoradiography

There seemed to be no difference between the microautoradiograms obtained after the ^{3}H DOPA- and H-5-HTP-injections.

High activity could be seen in the parafollicular cells already five minutes after the injection (Fig 9) and was still present after 24 hours. The activity was greater than the corresponding activity in the most active cells of the pancreatic islets at the corresponding time intervals.

The follicular cells contained a small amount of activity in comparison with the parafollicular cells. The activity which could be observed in them was as

in the parafollicular cells restricted to the cytoplasm of the cells. The activity in the follicle cells was a little higher than the activity in the colloid.

Combined microautoradiography—fluorescence microscopy

The combination of microautoradiography and fluorescence microscopy showed that the localization of catechol- and indolamines corresponded well (Fig. 10). The strongest fluorescing cells contained the highest radioactivity and vice versa. As can be seen in Fig. 11 fluorescence is present in the parafollicular cells 4 hours after the injection, while at this time no fluorescence is present in the pancreatic islets.

Discussion

There seems to be no principal difference between the monoaminergic mechanisms in the parafollicular cells and in the pancreatic islets.

Formation of catechol- and indolamines takes place in the same parafollicular cells. The accumulation of activity occurs rapidly. Inhibition of the decarboxylase has been shown to reduce a precursor induced fluorescence in the parafollicular cells and inhibition of MAO has been shown to produce a longer persistence of the fluorescence (Larsson *et al.* 1966). These mechanisms have been discussed in Chapter 1.

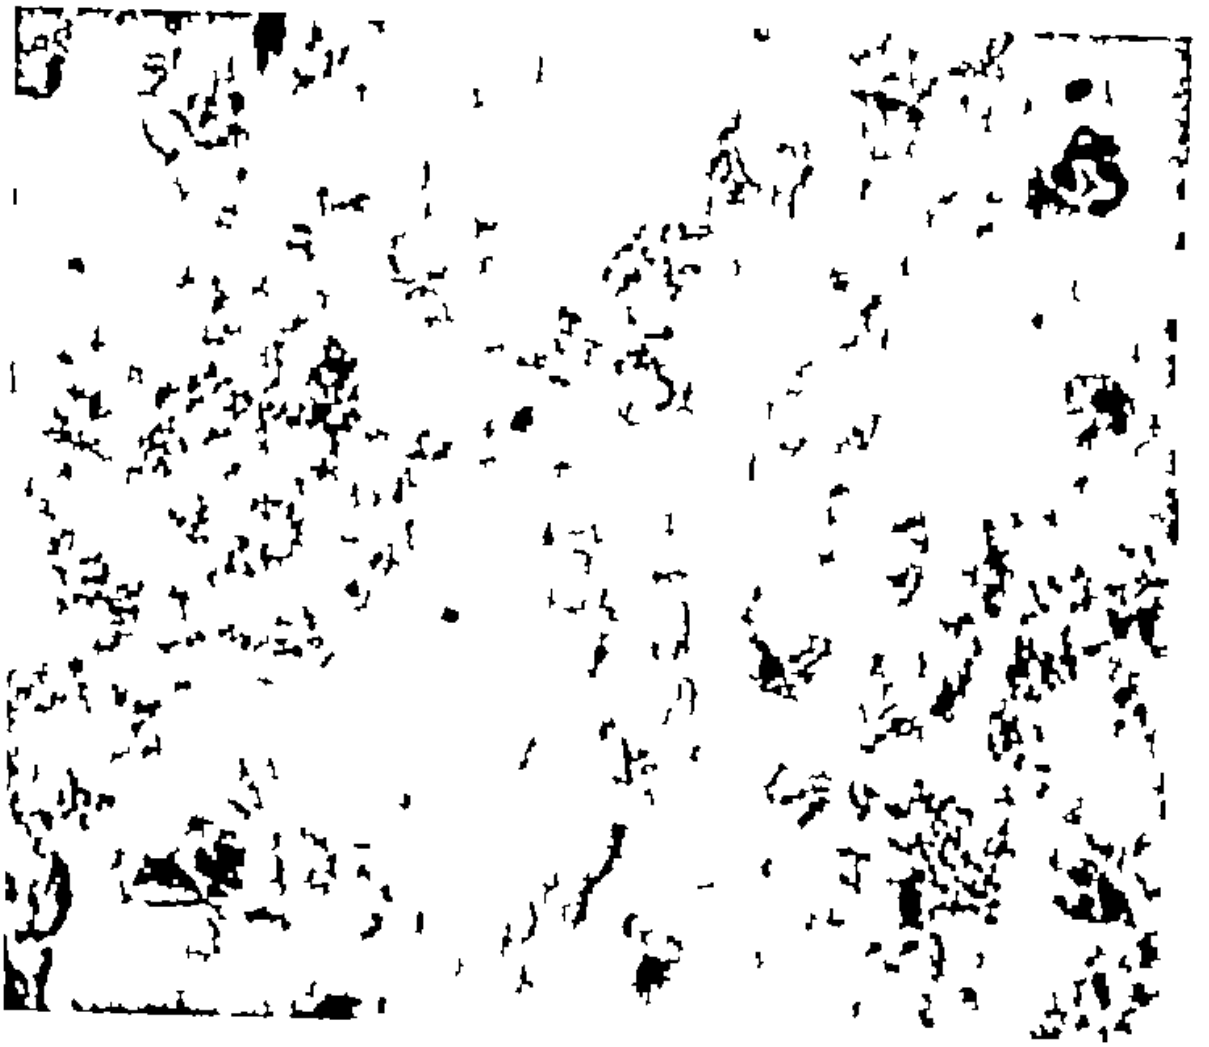

Fig. 11 b. Microautoradiogram of the same section obtained through the parallel injection of ^{3}H 5-HTP. Hix-exalin. Fluorescence and silver grains respectively are concentrated in the cytoplasm of the parafollicular cells and correspond with one another (×720)

CHAPTER 3

Uptake of DOPA and 5 HTP in the mucosa of the stomach of the mouse, studied by autoradiography fluorescence microscopy and combined autoradiography fluorescence microscopy

In the gastrointestinal tract the presence of serotonin has been known since long (Erspamer and Asero 1952) Most of this storage has been shown to be present in the enterochromaffin cells (see Pentulä 1966 Vialli 1966) In the cat and the rabbit dopamine containing enterochromaffin cells have been shown to be present (Håkanson *et al* 1970 a) In addition to these cells, other cells have been demonstrated, which lack endogenous demonstrable storage of monoamines, but possess the monoamine forming capability after injections of monoamine precursors (Håkanson *et al* 1967 a) These cells have recently been extensively studied with fluorescence methods (see Håkanson 1970) A third group of cells in the gastrointestinal mucosa capable of monoamine storage are the mast cells (see Enerbäck 1966 Håkanson *et al* 1970 a)

Apart from fluorescence methods, an uptake of monoamine precursors in the cells of the gastrointestinal mucosa has been shown with microautoradiography (Hammarström *et al.* 1966, Gershon and Ross 1966 a)

In the present investigation an attempt is made to establish in which of the three mentioned cell categories in the stomach of the mouse an uptake of DOPA and 5-HTP takes place and to investigate if the two precursors are taken up equally in the cells. For this purpose microautoradiography and combined microautoradiography—fluorescence microscopy has been employed. A mapping of the cells with endogenous fluorescence was found to be necessary for an evaluation of the results.

Material and methods

Ten untreated mice were used to study the cells with endogenous fluorescence Pieces of the stomach were taken along the smaller and the greater curvatures of the stomach and at varying distances from and parallel to these curvatures. The pieces were taken as to enable later studies of the forestomach, the fundic gland area and the pyloric gland area in the same section. The pieces were subjected to fluorescence microscopy as described earlier (see Chapter 1) Staining with toluidine blue in ethanol solution (Romeis 1948) was used

TABLE III. Stomach.

Microautoradiography

No. of animals at each survival time	Treatment (substance and dose)	Survival tim
3	H DOPA, 0.5 mCi corresponding to 0.18 mg/kg	5 mm. 1 h, 24 h
3	H-5-HTP 0.5 mCi corresponding to 2.16 mg/kg	5 min, 1 h, 24 h

Combined microautoradiography — fluorescence microscopy

No. of animals at each survival time	Treatment (substance and dose)	Survival time
2	H 5-HTP 0.5 mCi corresponding to 2.16 mg/kg + L-DOPA 100 mg/kg	2 h, 4 h
2	H DOPA, 0.5 mCi corresponding to 0.18 mg/kg + L-5-HTP 100 mg/kg	2 h, 4 h

to identify mast cells in the sections. By this staining mast cells show metachromasia.

The procedures used for the microautoradiographic and combined microautoradiographic—fluorescence microscopic studies have been described in Chapter 1. The number of animals used, the substances injected and the survival times are given in Table 3. In the microautoradiographic investigation pieces were taken from different parts of the stomach. In the combined microautoradiographic—fluorescence microscopic investigation pieces were taken from the fundic gland area of the stomach.

Results

Endogenous fluorescence

The fundic gland area adjacent to the forestomach contained a relatively high number of yellow fluorescing cells interspread among the epithelial cells. They were mostly located in the middle or in the superficial parts of the glands, but a few cells could also be seen basally in the glands (Fig. 12). They had their greatest extension along the greater curvature and became gradually limited to a narrower area towards the smaller curvature (Fig. 13). In a band

Fig. 12 Fluorescence photomicrograph of the stomach wall, f ndic gland area, from an untre ted mouse. Yellow fluorescing cells, probably mast cells, are seen. They are most numerous in the middle and the superficial parts of the glands. A few cells are also seen at the base of the glands and in the submucosa. The number of fluorescing cells are most numerous towards the forestomach (to the right in the picture) (×50)

They have their greatest extension along the greater curvature and become gradually limited to a more narrow area towards the smaller curvature. The enterochromaffin cells are present in the pyloric gland area and in the gradual transition between the fundic gland area and the pyloric gland area.

Fig. 16. Microautoradiogram of the stomach wall, fundic gland area, 5 minutes after an intravenous injection of ^{3}H 5-HTP into mouse. The highest radioactivity is seen in basally located cells, probably enterochromaffin-like cells. Smaller and often more superficially located cells, probably mast cells, also contain high activity. The radioactivity in the gastric pits is higher than in the gastric glands. Hts-eosin. (×180)

Microautoradiography

The distribution pictures obtained after the injection of DOPA and 5-HTP were similar.

Five minutes after the injection there was a very high uptake in the whole mucosa and submucosa.

In the forestomach there was a high and even distribution of activity in the squamous epithelium and in the lamina propria. In the submucosa a very high activity could be seen in single mast cells.

In the fundic gland area the concentration of activity was higher in the gastric pits than in the fundic glands. Scattered among the fundic glands there were also several cells with a very high activity (Fig. 16). Their number was greatest at the base of the glands, but they were also found in the superficial parts of the glands. The basally located cells seemed to contain the highest activity. These cells often had a wedge shaped appearance. Identification of mast cells in the mucosa by metachromasia after toluidine blue staining was

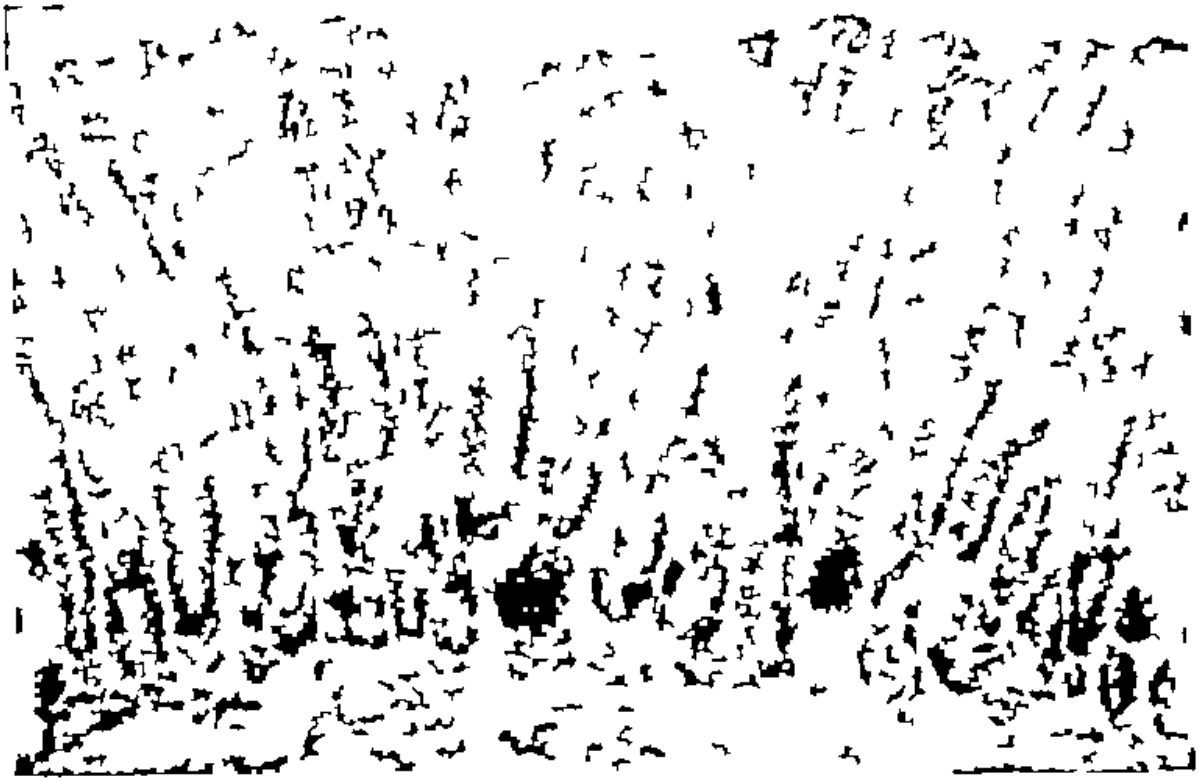

Fig. 17 Microa toradiogram of the stomach wall, pyloric gland area, 5 minutes after an intravenous injection of ^{3}H DOPA into a mouse. The highest activity is seen in basally located cells, probably enterochromaffin cells. High activity is also seen in gastric pits and pyloric glands. Htx-eosin. (×180)

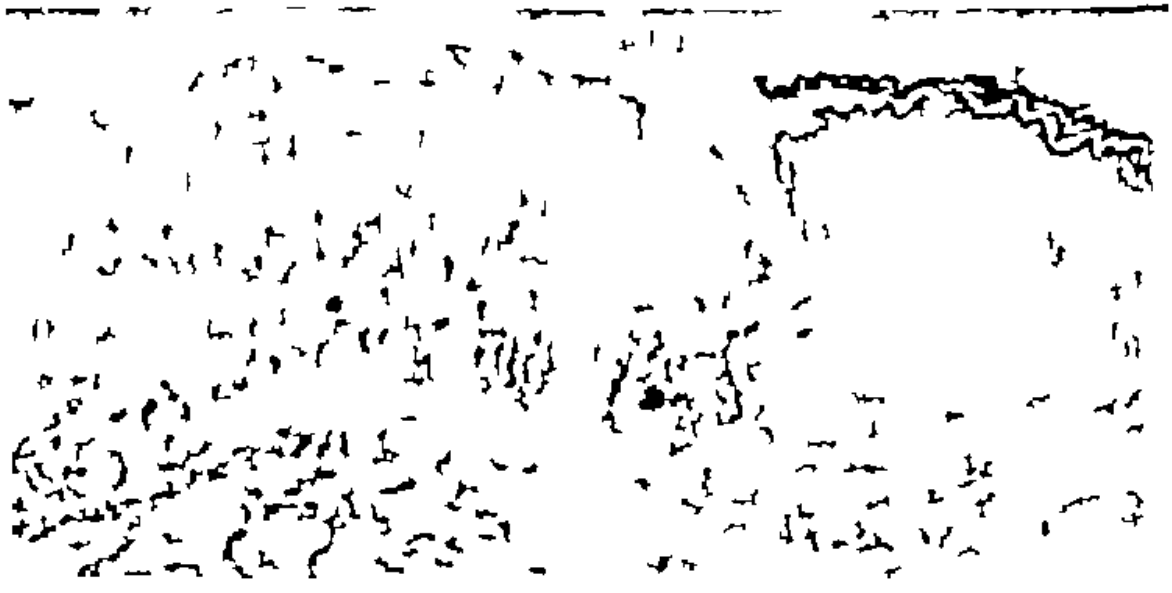

Fig 18. Microautoradiogram of the stomach wall, at the junction between the forestomach (to the right) and the fundic gland area (to the left) 1 hour after an intravenous injection of H 5-HTP int a mouse. Labelled mast cells are seen in the submucosa. In the fundic mucosa labelled cells can be observed both, at the base and more superficially Htx-eosin. (×60)

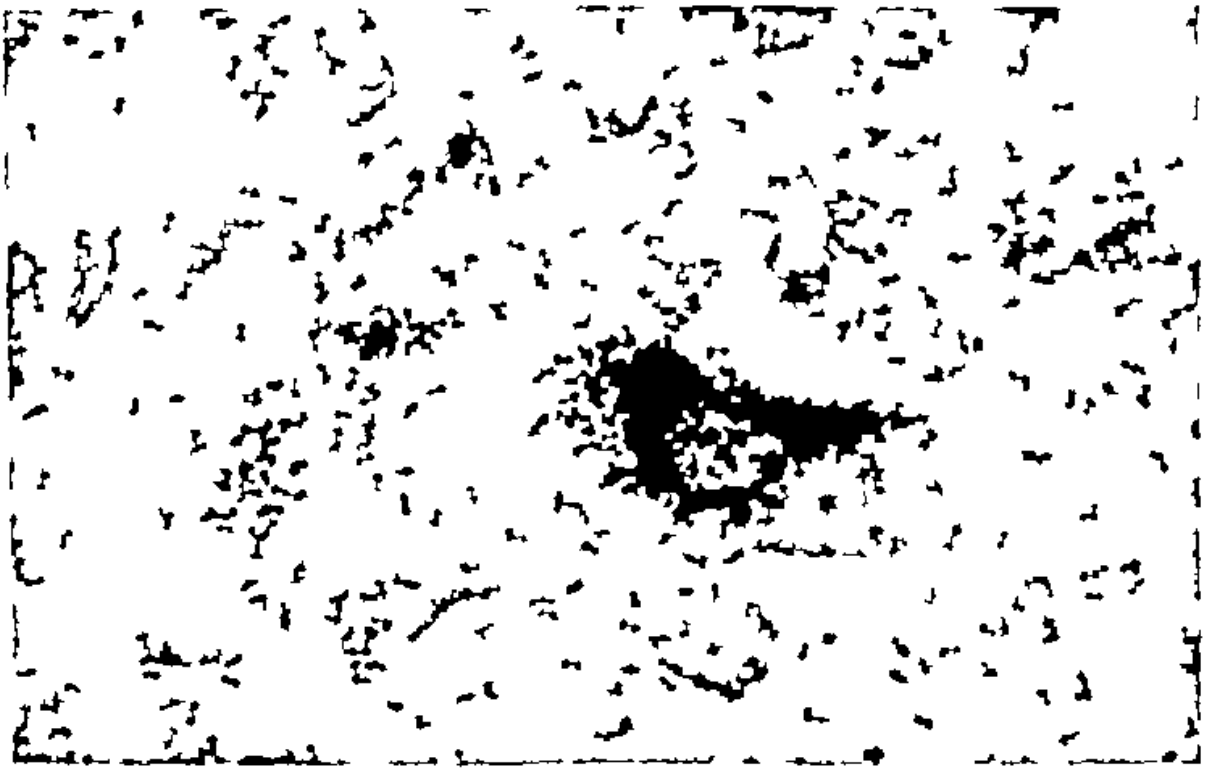

Fig. 19 Microautoradiogram from the fundic part of the stomach wall 1 hour after an intravenous injection of ^{3}H DOPA into a mouse. A strong accumulation of silver grains is seen in the cytoplasm of a wedge-shaped cell of enterochromaffin type. Toluidine blue. (×920)

not possible on sections covered with stripping film. Obviously the stripping film abolished the colour reaction.

In the mucosa of the pyloric gland area the activity was high 5 minutes after the injection with the same activity in gastric pits as in pyloric glands. In addition there were some, often wedge-shaped, cells with a basal location which had a very high activity (Fig. 17)

One hour after the injection the activity was low in the forestomach, in gastric pits in the fundic and the pyloric gland area and in fundic and pyloric glands. Intensely labelled cells could, however, be seen scattered in the fundic mucosa both basally and more superficially (Fig. 18). The more superficially located cells were considerably smaller than the basally located cells, which often showed a wedge-shaped appearance (Fig. 19). In the pyloric gland area highly labelled, [illegible] wedge-shaped cells with a basal location could be seen.

In the submucosa of [illegible] much scattered mast cells contained a high activity.

The picture seen 4 hours after the injection was similar to the one described after one [illegible] Fig. 20.

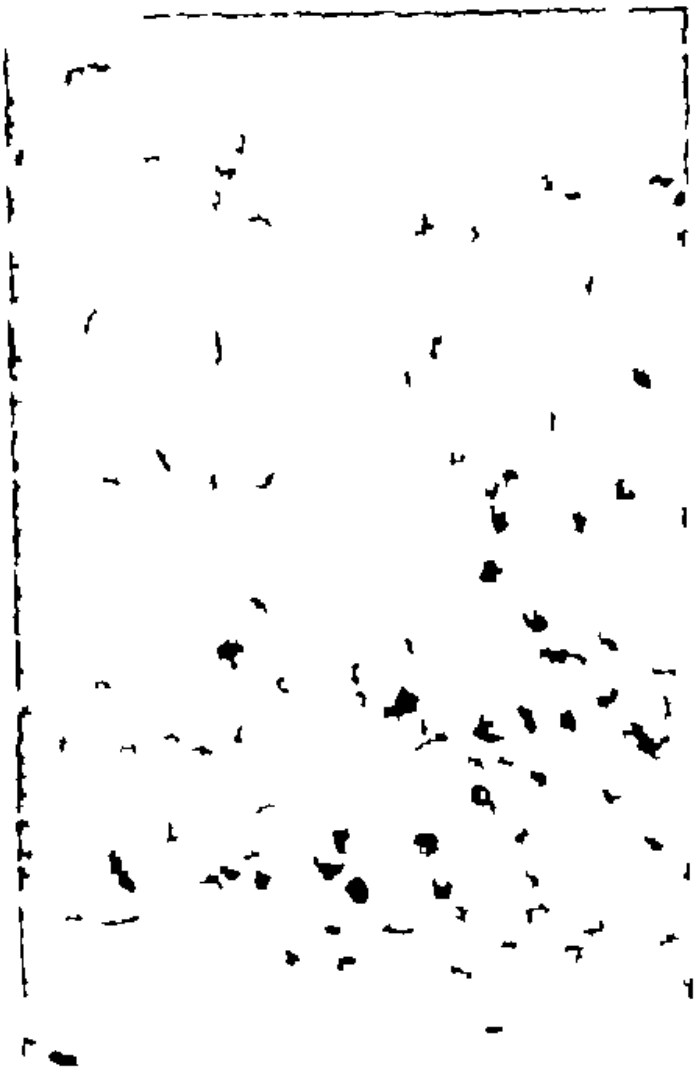

Fig. 20. Microautoradiogram of the stomach wall, fundic gland area, 24 hours after an intravenous injection of H 5-HTP into a mouse. Strongly labelled cells can still be seen in the mucosa and the submucosa. Htx-eosin. (×160)

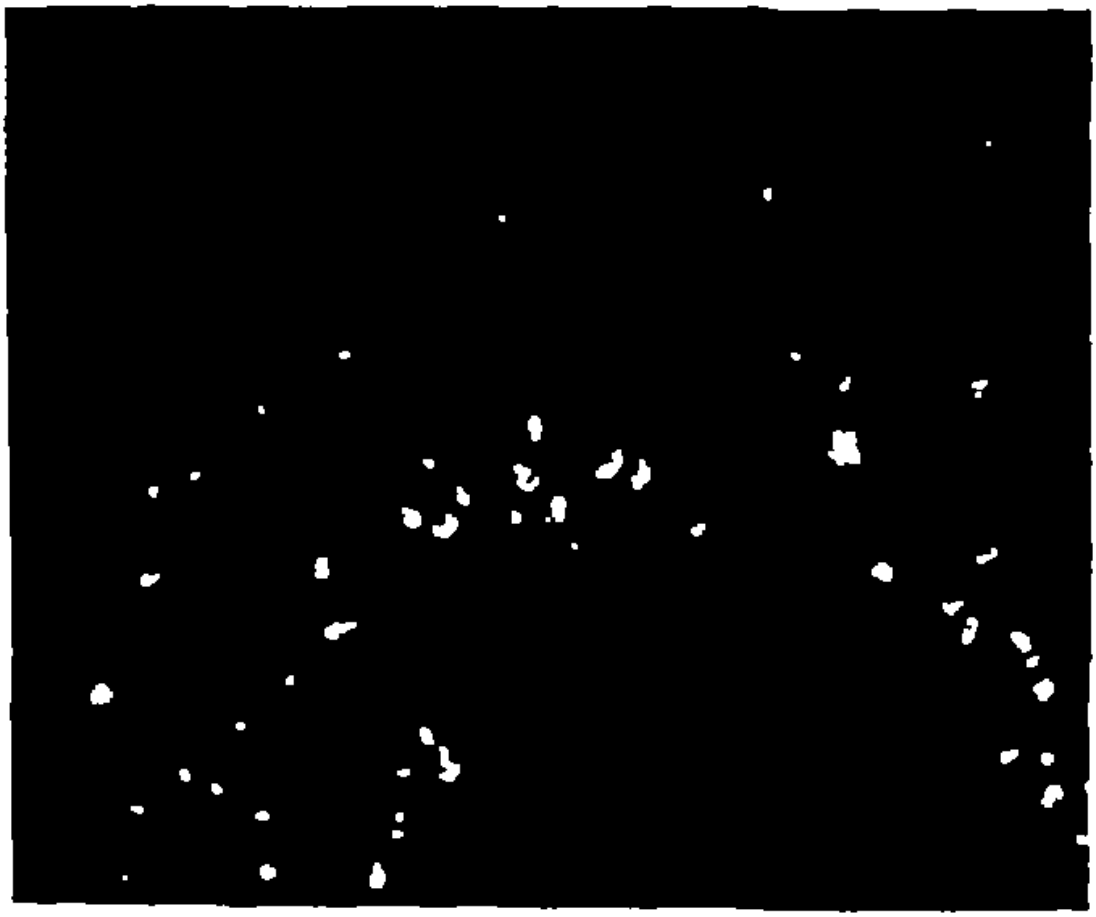
In comparison with the cells in the pancreatic islets and the parafollicular cells, the cells in gastric mucosa were more heavily labelled at all the studied time intervals.



Combined microautoradiography—fluorescence microscopy

The combination was performed on pieces from the fundic gland area.

The highest fluorescence and radioactivity could be observed in cells with a basal location in the fundic glands. The correspondence between highly fluorescent and highly labelled cells was good (Fig. 21). Also in angular small cells located more superficially in the mucosa the correspondence between fluorescence and activity was good.

Fig. 21. Fluorescence photomicrograph of the stomach wall, fundic gland area, 2 hours after an intravenous injection of non-labelled DOPA into a mouse.

Fig. 21 b. Microautoradiogram of the same section obtained through the parallel injection of ^{3}H 5-HTP. Htx-eosin. Fluorescing cells and radioactively labelled cells correspond well both in the basal and superficial parts of the mucosa. (×150)

Discussion

The cells with endogenous fluorescence which have been described in the pyloric gland area belong to the system of enterochromaffin cells with endogenous 5-HT storage in the gastrointestinal tract. The fluorescing cells in the fundic mucosa probably represent a type of mast cells. These cells, which have been found in mice and some other species (see Håkanson 1970) show characteristics which differ them from other mast cells they are smaller than other mast cells in the dog and the rat they have been found not to be degranulated by compound 48/80 (Enerbäck 1966, Aures *et al.* 1968) They also show a weaker and more inconstant metachromasia after toluidine blue staining than other mast cells (Enerbäck 1966) The inability observed in the present investigation to stain all cells with endogenous fluorescence in the fundic gland area metachromatically with toluidine blue is probably due to this variance in staining properties.

In the present investigation these cells were shown to be very numerous in the fundic gland area, adjacent to the forestomach, especially along the greater curvature. Noteworthy is the band of cells in the mucosa adjacent to the ridge separating the fundic gland area from the forestomach. In the rat a band of argentaffin cells with the corresponding localization has been observed (Gregg 1960) It has not been established whether these cells are mast cells, but the mast cells in the submucosa of the rat have been shown to be stained by argentaffin techniques (Soule and Gregg 1965)

In the microautoradiographic investigation cells with a localization corresponding to both the enterochromaffin cells in the pyloric gland area and the mast cells in the fundic gland area, could be observed. It seems therefore probable that both these endogenously fluorescing cells are capable of monoamine formation after the precursor injections.

In addition to these cells strongly labelled cells were seen basally in the fundic mucosa. These cells have been studied with fluorescence methods (Håkanson *et al.* 1967 a, see also Håkanson 1970) They have been termed enterochromaffin like cells by these authors. In the mouse and the rat they have been shown to contain histamine. The substance produced by them has been proposed to be the gastric antipernicious principle (the intrinsic factor) (Håkanson *et al.* 1969 a, 1970 b)

The combination of microautoradiography and fluorescence microscopy in the fundic gland area also show that the fluorescence and the radioactivity obtained after the precursor injections are in agreement both in the basally located cells, probably corresponding to the enterochromaffin-like cells and in the more superficially located cells probably representing mast cells.

The monoaminergic mechanisms in these cells seem to be similar to the

cells in pancreatic islets and the parafollicular cells the accumulation of activity appears rapidly in the enterochromaffin-like cells decarboxylase inhibition reduces and MAO inhibition prolongs the fluorescence (Håkanson *et al.* 1967 a) These principal mechanisms have been discussed in Chapter 1

CHAPTER 4

Electron microscope autoradiography of the mouse fundic mucosa after the injection of tritiated L-DOPA

In the electron microscope the cells of the enterochromaffin cell system show several characteristics common to endocrine cells. One of the characteristics is the specific granules present in the cytoplasm of the cells. Several types of enterochromaffin cells with different granules have been described lately (e.g. Forssmann *et al.* 1969 Vasallo *et al* 1969 Capella *et al* 1969) The different parts of the gastrointestinal tract have also in these studies been shown to contain more than one of the enterochromaffin cell types.

The fact that these cells have ultrastructural characteristics common to endocrine cells, together with their monoamine storing capability have led to the mentioned assumptions that the cells of the enterochromaffin type might be endocrine cells producing the gastrointestinal hormones.

For the study of the enterochromaffin cell system in the light microscope, silver impregnation methods have been extensively used. These methods are based on the ability of the cells to reduce ammoniacal silver salts. It has been proposed that 5-HT is the reducing agent in the cells (Erspamer and Asero 1952) Several silver impregnation methods exist (see Pearse 1960) Differences in staining properties by these techniques have led to assumptions that the cells might belong to several different categories (see Håkanson 1970) It is, however impossible to correlate the different cell types seen in the electron microscope with the cells identified in the light microscope by the silver impregnation methods. When the uptake of the monoamine precursors is studied with microautoradiography or fluorescence microscopy as hitherto has been the case, it is impossible to say which of the cell types seen in the electron microscope are capable of the precursor accumulation. In the present investigation therefore an attempt is made, by means of electron microscope autoradiography to establish in which cells a monoamine accumulation takes place after the injection of DOPA.

The fundic gland area of the mouse stomach has been chosen for the present investigation. This area contains cells with the monoamine precursor accumulating capability (see Chapter 3)

Material and methods

Two male albino mice (NMRI-strain) weighing about 20 g were injected through a tail vein with 1.5 mCi ring 2 5-6- H-labelled L-3(3,4-dihydroxy phenyl-alanine (^{3}H DOPA) spec. act. 28 Ci/mM (The Radiochemical Centre Amersham, England) The dose corresponded to 0.54 mg L-DOPA/kg body weight.

The mice were sacrificed two hours after the injection by cervical dislocation and small pieces of the stomach, from the part of the fundic gland area shown to contain only few cells with endogenous fluorescence (see Chapter 3) were rapidly removed and immersed in a cold solution of 2.5 % glutaraldehyde in a Tyrode medium, pH 7 4 After 2 hours of fixation the glutaraldehyde fixed specimens were rinsed briefly in Tyrodes solution and transferred to a cold isotonic solution of osmiumtetroxide buffered to pH 7 4 for an additional fixation period of 2 hours. After dehydration in ethanol the tissue pieces were embedded in Epon.

The procedure for electron microscopic autoradiography was in principle the same as described by Maunsbach (1966) 400—600 A thick sections were cut on a LKB Ultrotome. The sections were picked up on Formvar-coated molybdenum grids (Ernest F Fullam, Inc., Schenectady U.S.A.) Ilford L 4 emulsion was applied to the grids by means of a wireloop. During the exposure time of 8 weeks the grids were stored in a refrigator at +4 C. The preparations were developed for 1 minute in Kodak D 19 and fixed for 4 minutes in Kodak Rapid Fix.

The specimens were studied in a Siemens Elmiskop I at an accelerating voltage of 80 kV with the double condensor and a 50 μ objective aperture Micrographs were taken at magnifications ranging from about 5 000 to 10.000 times.

Controls

Control sections from the fundic mucosa of 2 mice not injected with H DOPA were taken and handled for autoradiography the same way as described for the ^{3}H DOPA-injected animals.

Results

On the electron microscope autoradiographs a strong accumulation of silver grains could be seen over cells of enterochromaffin type which on basis of the different appearance of the granules, could be said to be of at least two different types. Silver grains over zymogen cells or over parietal cells were few

Most, but not all of the fluorescing cells in the fundic mucosa are stained metachromatically with toluidine blue. (×180)

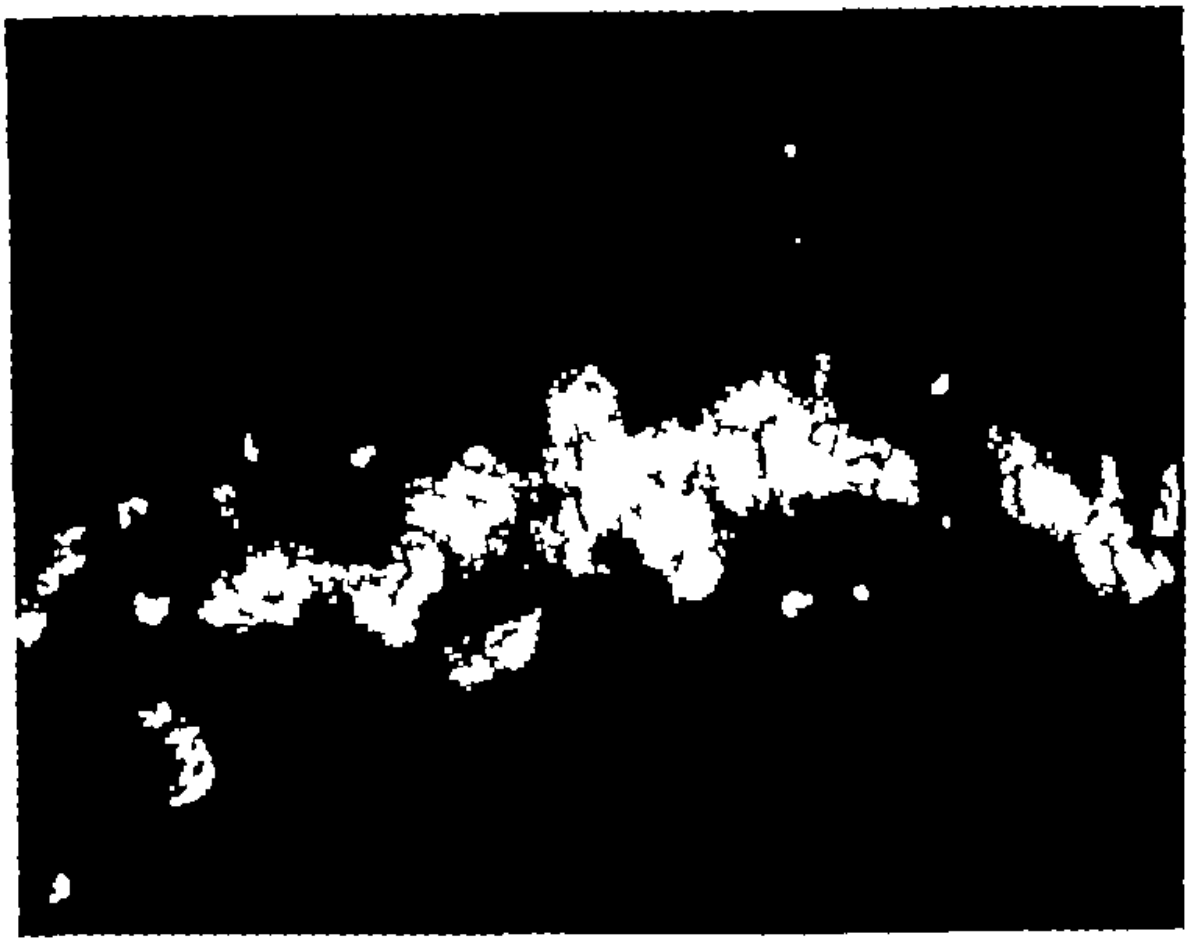

Fig. 15. Fluorescence photomicrograph of the stomach wall, pyloric gland area, of an untreated mouse. Fluorescing enterochromaffin cells can be seen in the basal half of the mucosa. (× 150)

of the mucosa seen immediately adjacent and parallel to the dividing ridge separating the forestomach from the fundic gland area, especially many yellow fluorescing cells could be seen (Fig. 14). When the sections were successively stained with toluidine blue, most of these cells showed a distinct metachromasia characteristic for mast cells. Some of the cells were however not stained with toluidine blue.

A great part of the fundic gland area was devoid of fluorescing cells or contained only a few fluorescing cells (see Fig. 13).

In the gradual transition between the fundic gland area and the pyloric gland area yellow fluorescing enterochromaffin cells could be observed. In the pyloric gland area they became rather numerous. They were restricted to the basal half of the mucosa, they were large and often flask-shaped and they did not show metachromasia after toluidine blue staining (Fig. 15).

In addition to the described cells yellow fluorescing mast cells (identified through their metachromasia) could be seen in the submucosa and in the lamina propria in all parts of the stomach.

Fig. 16. Microautoradiogram of the stomach wall, fundic gland area, 5 min tes after an intravenous injection of H-5-HTP into a mouse. The highest radioactivity is seen in basally located cells, probably enterochromaffin-like cells. Smaller and often more superficially located cells, probably mast cells, also contain high activity The radioactivity in the gastric pits is higher than in the gastric glands. Hts-eosin. (×180)

Microautoradiography

The distribution pictures obtained after the injection of DOPA and 5-HTP were similar

F've minutes after the injection there was a very high uptake in the whole mucosa and submucosa.

In the forestomach there was a high and even distribution of activity in the squamous epithelium and in the lamina propria. In the submucosa a very high activity could be seen in single mast cells.

In the fundic gland area the concentration of activity was higher in the gastric pits than in the fundic glands. Scattered among the fundic glands there were also several cells with a very high activity (Fig. 16) Their number was greatest at th base of the glands, but they were also found in the superficial parts of the glands. The basally located cells seemed to contain the highest activity These cells often had a wedge-shaped appearance. Identification of mast cells in th mucosa by metachromasia after toluidine blue staining was

Fig. 17 Microa toradiogram of the stomach wall, pyloric gland area, 5 minutes after an intra enous injection of ^{3}H DOPA into mouse. The highest activity is seen in basally located cells probably enterochromaffin cells. High activity is also seen i gastric pits and pyloric glands. Htx-eosin. (×180)

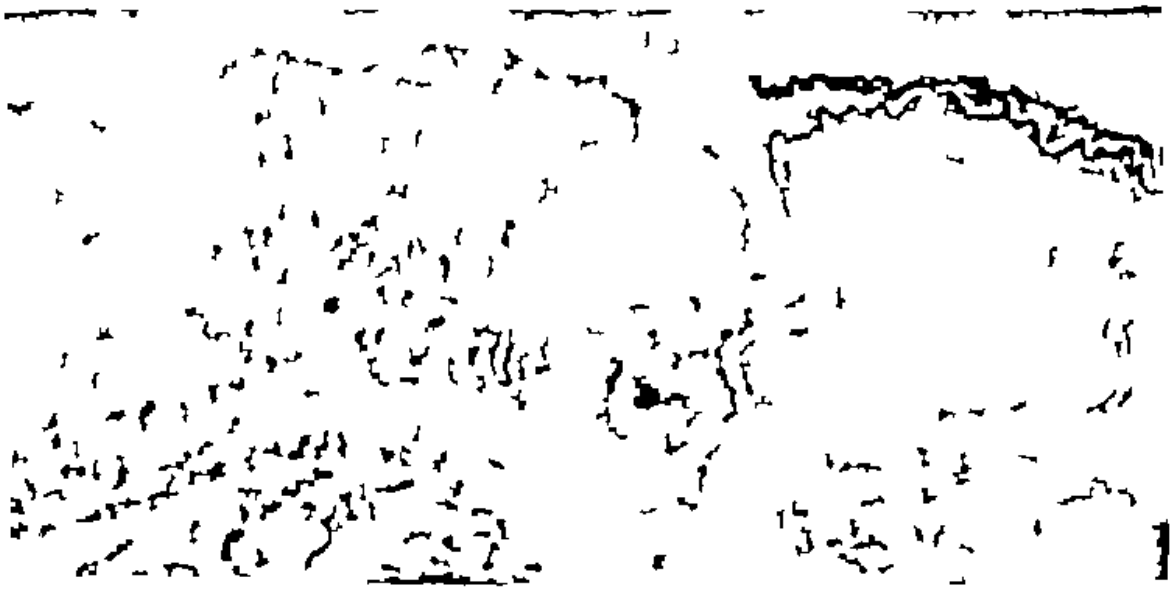

Fig. 18. Microautoradiogram of the stomach wall, at the junction between the forestomach (to the right) and the fundic gland area (to the left) 1 hour after an intravenous injection of H 5-HTP into a mouse. Labelled mast cells are seen in the submucosa In the fundic mucosa labelled cells can be observed both, at the base and more superficially Htx-eosin. (×60)

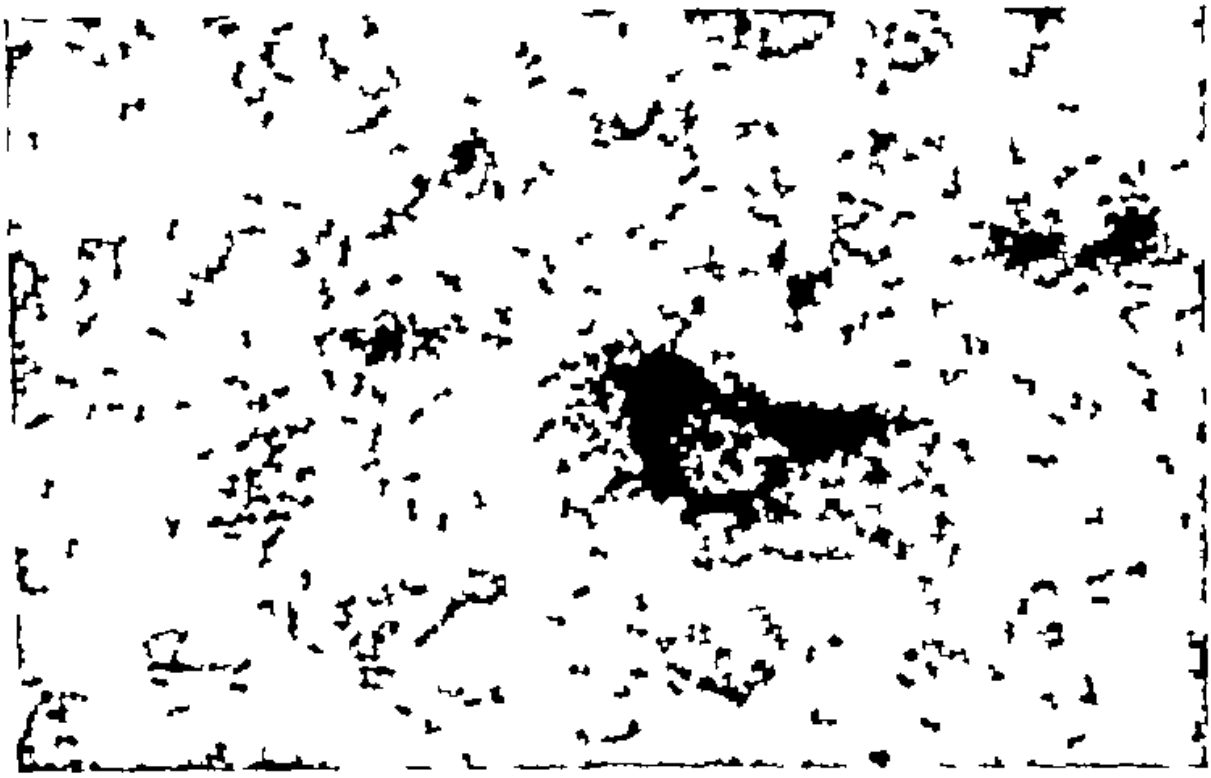

Fig. 19 Microautoradiogram from the fundic part of the stomach wall 1 hour after an intravenous injection of ^{3}H DOPA into mouse. A strong accumulation of silver grains is seen in the cytoplasm of a wedge-shaped cell of enterochromaffin type. Toluidine blue. (×920)

not possible on sections covered with stripping film. Obviously the stripping film abolished the colour reaction.

In the mucosa of the pyloric gland area the activity was high 5 minutes after the injection with the same activity in gastric pits as in pyloric glands. In addition there were some, often wedge-shaped, cells with a basal location which had a very high activity (Fig. 17)

One hour after the injection the activity was low in the forestomach, in gastric pits in the fundic and the pyloric gland area and in fundic and pyloric glands. Intensively labelled cells could, however be seen scattered in the fundic mucosa both basally and more superficially (Fig. 18) The more superficially located cells were considerably smaller than the basally located cells, which often showed a wedge-shaped appearance (Fig. 19) In the pyloric gland area highly labelled often wedge shaped cells with a basal location could be seen.

In the submucosa of the stomach scattered mast cells also contained a high activity

The picture seen 24 hours after the injection was similar to the one described after one hour (Fig 20)

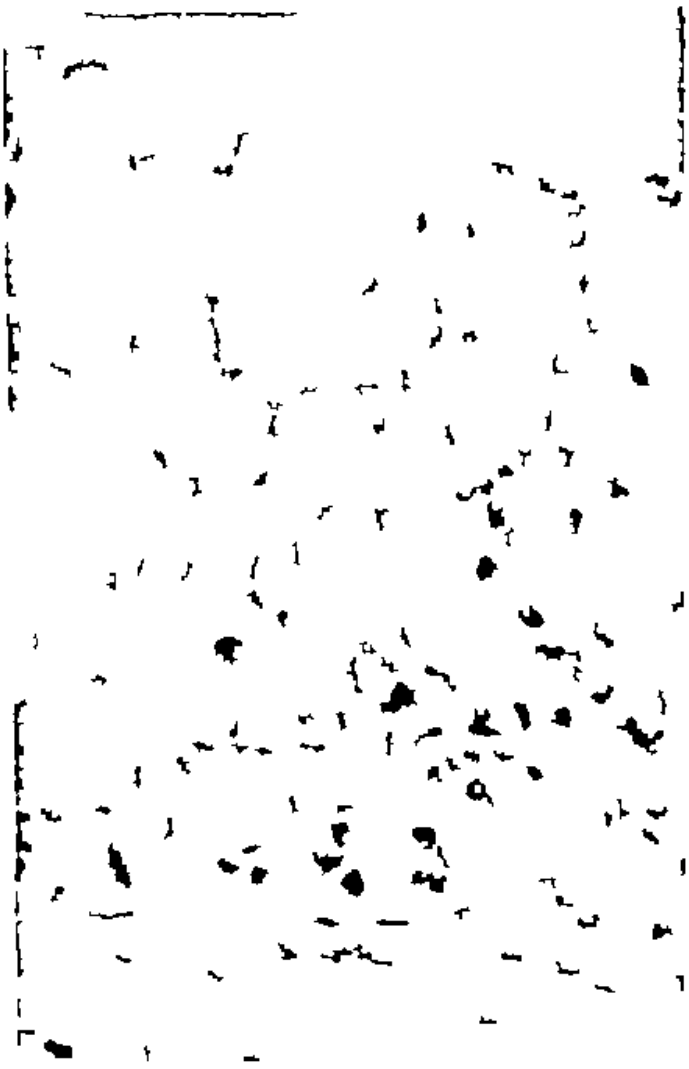

Fig. 20. Microautoradiogram of the stomach wall, fundic gland area, 24 hours after an intravenous injection of H 5-HTP into mouse. Strongly labelled cells can still be seen in the mucosa and the submucosa. Hx-eosin. (×160)

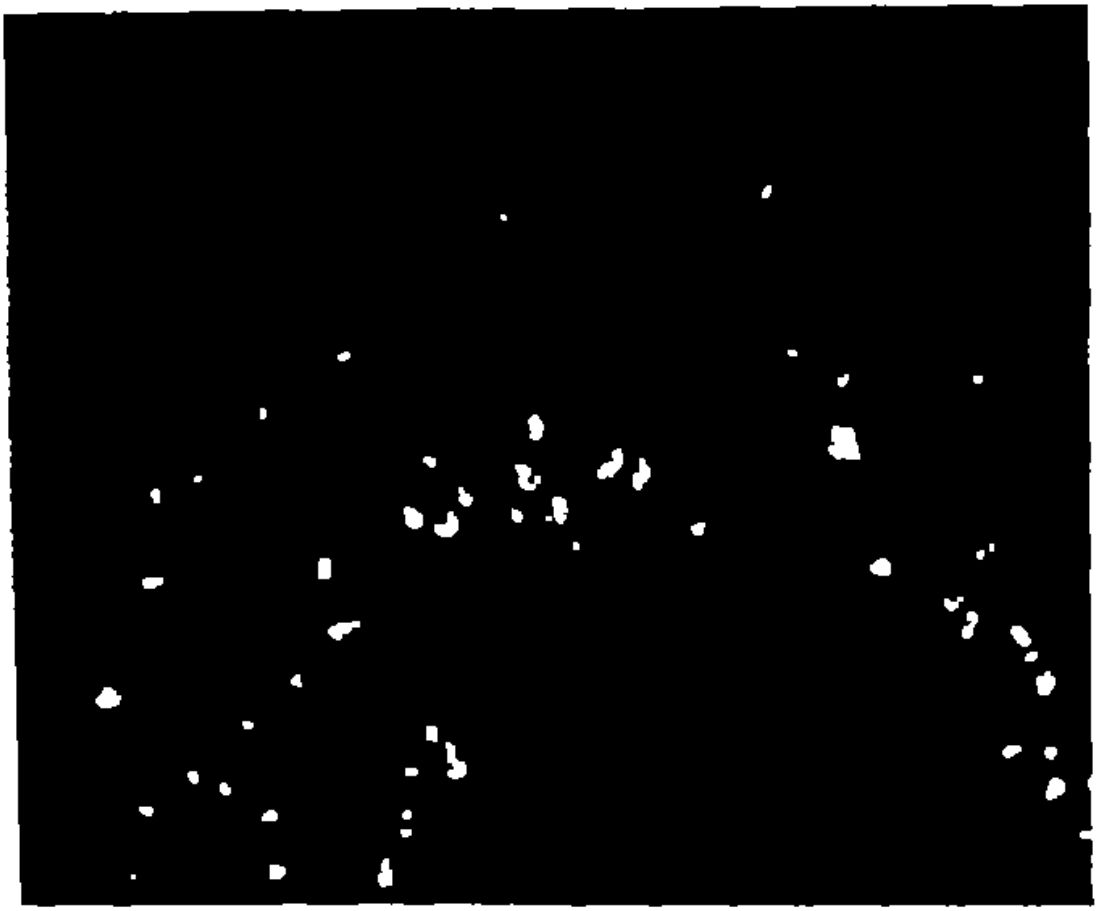
In comparison with the cells in the pancreatic islets and the parafollicular cells, the cells in gastric mucosa were more heavily labelled at all the studied time intervals.



Combined microaut radiography—fluorescence microscopy

The combination was performed on pieces from the fundic gland area.

The highest fluorescence and radioactivity could be observed in cells with a basal location in the fundic glands. The correspondence between highly fluorescent and highly labelled cells was good (Fig. 21). Also in singular small cells located more superficially in the mucosa the correspondence between fluorescence and activity was good.

Fig. 21 b. Microautoradiogram of the same section obtained through the parallel injection of ^{3}H 5-HTP. Hx-eosin. Fluorescing cells and radioactively labelled cells correspond well both in the basal and superficial parts of ×1 0

Discussion

The cells with endogenous fluorescence which have been described in the pyloric gland area belong to the system of enterochromaffin cells with endogenous 5-HT storage in the gastrointestinal tract. The fluorescing cells in the fundic mucosa probably represent a type of mast cells. These cells, which have been found in mice and some other species (see Håkanson 1970) show characteristics which differ them from other mast cells they are smaller than other mast cells in the dog and the rat they have been found not to be degranulated by compound 48/80 (Enerbäck 1966, Aures *et al.* 1968) They also show a weaker and more inconstant metachromasia after toluidine blue staining than other mast cells (Enerback 1966) The inability observed in the present investigation to stain all cells with endogenous fluorescence in the fundic gland area metachromatically with toluidine blue is probably due to this variance in staining properties.

In the present investigation these cells were shown to be very numerous in the fundic gland area, adjacent to the forestomach, especially along the greater curvature. Noteworthy is the band of cells in the mucosa adjacent to the ridge separating the fundic gland area from the forestomach. In the rat a band of argentaffin cells with the corresponding localization has been observed (Gregg 1966) It has not been established whether these cells are mast cells, but the mast cells in the submucosa of the rat have been shown to be stained by argentaffin techniques (Soule and Gregg 1965)

In the microautoradiographic investigation cells with a localization corresponding to both the enterochromaffin cells in the pyloric gland area and the mast cells in the fundic gland area, could be observed. It seems therefore probable that both these endogenously fluorescing cells are capable of monoamine formation after the precursor injections.

In addition to these cells strongly labelled cells were seen basally in the fundic mucosa. These cells have been studied with fluorescence methods (Håkanson *et al* 1967 a, see also Håkanson 1970) They have been termed enterochromaffin like cells by these authors. In the mouse and the rat they have been shown to contain histamine. The substance produced by them has been proposed to be the gastric antipernicious principle (the intrinsic factor) (Håkanson *et al* 1969 a, 1970 b)

The combination of microautoradiography and fluorescence microscopy in the fundic gland area also show that the fluorescence and the radioactivity obtained after the precursor injections are in agreement both in the basally located cells, probably corresponding to the enterochromaffin-like cells and in the more superficially located cells, probably representing mast cells.

The monoaminergic mechanisms in these cells seem to be similar to the

cells in pancreatic islets and the parafollicular cells the accumulation of activity appears rapidly in the enterochromaffin-like cells decarboxylase inhibition reduces and MAO inhibition prolongs the fluorescence (Håkanson *et al.* 1967 a) These principal mechanisms have been discussed in Chapter 1

CHAPTER 4

Electron microscope autoradiography of the mouse fundic mucosa after the injection of tritiated L-DOPA

In the electron microscope the cells of the enterochromaffin cell system show several characteristics common to endocrine cells. One of the characteristics is the specific granules present in the cytoplasm of the cells. Several types of enterochromaffin cells with different granules have been described lately (e.g. Forssmann *et al.* 1969 Vassallo *et al.* 1969 Capella *et al.* 1969) The different parts of the gastrointestinal tract have also in these studies been shown to contain more than one of the enterochromaffin cell types.

The fact that these cells have ultrastructural characteristics common to endocrine cells, together with their monoamine storing capability have led to the mentioned assumptions that the cells of the enterochromaffin type might be endocrine cells producing the gastrointestinal hormones.

For the study of the enterochromaffin cell system in the light microscope, silver impregnation methods have been extensively used. These methods are based on the ability of the cells to reduce ammoniacalic silver salts. It has been proposed that 5-HT is the reducing agent in the cells (Erspamer and Asero 1952) Several silver impregnation methods exist (see Pearse 1960) Differences in staining properties by these techniques have led to assumptions that the cells might belong to several different categories (see Håkanson 1970) It is, however impossible to correlate the different cell types seen in the electron microscope with the cells identified in the light microscope by the silver impregnation methods. When the uptake of the monoamine precursors is studied with microautoradiography or fluorescence microscopy as hitherto has been the case it is impossible to say which of the cell types seen in the electron microscope are capable of the precursor accumulation. In the present investigation therefore an attempt is made, by means of electron microscope autoradiography to establish in which cells a monoamine accumulation takes place after the injection of DOPA.

The fundic gland area of the mouse stomach has been chosen for the present investigation. This area contains cells with the monoamine precursor accumulating capability (see Chapter 3)

Material and methods

Two male albino mice (NMRI-strain) weighing about 20 g were injected through a tail vein with 1.5 mCi ring ? 5-6- H labelled L-3(3 4-dihydroxy phenyl-alanine (H DOPA) spec. act. 28 Ci/mM (The Radiochemical Centre, Amersham, England) The dose corresponded to 0.54 mg L-DOPA/kg body weight.

The mice were sacrificed two hours after the injection by cervical dislocation and small pieces of the stomach, from the part of the fundic gland area shown to contain only few cells with endogenous fluorescence (see Chapter 3) were rapidly removed and immersed in a cold solution of 2.5 % glutaraldehyde in a Tyrode medium, pH 7 4 After 2 hours of fixation the glutaraldehyde fi ed specimens were rinsed briefly in Tyrodes solution and transferred to a cold isotonic solution of osmiumtetroxide buffered to pH 7 4 for an additional fixa tion period of 2 hours. After dehydration in ethanol the tissue pieces were embedded in Epon.

The procedure for electron microscopic autoradiography was in principle the same as described by Maunsbach (1966) 400—600 A thick sections were cut on a LKB Ultrotome. The sections were picked up on Formvar-coated molybdenium grids (Ernest F Fullam, Inc. Schenectady U.S.A.) Ilford L 4 emulsion was applied to the grids by means of a wireloop. During the exposure time of 8 weeks the grids were stored in a refrigator at +4° C. The prepara tions were developed for 1 minute in Kodak D 19 and fixed for 4 minutes in Kodak Rapid Fix.

The specimens were studied in a Siemens Elmskop I at an accelerating voltage of 80 kV with the double condensor and a 50 μ objective aperture. Micrographs were taken at magnifications ranging from bout 5.000 to 10 000 times.

Controls

Control sections from the fundic mucosa of 2 mice not injected with ^{3}H DOPA were taken and handled for autoradiography the same way as described for the H DOPA injected animals.

Results

On the electron microscope autoradiographs a strong accumulation of sil r grains could be seen over cells of enterochromaffin type which on basis of the different appearance of the granules, could be said to be of t least two dif ferent types. Silver grains over zymogen cells or over parietal cells were few

and seemed to be without any preferential localization. The first enterochromaffin cell type (Fig 22 23 and 26) over which an accumulation of silver grains could be seen contained granules of an almost uniformly round shape. The granules had a homogenous appearance with a rather high electron opacity The diametre varied from 150 to 250 mμ The observed cells of this type had a basal localization in the epithelium of the deeper parts of the gastric glands without any contact with the gland lumen. Within the cells the granules were localized especially in the basal region. The distribution of silver grains showed a good concurrence with the distribution of the granules. Silver grains with localization other than over the specific granules were few

The second enterochromaffin cell type (Fig 24 25 and 27) over which an accumulation of sil ver grains could be seen, had granules of a completely dif ferent appearance. Some of them were small (about 150 mμ) containing a round or irregular osmophilic body surrounded by a clear space. Other granules were considerably larger (300—600 mμ) and seemed to lack content or contained only a small osmophilic body These cells also had a basal location, mostly in the deeper parts of the gastric glands, and appeared to lack con tact with the gland lumen. The sil ver grains in these cells were seen in association with the granules, and then in association with both types of granules.

Other cells of enterochromaffin type, labelled or non-labelled than the two described could not be observed.

Specific accumulation of silver grains over special cells or cell-structures could not be seen in any of the sections from the control mice.

Discussion

The present study clearly demonstrates a very selective localization of th label in cells of enterochromaffin type Signs of diffusion or displacement of the activity have not been observed. The same selective localization of th label in cells of this type has also been observed in light microscope in vestigations (see Chapter 3) Gershon and Ross (1966 b) demonstrated that 5-HT which is formed in tissues after the injection of 5-HTP is very firmly bound to the tissues while this is not the case for the 5-HTP or the 5-HT metabolites. It has also been shown that the binding of amines in tissues exists after the applica-

Fig. 22. Electron microscopic toradiogr ph of an enterochromaffin cell of the first described type lying on the basement membrane (bm) of fundic gland of the stomach of mouse. The mouse was injected intr enously with 11 DOPA 2 hours before it was killed. Silver grains are seen predominantly over the round dense granules in the cytoplasm. Zymogen granules (zg) and endoplasmatic reticulum (er) of adjacent chief cells (×15.000)

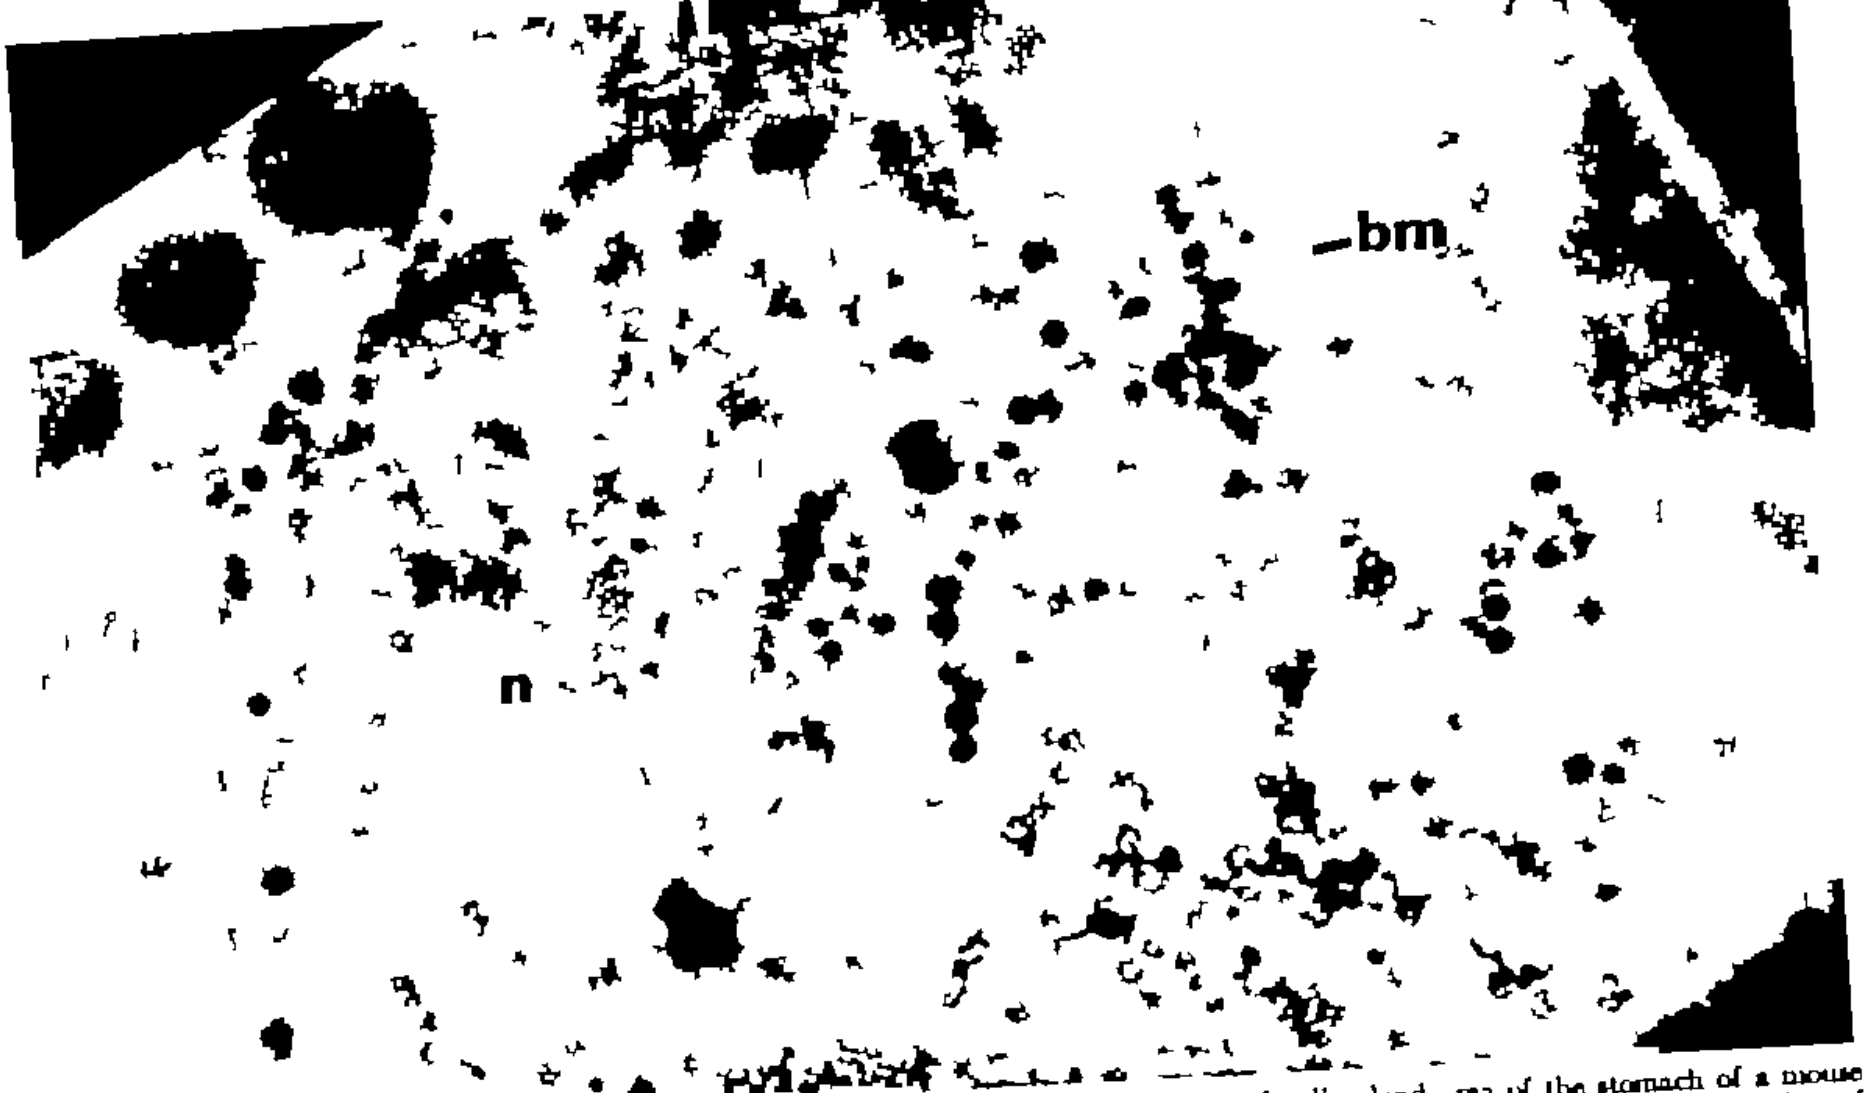

Fig. 23. Electron microscopic autoradiograph of a cell of enterochromaffin type from the fundic gland area of the stomach of a mouse 2 hours after an intravenous injection of H-DOPA. The enterochromaffin cell is of the same type as in Fig. 22. The distribution of the specific granules and the silver grains correspond well. The nucleus (n) shows a narrow chromatin border. Basement membrane (bm); zymogen granule (zg). (×16,000)

tion of chemical fixatives, and that the combination of glutaraldehyde and OsO_4 in such a case is the most effective fixative (Gershon and Ross 1966 b, Hökfelt and Jonsson 1968)

As mentioned in Chapter 3 it has also been shown that the products obtained in the enterochromaffin cell types after the injection of the monoamine precursors are the primary amines (see Håkanson 1970)

The application of an electron microscopic technique, as has been the case in the present investigation, requires a binding to the tissues of the amines which are formed after the injection of their precursors. Such a binding thus occurs, either directly *in vivo* or in connection with the chemical fixation. In an earlier electron microscope autoradiographic investigation the localization of 5-HT in the parafollicular cells after the injection of 5-HTP into mice has been studied in a similar way (Ericson 1970)

In the present investigation a monoamine accumulation after injection of DOPA has been observed in two enterochromaffin cell types with completely different granules in the fundic mucosa of the mouse.

One of these cell types has round granules with a homogenous appearance and a rather high electron opacity These cells have a resemblance to cells described by Helander (1961 1967) in the fundic mucosa of the mouse, and called argyrophil cells by him. Forssmann *et al.* (1969) describe a similar cell in the rat fundic mucosa and call them intestinal A cells. In both these investigations the similarities between these cells and the α-cells of the pancreatic islets are pointed out. This cell type might also be identical with the cholinesterase-rich cell type described by Carvalheira *et al.* (1968) Similar cells have also been described in the stomach of the dog, cat, guinea-pig, rabbit and in man (Solcia and Sampietro 1965 Forssmann *et al.* 1968, Orci *et al.* 1968 Vassallo *et al* 1969 Capella *et al* 1969) Forssmann *et al* (1969) describe besides the A-cells another cell type in the rat fundic mucosa with a very similar morphology called D-cells, which might correspond to the D-cells of the pancreatic islets. This cell has, however not been described in the mouse and the morphological differences between the granules of these two cell types are too small to be observed in the present investigation.

The second cell type over which silver grains could be observed had very characteristic granules. They were partly small containing a round or irregular osmophilic body partly big without or with only a small osmophilic body Similar cells have earlier been described in the fundic mucosa of the rat (Forssmann *et al* 1969) rabbit (Capella *et al* 1969) and cat (Vassallo *et al* 1969) This cell type shows similarities with cells in the sympathetic trunk (Siegrist *et al* 1966) They have by some authors been called enterochromaffin-like cells (Vassallo *et al.* 1969 Capella *et al.* 1969) It has been pointed out by

ch
p
ch
n

these authors that the cells at least to some extent might correspond to the cells which by Håkanson *et al.* (1967 a) have been called enterochromaffin like cells.

As mentioned in the results other enterochromaffin cell types besides the two which have been described, could not be found in the fundic mucosa of the mouse in the present investigation. There was, however an accumulation of silver grains over both cell types found. The classical enterochromaffin cell with endogenous 5-HT content, is lacking almost totally in big parts of the fundic mucosa of the mouse (see Chapter 3)

It is not definitively proven whether these cells are also capable of monoamine precursor accumulation, but the localization of the cells accumulating the precursors in the pyloric gland area in the microautoradiographic investigation in Chapter 3 was similar to the localization of the enterochromaffin cells with endogenous fluorescence. Perhaps all the cells of enterochromaffin type possess this capability

Several other cells with endocrine functions, such as the different cells of th islets of Langerhans in the pancreas and the parafollicular cells of the thyroid have, as mentioned, the same capability Each of these cell types has distinctive electron-microscopic features, and is the producer of a specific polypeptide hormone. It seems therefore natural that each of the different enterochromaffin cell-types in the gastrointestinal tract might have a specific product, which then might be of polypeptide hormone nature. As has been suggested (see Aures *et al.* 1970) th polypeptide hormones produced in these cells might be the different gastrointestinal hormones as for example gastrin, secretin and pancreozymin-cholecystokinin. The presence of gastrin in cells of enterochromaffin type in the pyloric gland area of man and pig has actually been demonstrated with an immunofluorescent technique (Mc Guigan 1968) These results have been confirmed in a recent work (Bussolati and Pearse 1970)

As at least two enterochromaffin cell types exist in the mouse fundic mucosa it seems probable that these cells ha ve at least tv o different products.

The first cell type described in this work might be the producer of the intestinal glucagon (Unger *et al* 1966) which, considering the similarities with the α-cells of the pancreatic islets, has been proposed to be the function of the corresponding cell in the rat (Forssmann *et al* 1969) It has been surmised that the gastric antipernicious principle (the intrinsic factor) might be produced by the so called enterochromaffin-like cells in the mouse, rat, hamster

Fig. 4 Electron microscopic autoradiograph showing tw enterochromaffin cells of the second described type in the fundic mucosa of the stomach, two hours after an intravenous injection of H-DOPA into mouse. and guinea-pig (see Håkanson *et al.* 1970 b). This might then take place in the second cell type which has been described in the present investigation. This cell, like the other described cell type has however not been observed to have any contact with the gland lumen in the present investigation or in most earlier investigations, where the corresponding cells have been observed (Helander 1962, Forssmann *et al.* 1969, Vassallo *et al.* 1969, Capella *et al.* 1969). From the morphological point of view it therefore does not seem probable that the products of these cells are secreted into the gland lumen. Håkanson and Owman (1967) have also shown that histamine is present in most, but not all of the enterochromaffin-like cells in the mouse and the rat. This can be ex-

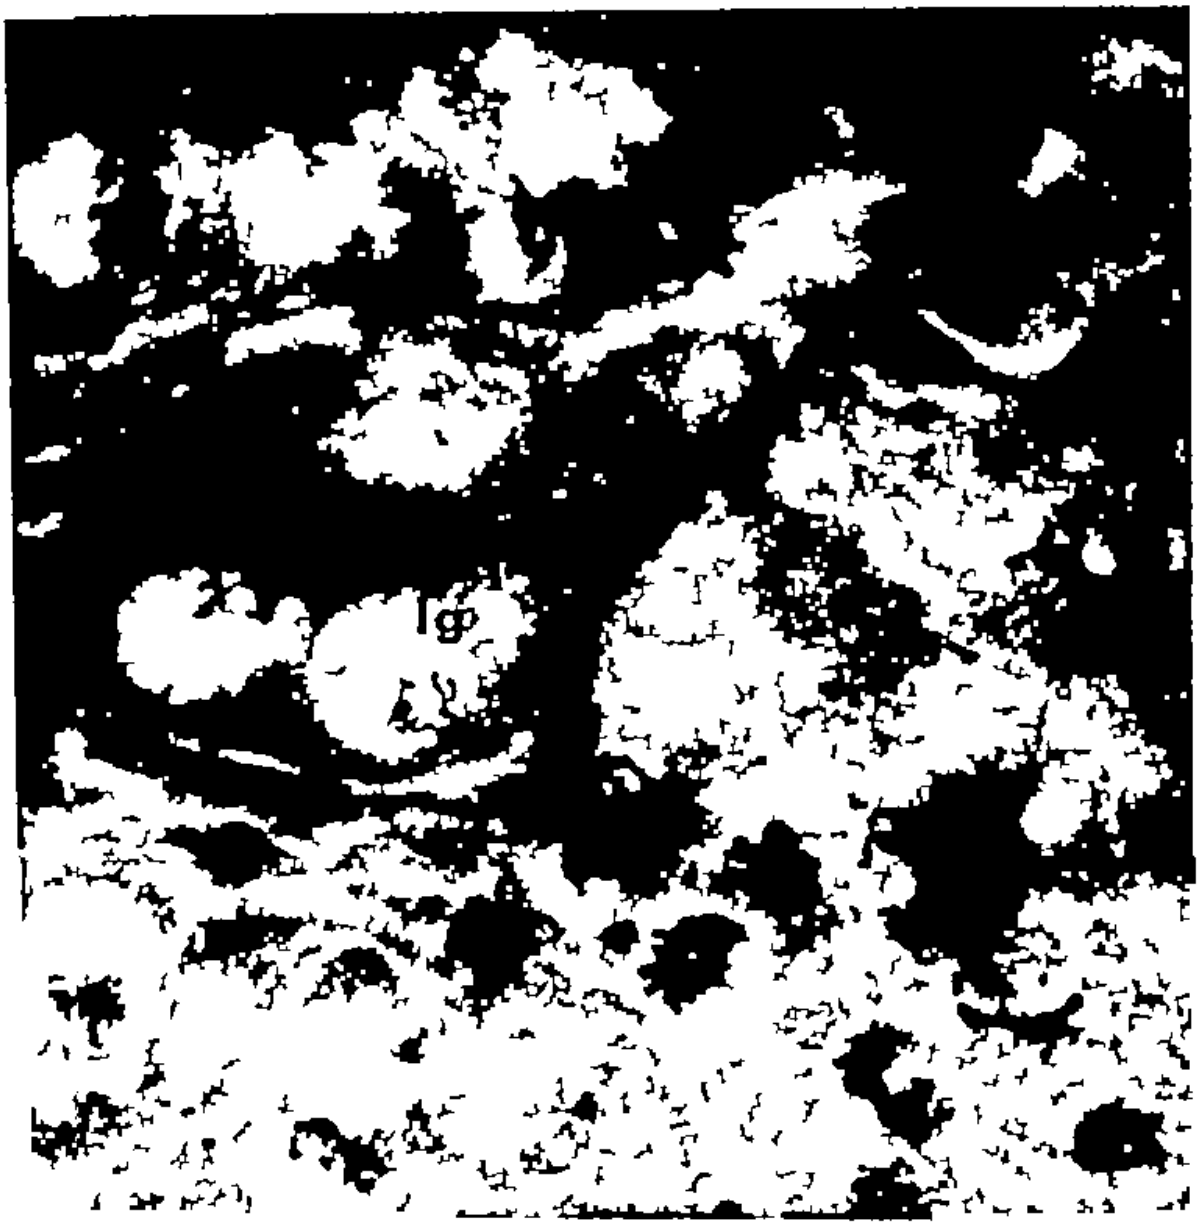

Fig. 27 Electron microscopic autoradiograph showing a detail of th second enterochromaffin cell type. The silver grains can be seen in association with both types of granules. Small granules (sg) large granules (lg) (×47.000)

plained by the presence of histamine in one of the two enterochromaffin cell types observed in the present work, but not in the other

Beside the fact that there are two different enterochromaffin cell types in the fundic mucosa of the mouse capable of monoamine formation from injected DOPA, it is also apparent from th present investigation that the monoamines are localized predominantly to the specific granules of the cells. A localization of 5-HT in the specific granules in the parafollicular cells of the thyroid has

recently been demonstrated in an electron microscope autoradiographic investigation where 5-HTP was injected into mice (Ericson 1970)

In some species 5-HT or dopamine is present endogenously in the pancreatic islets and the parafollicular cells. Such an endogenous monoamine storage has also been demonstrated with a cytochemical electron microscope method to be in accordance with the specific granules in one investigation on guinea-pig pancreatic islets (Jaim-Etcheverry and Zieher 1968 a) and in one investigation on sheep parafollicular cells (Jaim-Etcheverry and Zieher 1968 b) The specific granules of the endocrine cells are considered to be the storage sites for the hormones produced in the cells. If then the enterochromaffin cells are the producers of polypeptides, it is probable that these products are also stored in the specific granules of the cells. The possible participation of the monoamines in the synthesis, or release of the substances produced in the cells, is underlined by the common localization in the same granules. For the different enterochromaffin cell types, however such a function remains to be proved.

The effect of monoamines in the release of insulin is discussed in Chapter 8.

CHAPTER 5

Distribution of DOPA 1 ^{14}C (carboxyl ^{14}C-labelled DOPA) in relation to DOPA 2 ^{14}C in mice before and after inhibition of DOPA-decarboxylase, studied by whole body autoradiography

If amino acids are injected into animals, the highest uptake takes place in organs with a rapid protein synthesis such as the pancreas, the gastrointestinal mucosa, the bone marrow and the lymphatic tissues (see Hansson 1959) The uptake of DOPA by various organs seems to be similar to that of other aromatic amino acids (Guroff and Udenfriend 1962) After the injection of DOPA an initial accumulation also occurs in organs characterized by a rapid protein synthesis (Rosell *et al* 1963) The DOPA, however rapidly leaves the protein forming organs indicating that it is not incorporated into the proteins (Rosell *et al.* 1963)

In addition it is generally accepted that DOPA constitutes a precursor in the biosynthesis of catecholamines (see Blaschko 1959) Such a catecholamine formation also occurs in various organs after injection of DOPA (e g Gey and Pletscher 1964) The first step is the decarboxylation of DOPA via the action of aromatic L-amino acid decarboxylase.

If the uptake of DOPA and/or the catecholamines formed from DOPA is studied by autoradiographical methods, it must therefore be taken into account that the activity observed can either represent the DOPA itself or the formed catecholamines. A third alternative is that the activity can be due to formed metabolites of DOPA or catecholamines.

In the present investigation a whole-body autoradiographic study has been performed in mice using ^{14}C-DOPA labelled either in the carboxyl-group (C-1-group) or in the C-2-group (Fig 28) On the autoradiograms obtained from mice injected with carboxyl labelled DOPA, the catecholamines and the catecholamine metabolites are not visualized since the labelled carboxyl group is split off by the decarboxylation. The so formed $^{14}CO_2$ is then to the greatest extent exhaled (see Hansson *et al.* 1964) In mice injected with DOPA labelled in the C-^{2}-group the amino acid as well as the formed catecholamines and the metabolites are visible. This investigation has been performed on untreated mice and on mice pre treated with the DOPA-decarboxylase inhibitor Ro 4-1602 (Roche)

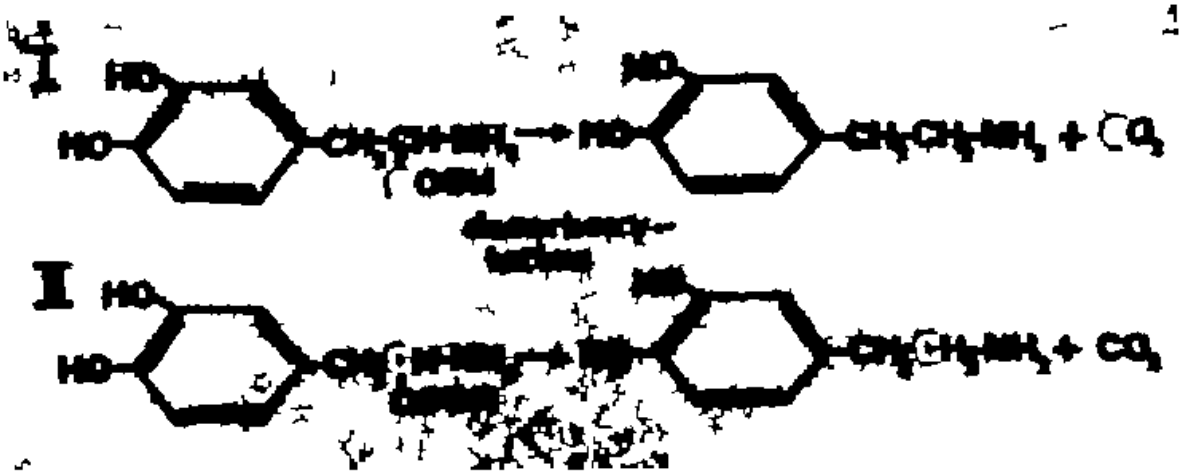

Fig. 28. When the carboxyl-labelled DOPA is decarboxylated the so formed catechol amines become non-labelled and therefore invisible in the autoradiograms (reaction I). When the DOPA labelled in the C-2-group is decarboxylated, the so formed catechol-amines become labelled and can therefore be seen in the autoradiograms (reaction II). The CO_2 formed in the reactions is exhaled. The white letters indicate the site of labelling.

Material and methods

The labelled substances DL-3(3,4-dihydroxyphenyl) alanine-1-^{11}C (DOPA 1-^{11}C) spec. act. 12.5 mCi/mM and DL-3(3,4-dihydroxyphenyl)alanine-2-^{11}C, spec. act. 52 mCi/mM were obtained from The Radiochemical Centre, Amersham, England. The DOPA-decarboxylase inhibitor Ro 4-4602 (2,3,4-trihydroxybenzyl hydrazine) was obtained from Hoffman-La Roche, Switzerland. The substances were dissolved in physiological saline and 0.2 ml was injected into the mice. In the case of intravenous injection which was performed into a tail vein, the injection time was about 10 seconds.

White mice of the NMRI-strain were used as experimental animals. The weight of the mice was about 20 g.

Four series of mice were injected.

1. 6 male and 3 female mice were injected intravenously with 5 μCi DOPA 1-^{11}C corresponding to 4.0 mg/kg body weight. The male mice were sacrificed at 1 minute, 5 minutes, 30 minutes, 1 hour, 4 hours and 8 hours after the injection. The female mice were sacrificed at 30 minutes, 1 hour and 2 hours after the injection.

2. 6 male and 3 female mice were injected intravenously with 5 μCi DOPA 1-^{11}C, corresponding to 1.0 mg/kg body weight. The male mice were sacrificed at 1 minute, 5 minutes, 30 minutes, 1 hour, 4 hours and 8 hours after the injection. The female mice were sacrificed at 30 minutes, 1 hour and 2 hours after the injection.

3 2 male mice were injected intraperitoneally with Ro 4-4602, dose 200 mg/kg body weight. Thirty minutes later they were injected intravenously with 5 μ Ci DOPA 1 ^{1} C (4.0 mg/kg) and killed 5 minutes and 30 minutes after the second injection.

4 5 mice were injected intraperitoneally with Ro 4-4602 dose 200 mg/kg body weight. Thirty minutes later they were injected intravenously with 5 μ Ci DOPA 2 ^{14}C (1 0 mg/kg) and killed 5 minutes, 30 minutes, 1 hour 2 hours and 4 hours after the second injection. The mice killed 30 minutes and ? hours after the DOPA injection were females, the others were males.

After the survival periods stated above, the animals were anaesthetized with ether and then immersed into a mixture of hexane and solid CO_2 (-78 C) The mice killed after a survival period of 1 minute were killed by direct immersion in the hexane-CO_2 mixture. They were then embedded in a mixture of carboxymethyl cellulose and water Sagittal sections (20 μ) of the whole body were cut and dried at -15 C according to Ullberg s autoradiographic technique, by which each section is attached onto tape (No. 810 Minnesota Mining and Manufacturing Co) (Ullberg 1954 1958) The tape mounted sections were allowed to reach room temperature in an air tight box. Autoradiograms were made by apposition of the sections against x ray films (Structurix, Gevaert) During the exposure time of 2 weeks to 3 months, the sections were stored in a refrigerator at -15 C. After the exposure, the sections were separated from the films. The films were then developed in Gevaert G 230 and fixed in Gevaert G 305 A.

Results

The ^{14}C-DOPA was rapidly taken up from the blood by various tissues. The distribution pictures from the mice not pre treated with, and those pretreated with the DOPA-decarboxylase inhibitor will be described separately

DOPA injected into mice not pre-treated with the decarboxylase inhibitor Ro 4-4602 (series 1 and 2 und r Meth ds)

Adrenal. One minute after the injection, there was a strong accumulation of activity in the adrenal medulla of the DOPA 2 ^{4}C-injected animal. In the animal injected with DOPA 1 ^{4}C the activity was low and even considerably lower than in the adrenal cortex (Fig 29 and 30)

The high activity in the adrenal medulla could be observed at all survival periods in animals injected with DOPA ? ^{14}C. In animals injected with DOPA 1 ^{1} C, the acti ity was low during the observation period (see Fig 31) On some autoradiograms, however small spots with a slightly higher activity

Fig. 29 a. Autoradiogram of mouse 1 minute after an intravenous injection of DOPA-2 ^{14}C.

Fig. 29 b. Autoradiogram of mouse 1 minute after an intravenous injection of DOPA-1 ^{14}C. Note the high accumulation of radioactivity (light areas) in the adrenal medulla, liver and intestinal mucosa in the DOPA-2 ^{14}C-injected animal, but not present in the DOPA-1 ^{14}C-injected animal.

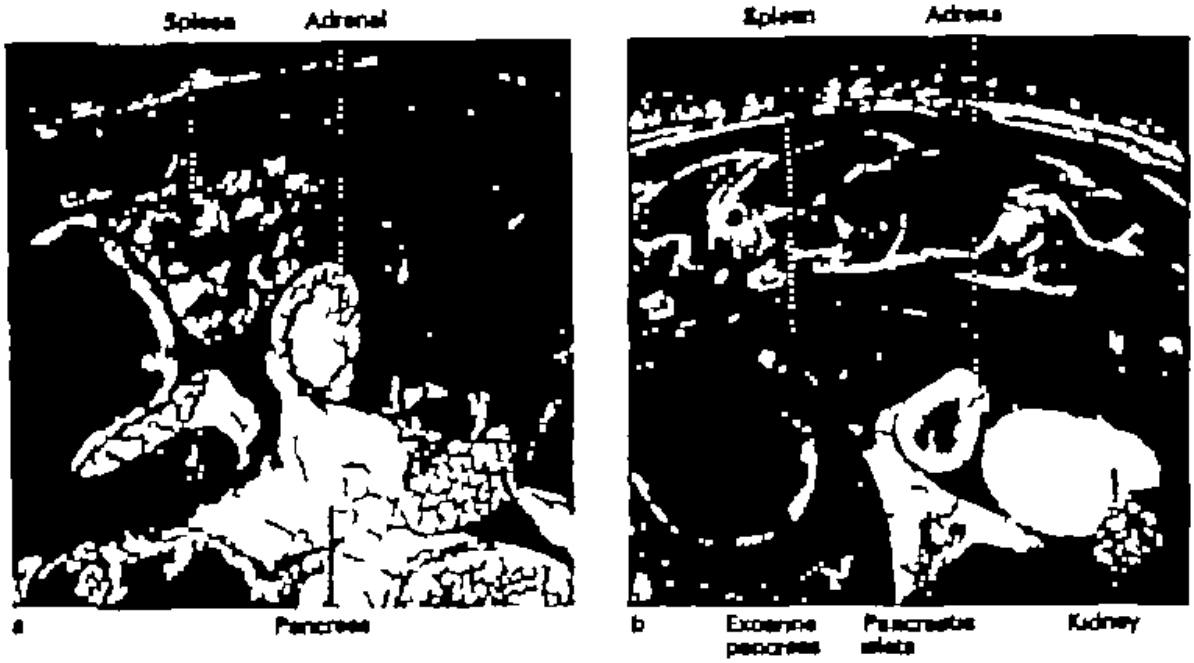

Fig. 30 a and b. Details of Fig. 29 a and b respectively. In the DOPA 2 ^{14}C-injected animal there is a high accumulation of radioactivity (light area) in the adrenal medulla (Fig. 30 a). In the DOPA-1 ^{14}C-injected animal there is no accumulation of radioactivity in the adrenal medulla (Fig. 30 b). In the exocrine pancreas there is a strong accumulation of radioactivity in both animals. In the animal injected with DOPA 1 ^{14}C there is no accumulation of radioactivity in the pancreatic islets.

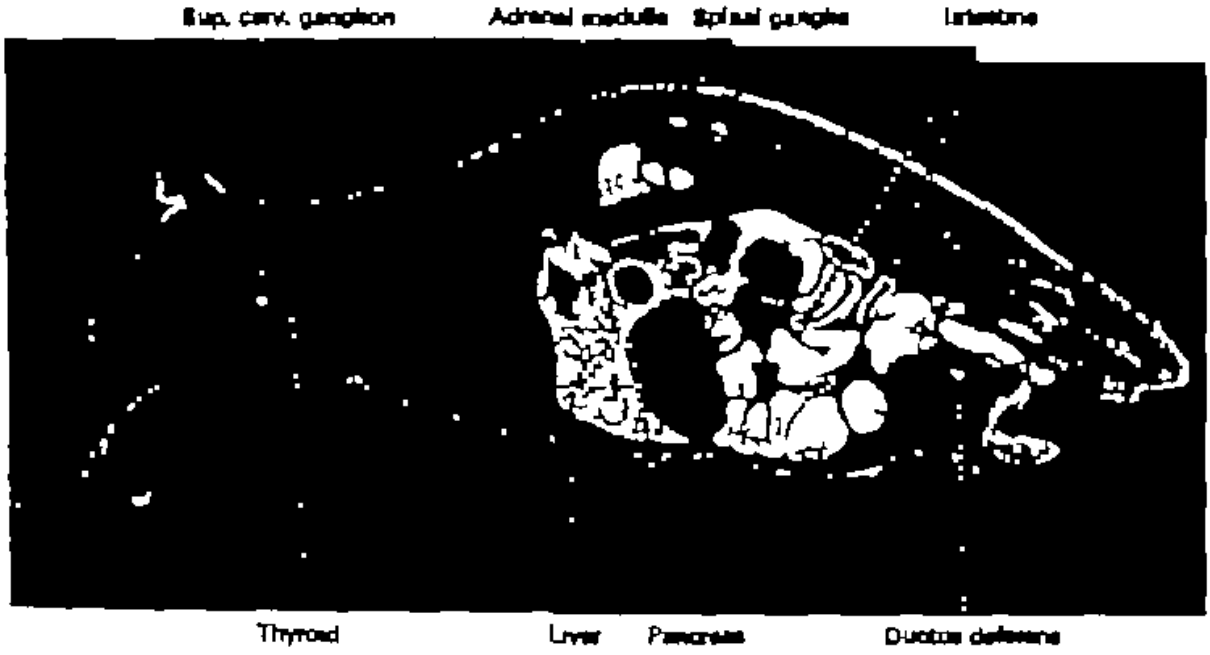
could be observed in the adrenal medulla in animals injected with DOPA 1 ^{14}C (Fig. 32). These spots were preferentially localized in the periphery of the medulla. In the adrenal cortex, the activity was relatively high shortly after the injection of both DOPA 2 ^{14}C and DOPA 1 ^{14}C. Then the activity diminished rapidly.

Thyroid. A persevering activity could be seen in the thyroid after the DOPA 2 ^{14}C-injections, while following the DOPA 1 ^{14}C-injections no activity could be observed in the thyroid, not even shortly after the injection.

Pancreatic islets. The same as for the thyroid applied to the pancreatic islets (see Fig. 30 b).

Exocrine pancreas. One minute after the injection, there was a strong accumulation of activity in the pancreas (Fig. 29). This could then be observed up to 4 hours after the injection of both DOPA 2 ^{14}C and DOPA 1 ^{14}C.



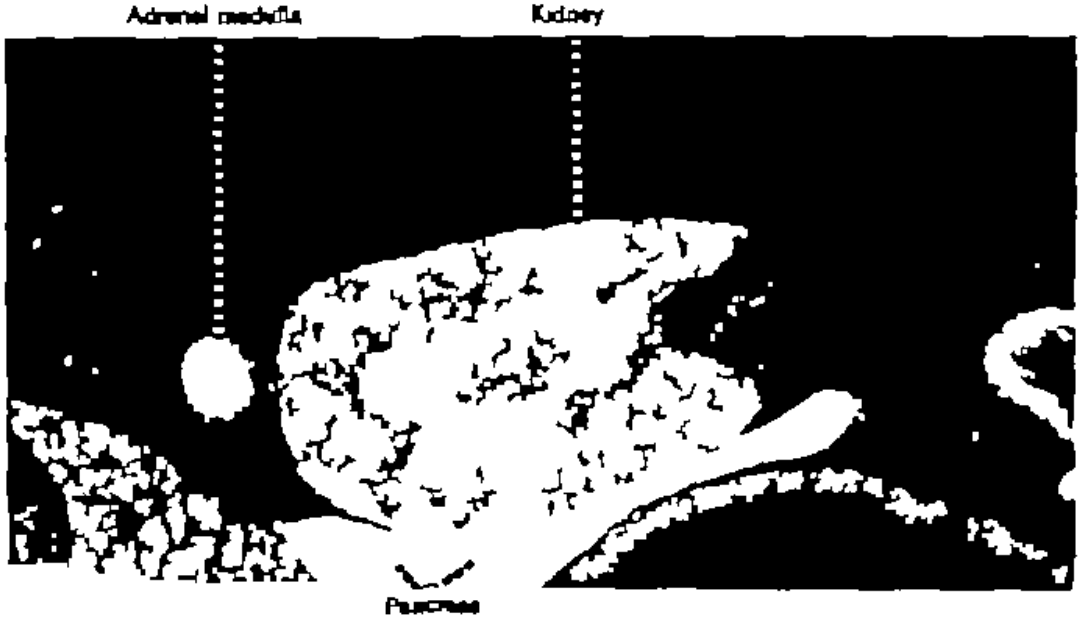


Fig. 31 a. Autoradiogram of a mouse 30 minutes after an intravenous injection of DOPA-2 ^{14}C.

Fig. 31 b. A toradiogram of mo er aft an intra enous injection of DOP V- 1-^{14}C. Note the high accu f uscular ity (light areas) in the adrenal med lla, liver and intestine in the D P\ 2 ^{14}C-injected animal, but not in the DOPA I ^{14}C-injected animal I the D(^{14}C-injected animal there is higher accumulation of radioactivity in sup er ganglion than in the spinal ganglia. In the DOPA I ^{14}C-injected animal there is some accumulation of radioacti y equal in the sup. cerv ganglion and in the spinal ganglia.

Liver The activity in the liver in the animal injected with DOPA 2 ^{1}C, was one minute after the injection almost as high as the activity in the blood. In the animal injected with DOPA 1 ^{14}C, the activity was considerably lower in the liver than in the blood at the one minute interval (Fig 29) Also at later time intervals the activity in the liver was higher in relation to the blood in animals injected with DOPA 2 ^{14}C than in animals injected with DOPA 1 ^{1}C (Fig 31)

Alimentary tract. As in the liver the intestinal mucosa and the mucosa of the glandular part of the stomach contained a higher activity in relation to the blood in the animal injected with DOPA $^{?}$ C than in the one injected with DOPA 1 ^{14}C, at the one minute interval (Fig 29)

Also longer lapses of time still produced the same situation, as has been described for the li er (Fig 31) The intestinal lumen contained a higher activity at longer survival periods after DOPA 2 ^{4}C-injections, than in animals injected with DOPA 1 ^{14}C

The mucous membranes of the mouth, the oesophagus and the forestomach contained a relatively high activity shortly after the injection of both DOPA 2 C and DOPA 1 ^{14}C. This activity then diminished rather quickly

The uptake of both DOPA $^{?}$ C and DOPA 1 ^{14}C in the salivary glands was high shortly after the injection and then diminished successively

Peripheral nervous system. An accumulation of activity could be seen in spinal and in sympathetic ganglia both after DOPA $^{?}$ ^{14}C- and DOPA 1 ^{14}C-injec tions (Fig. 31) In the DOPA 1 ^{14}C-injected animals the acti ity was about equal in the sympathetic and the spinal ganglia, while in the DOPA C-injected animals, the activity in the sympathetic ganglia was higher than in the spinal ganglia.

C ntral nervous system The injected DOPA passed the blood brain barrier slowly (see Fig 29 and 31) The slight acti ty which could be observed, as mainly localized in the grey matter The pictures seen after DOPA 2 ^{1}C- and DOPA 1 ^{14}C-injections were similar In the choroid plexus the activity was rather high both after DOPA C- and DOPA 1 ^{1} injections. The same applied to the hypophysis.

U genital rgans. The kidneys contained a high activity in animals injected both with DOPA 2 ^{4}C and DOPA 1 ^{1}C. High acti ty could also be seen in the urinary bladder

In the testicles the interstitial cells showed a moderate activity both after

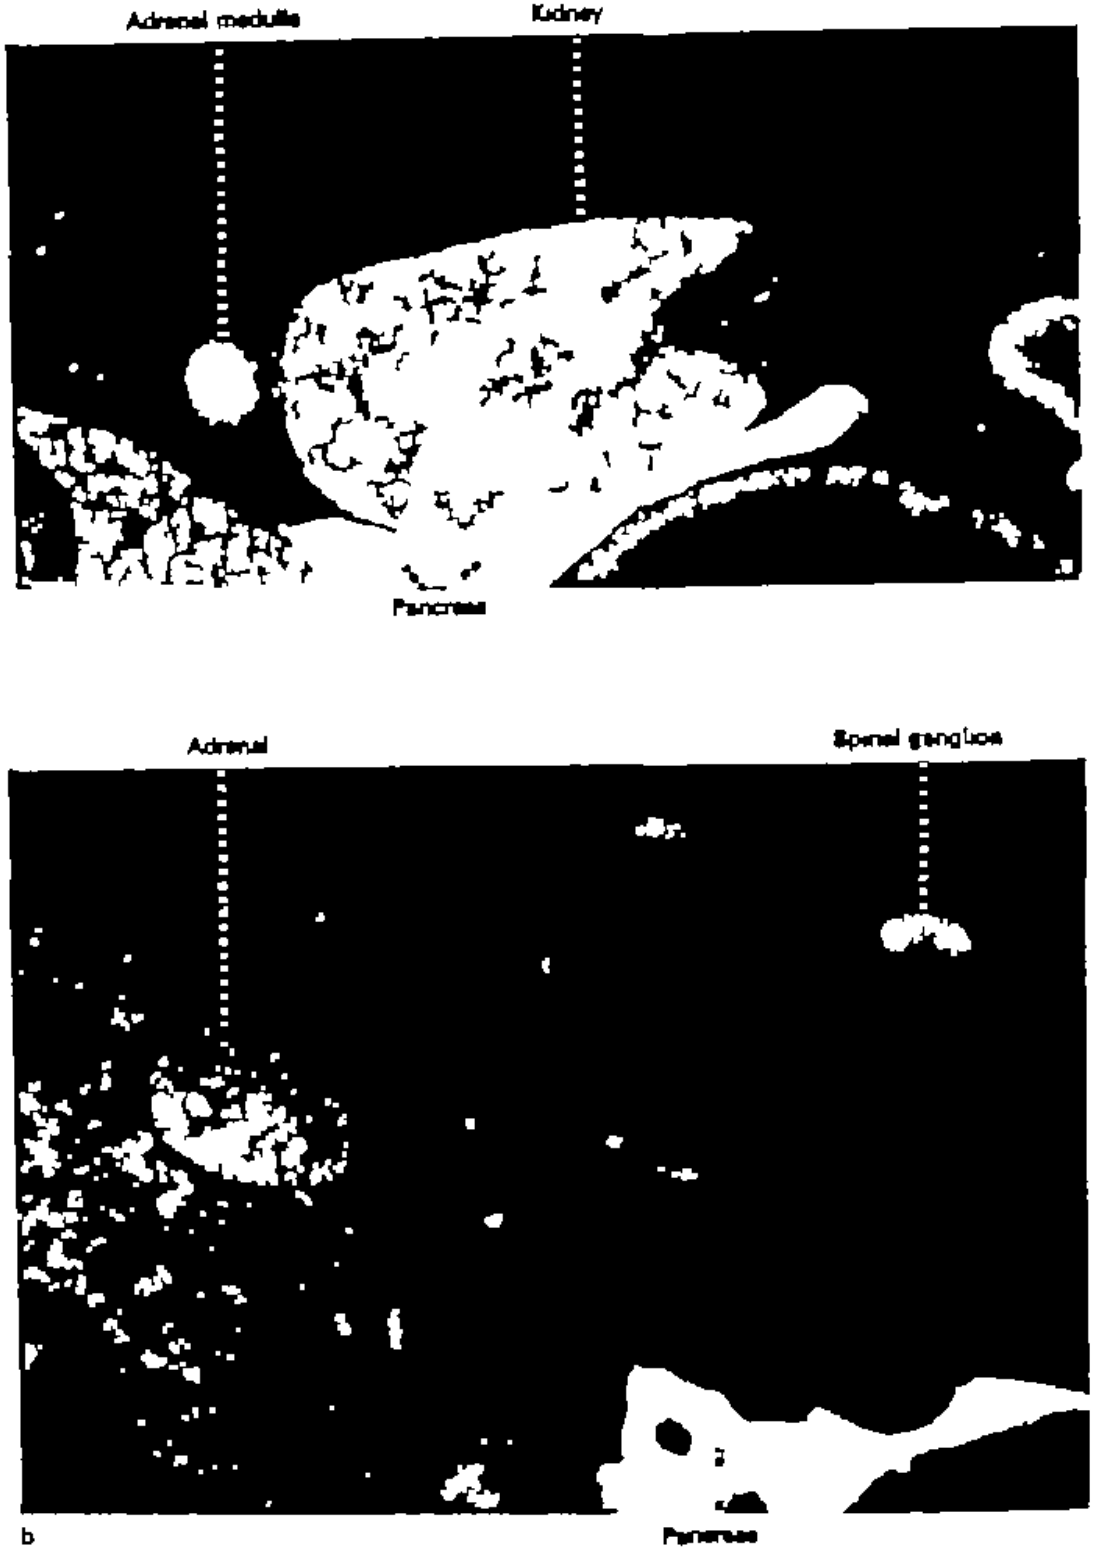

Fig. 32. Details of whole-body autoradiograms from mice 30 min tes after intravenous injections of) DOPA-2 ^{4}C and b) DOPA 1 C. In the DOPA C-injected animal there is strong accumulation of radioactivity (light area) in the adrenal medulla (Fig. 32) In the DOPA 1 ^{4}C-injected animal there are small spots in the periphery of the med lla which hav slightly higher activity than the rest of the medulla, where the activity is low (Fig. 32 b) The activity in these spots is about the same as in the spinal ganglion in the picture.

Liver The activity in the liver in the animal injected with DOPA 2 ^{14}C, was one minute after the injection almost as high as the activity in the blood. In the animal injected with DOPA 1 ^{14}C, the activity was considerably lower in the liver than in the blood at the one minute interval (Fig 29) Also at later time intervals the activity in the liver was higher in relation to the blood in animals injected with DOPA 2 ^{14}C, than in animals injected with DOPA 1 ^{14}C (Fig. 31)

Alimentary tract. As in the liver the intestinal mucosa and the mucosa of the glandular part of the stomach contained a higher activity in relation to the blood in the animal injected with DOPA 2 ^{14}C, than in the one injected with DOPA 1 ^{14}C, at the one minute interval (Fig 29)

Also longer lapses of time still produced the same situation, as has been described for the liver (Fig. 31) The intestinal lumen contained a higher activity at longer survival periods after DOPA 2 ^{14}C-injections, than in animals injected with DOPA 1 ^{14}C.

The mucous membranes of the mouth, the oesophagus and the forestomach contained a relatively high activity shortly after the injection of both DOPA 2 ^{14}C and DOPA 1 ^{14}C. This activity then diminished rather quickly

The uptake of both DOPA 2 ^{14}C and DOPA 1 ^{14}C in the salivary glands was high shortly after the injection and then diminished successively

Peripheral nervous system An accumulation of activity could be seen in spinal and in sympathetic ganglia both after DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections (Fig. 31) In the DOPA 1 ^{14}C-injected animals the activity was about equal in the sympathetic and the spinal ganglia, while in the DOPA 2 ^{14}C-injected animals, the activity in the sympathetic ganglia was higher than in the spinal ganglia.

Central nervous system. The injected DOPA passed the blood-brain barrier slowly (see Fig 29 and 31) The slight activity which could be observed, was mainly localized in the grey matter The pictures seen after DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections were similar In the choroid plexus the activity was rather high both after DOPA 2- ^{14}C- and DOPA 1 ^{14}C injections. The same applied to the hypophysis

Urogenital organs. The kidneys contained a high activity in animals injected both with DOPA 2 ^{14}C and DOPA 1 ^{14}C. High activity could also be seen in the urinary bladder

In the testicles the interstitial cells showed a moderate activity both after

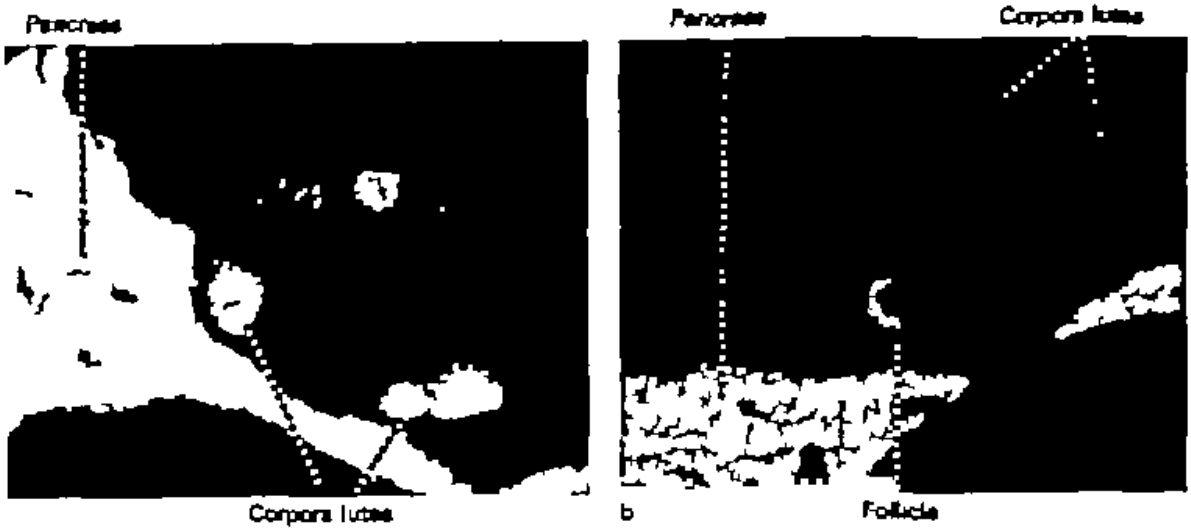

Fig. 33 Details of whol -body autoradiograms showing the accumulation of radioactivity in the ovaries of mice, a. 30 minutes and b. 2 hours after intravenous injections of DOPA 1 ^{14}C. Note the high accumulation of radioactivity (light areas) in the follicle walls and corpora lutea.

DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections, the activity being highest at the short survival periods. A part of caput epididymidis showed a high uptake of activity both after DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections. The activity persisted up to 4 hours after the injection. Ductus deferens accumulated a rather high activity after the injection of DOPA 2 ^{14}C. After the injection of DOPA 1 ^{14}C the activity there was low.

A relatively high uptake of activity could also be seen in the ovary especially in the follicle walls and corpora lutea (Fig. 33). This activity was seen up to 2 hours after the injection of both DOPA 2 ^{14}C and DOPA 1 ^{14}C. During this observation period there was also considerable activity in the oviduct and in the uterus.

Respiratory organs In the lungs, the activity was high both after DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections shortly after the injection. The activity then successively diminished. The nasal mucosa showed a rather high activity during the observation period after both DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections.

Circulatory organs There was a relatively high uptake of activity in the myocardium shortly after injection of both DOPA 2 ^{14}C and DOPA 1 ^{14}C. The activity then diminished rather rapidly.

The bone marrow initially accumulated a rather high activity both after DOPA 1 ^{14}C- and DOPA 2 ^{14}C-injections.

In the spleen the white pulp showed a rather high uptake shortly after the injection of either DOPA 2 ^{14}C or DOPA 1 ^{14}C (Fig 30) At short time intervals the red pulp contained a higher activity in relation to the white pulp in animals injected with DOPA 2 ^{14}C, than with DOPA 1 ^{14}C. At long time intervals the activity was low in the entire spleen both after DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections.

The thymus did not accumulate any appreciable amount of activity

Lens Initially there was no accumulation in the lens, but from 30 minutes up to 4 hours the activity was considerable. The activity was highest in the lens capsule and the pictures from DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injected animals were similar

Skin. There was a relatively high accumulation of activity in the connective tissue of the dermis, in the corneal layer and in hair follicles and hair The activity could be observed both after DOPA 2 ^{14}C- and DOPA 1 ^{14}C-injections. It appeared rapidly and persisted throughout the observation period.

Animals pre-treated with the decarboxylase inhibitor R 4-4602 (series 3 and 4 under Methods)

At the observed survival intervals the distribution pictures after the DOPA 1 ^{14}C-injections were similar to the pictures seen after the DOPA 2 ^{14}C-injections (see Fig 34 and 35) These pictures were similar to those obtained after injection of DOPA 1 ^{14}C into untreated animals.

The activity in the blood diminished rapidly after the injection.

The highest accumulation of activity could, during the whole observation period, be seen in the pancreas.

A high activity could also be seen in the kidney In the urinary bladder in part of the caput epididymidis and in follicle walls and corpora lutea of the ovary Also in the skin and the nasal mucosa the activity was rather high.

The salivary glands, the intestinal mucosa and the mucosa of the glandula part of the stomach accumulated a moderate activity From 30 minutes to 4 hours the activity in the lens, especially in the capsule, was rather high.

In the adrenal medulla there was low accumulation of activity up to 2 hours after the injection (Fig 35) However small spots with a slightly higher activity preferentially in the periphery of the medulla, could be observed Four hours after the injection of DOPA ^{14}C a high activity could be seen in the adrenal medulla (Fig 36)

In the thyroid and the pancreatic islets there was a low accumulation of activity

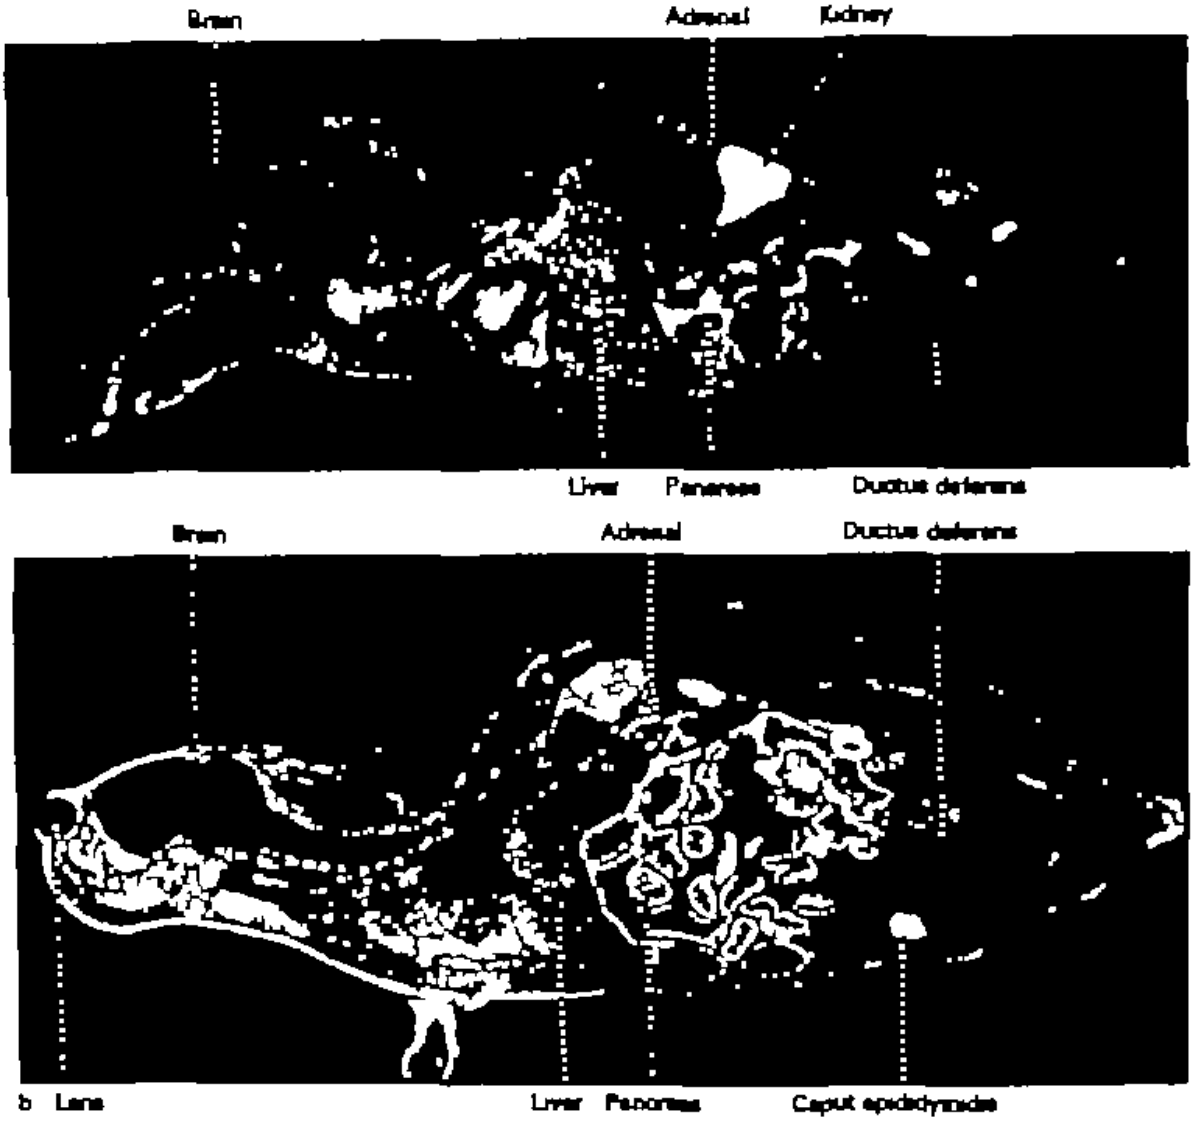

Fig. 34 a. Autoradiogram of mouse 5 minutes after an intra enous injection of DOPA 2 ^{14}C.

b. Autoradiogram of mouse 5 min tes after an intravenous injection of DOPA 1 ^{14}C. The animals have been pre-treated with th DOPA-decarboxylase Inhibitor Ro 4 4602. Th distribution pictures are similar Note the high accumulation of radioactivity (light areas) in the pancreas and in the caput epididymidis. There is no accumulation of adioactivity in the adrenal medulla.

In the liver the lung, the bone marrow and the spleen, the distribution patterns were similar to each other The activity was never high in these organs, but exceeded the activity in the blood to some extent up to 30 minutes after the injection.

In the central nervous system the activity was low during the observation period with exception of the choroid plexus and the hypophysis, which contained a rather high activity

In the peripheral nervous system there was a moderate activity both in sympathetic and spinal ganglia.

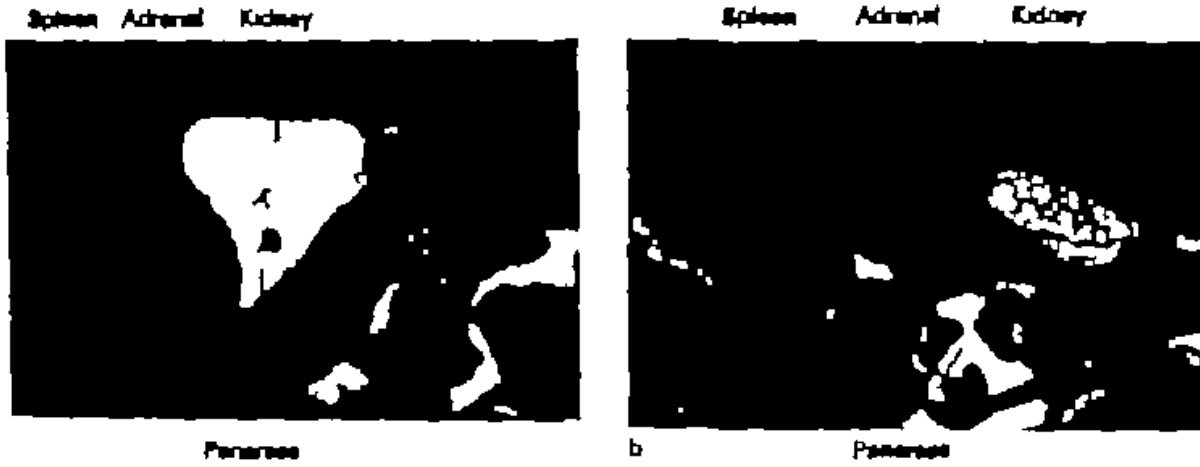

Fig. 35 a and b. Details of Fig. 34 a and b respectively. There is no accumulation of radioactivity (light areas) in the adrenal medulla in the animal injected with DOPA-2-^{14}C (a) or with DOPA 1-^{14}C (b)

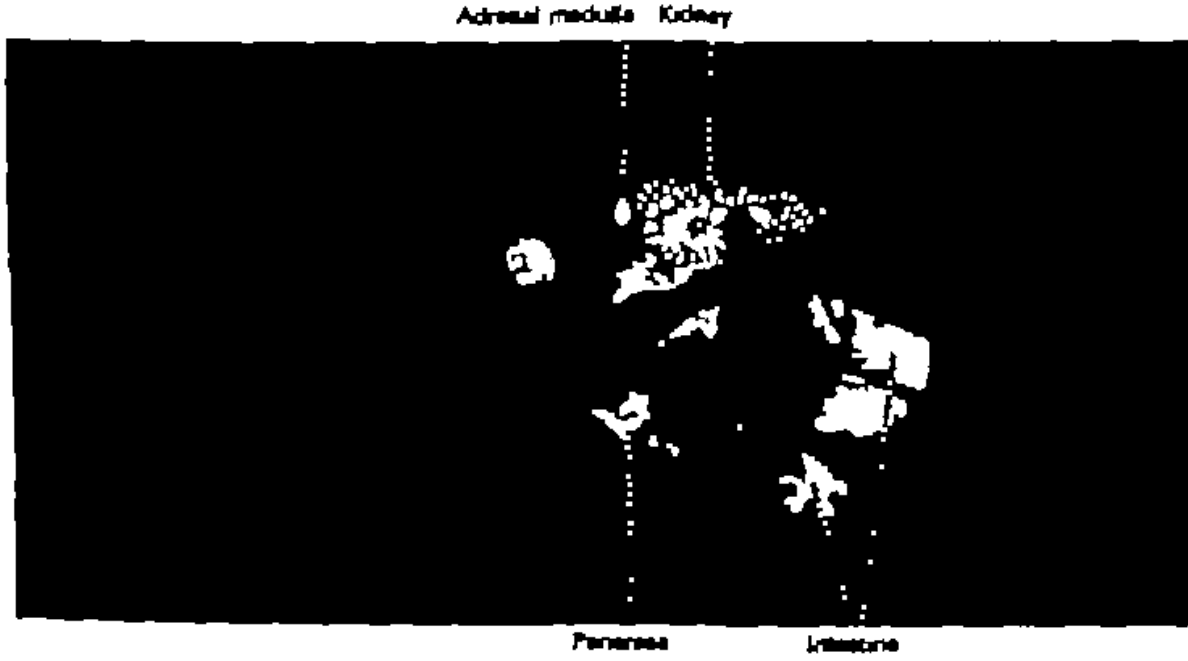

Fig. 36. Autoradiogram of a mouse 4 hours after an intravenous injection of DOPA-2-^{14}C. The animal was pre-treated with the DOPA-decarboxylase inhibitor Ro4-4602 30 minutes before the DOPA-2-^{14}C-injection. Radioactivity (light area) can be seen in the adrenal medulla. The DOPA-decarboxylase-inhibiting effect of Ro4-4602 has probably disappeared at this time interval.

Discussion

Some general mechanisms will be discussed first, followed by a discussion of the distribution patterns obtained in some organs.

The injection of DOPA rapidly leads to a formation of large amounts of catecholamines, especially dopamine in various tissues (Weiss and Rossi 1963

Gey and Pletscher 1964 Wurtman *et al* 1970) It is therefore obvious that a decarboxylation is of great importance in the metabolism of exogenous DOPA.

The second major pathway in the metabolism of exogenous DOPA seems to be an O-methylation via the action of the enzyme catechol O-methyl transferase (COMT) (Gey and Pletscher 1964 Wurtman *et al.* 1970) 4-hydroxy 3-methoxy-phenylalanine (methoxy-DOPA) is formed by this process.

The metabolism of the catecholamines formed from DOPA takes place via two different ways. The first way is an oxidative deamination through the action of the enzyme monoamine oxidase (MAO) (e.g. Zeller 1962) The second way is an O-methylation through the action of COMT (e.g Axelrod 1966) MAO is in its action limited to amines (see Arvy 1963) while COMT O-methylates all catechols, regardless of the substituent on the aromatic nucleus (Axelrod 1966)

The oxidative deamination and the O-methylation are inactivating processes, since the physiological activities of the products are weak and the products also leave the body rapidly (Kopin 1964 Axelrod 1966) It has recently been reported that methoxy-DOPA might be an exception from this rule since it seems to stay in the pancreas for rather a long time (Bartholini *et al.* 1970)

Other pathways of metabolism for DOPA or catecholamines except those mentioned seem to be of minor importance. Thus after the injection of DOPA into mice, the major compounds found in the body have been reported to be DOPA methoxy DOPA catecholamines and catecholamine metabolites (Wurtman *et al* 1970)

The radioactivity seen in the autoradiograms after the injection of DOPA 1 C in the present investigation should therefore largely represent DOPA and methoxy DOPA. When catecholamines are formed from DOPA 1 ^{14}C the labelled C is split off and $^{14}CO_2$ is formed. This is then to the greatest extent exhaled (Hansson and Clark 1962, Hansson *et al.* 1964) The catecholamines and the catecholamine-metabolites are rendered autoradiographically visible In mice injected with DOPA 2 C, DOPA and methoxy-DOPA as well as catecholamines and catecholamine metabolites are visible. The proportion of these components varies of course considerably in different organs. In organs such as the liver the intestine and the kidneys, the proportion of metabolites is great while in organs such as the adrenals and the pancreas, the proportion of respectively catecholamines and DOPA is great (Rosell *et al* 1963 Gey and Pletscher 1964)

When DOPA is injected into mice, where the DOPA-decarboxylase has been inhibited an autoradiographic condition similar to the one seen after injection of DOPA 1 C, is obtained inasmuch as no catecholamines are formed and the radioactivity therefore does neither represent catecholamines nor cate-

cholamine metabolites. The precedent condition being that the decarboxylase inhibitor used is effective. Ro 4-4602, which has been used in the present investigation, has been shown to be very effective *in vivo* (Pletscher and Gey 1963 Hanuson *et al.* 1964) Evidence for the effectiveness of the decarboxylase inhibitor in the present investigation is the fact that the autoradiograms obtained after the injection of DOPA 1 ^{14}C and DOPA 2 ^{3}C into animals, in whom the decarboxylase has been inhibited, are similar

The possibility exists that the decarboxylase inhibitor in itself might interfere with the uptake of DOPA in various organs. Such an interference has, however only been achieved with other aromatic amino acids (see Gey and Pletscher 1964) Interference with decarboxylase inhibitors such as α-methyl-DOPA (Schanberg 1963) or Ro 4-4602, has not been observed and there are no indications that this is the case in the present investigation (see below)

It should be pointed out that DL-DOPA was used in the present investigation. The D-forms of aromatic amino acids appear to enter different tissues less than the L-forms (Guroff and Udenfriend 1962, Yoshida *et al.* 1963) In addition the catecholamine formation only takes place from L-DOPA.

The distribution patterns obtained in some organs will be discussed separately below

Adrenal

The autoradiograms illustrate the rapidity by which the decarboxylation takes place, and by which the so formed catecholamines are accumulated in the adrenal medulla after the injection of DOPA. The catecholamine formation in the adrenal medulla, which is obtained after the injection of DOPA, has been studied with autoradiographic methods by several authors (Rosell *et al.* 1963 Hempel 1963 Elfvin *et al.* 1966, Moppert 1966, Hempel and Kraft 1968) L-amino acid decarboxylase has been shown in the adrenal medulla of several species (Langemann 1951 Westermann 1956)

The autoradiograms from animals in whom the decarboxylase was inhibited, show that DOPA in itself is not accumulated in the adrenal medulla. Hempel and Männl (1966, 1967) similarily observed that ^{3}H DOPA formed from ^{3}H tyrosine in the adrenal medulla of the cat and bird, could not be stored there *when the decarboxylase was inhibited.* The catecholamines formed in the adrenal medulla have a very long half life (Burack and Draskóczy 1964 Hempel and Kraft 1968) In the adrenal medulla the catecholamines are stored in the chromaffin granules of the cytoplasm. It has been proposed that the amines are bound there in a nondiffusible form as a complex with ATP and protein (Hillarp 1958) but the exact mechanism for this is not known (Smith 1968) Obviously the catechol-configuration is not in itself of chief

importance for the storage, as has been proposed by Weiner and Jardetzky (1964). Four hours after the injection of DOPA 2 ^{14}C into a Ro 4-4602 -pre-treated animal activity could be seen in the adrenal medulla. At this point the decarboxylase inhibating effect of Ro 4-4602 has probably disappeared, since this effect has been shown to be of a rather short duration (Hansson *et al* 1964). The spots with a slightly higher activity observed preferentially in the periphery of the medulla in mice injected with DOPA 1 ^{14}C and in mice in whom the decarboxylase had been inhibited, might be activity in ganglion cells, which have been shown to be present in the medulla (Coupland 1965). The activity there is similar to the activity observed in other ganglion cells under the same conditions (see below).

The activity observed in *the thyroid* after injection of DOPA 2 ^{14}C into animals in whom the decarboxylase was not inhibited probably represents activity in the parafollicular cells. As in *the pancreatic islets* there was no accumulation of radioactivity in the thyroid in animals where the decarboxylase was inhibited or after the injection of DOPA 1 ^{14}C into untreated animals. As in the adrenal medulla decarboxylation is obviously necessary for retention of radioactivity in the pancreatic islets and in the parafollicular cells. This has been discussed earlier (Chapter 1 and 7).

Exocrine pancreas

Injected amino acids are strongly accumulated in protein forming organs, such as the pancreas (see Hansson 1959). DOPA is also initially accumulated in these organs, but because it is not incorporated into proteins, it is rapidly cleared from such organs (Rosell et al 1963). In the present investigation an accumulation in the pancreas could be observed independent of whether the animals were pre-treated with Ro 4-4602, or whether the DOPA was labelled in C1 or in C2 position.

Using a fluorescence method for monoamine demonstration Alm *et al.* (1969) noted that after a DOPA injection, when the decarboxylase had been inhibited, the fluorescence over zymogen granules diminished, while the DOPA fluorescence in the rest of the cell persisted. They concluded that catecholamines were formed in the zymogen granules and that this process was blocked by the decarboxylase inhibition.

As has been mentioned methoxy DOPA seems to stay in the pancreas for a rather long time (Bartholini *et al* 1970).

The liver and the intestinal mucosa are characterized by a rapid protein synthesis and therefore an initial accumulation of DOPA might be expected here. These organs, however also possess a high DOPA-decarboxylase activity (see Erspamer 1961). From the present investigation it is also obvious that

the high accumulation of radioactivity seen shortly after the injection of DOPA 2 ^{14}C to a large extent represent the decarboxylated product, since after DOPA 1 ^{14} injections, the activity is considerably lower in these organs than after the injections of DOPA 2 ^{14}C. At longer time intervals a higher activity is seen in the intestinal lumen after the injection of DOPA 2 ^{14}C, than after DOPA 1 ^{14}C. This activity therefore also represents the decarboxylated products.

Nervous system

In ganglia a moderate accumulation of radioactivity could be seen after the injection of DOPA 1 ^{14}C and when the decarboxylase was inhibited. After the injection of DOPA 2 ^{14}C into untreated animals, a stronger accumulation could be observed in sympathetic ganglia than in spinal ganglia, suggesting a catecholamine formation in the sympathetic ganglia. Small dopamine containing cells (SIF-cells) have been demonstrated in sympathetic ganglia (Björklund *et al.* 1970). The presence of DOPA-decarboxylase in the sympathetic ganglia has also been shown (see Roch-Ramel 1968). Adrenergic nerves have been demonstrated both in autonomic and in spinal ganglia (Hamberger *et al.* 1965 b, Owman and Santini 1966). The amount of catecholamines in ganglia has been correlated to the number of neurons in the ganglia (Norberg and Sjöqvist 1966). The low radioactivity in the brain demonstrates the unique property of the brain with respect to amino acid penetration observed earlier (Guroff and Udenfriend 1962, Udenfriend and Zaltzman-Nirenberg 1963, Gey and Pletscher 1964). The injection of DOPA has been shown to give a catecholamine formation in the walls of cerebral vessels (Bertler *et al.* 1966).

Sexual glands

High activity of both DOPA 2 ^{14}C and DOPA 1 ^{14}C could be seen in ovarian structures, such as the follicle walls and corpora lutea in females and in parts of the caput epididymidis in males. In these structures a high enzyme activity (and hereby protein synthesis) seems to be present. The stratum granulosum is suggested to be the source of the ovarian estrogen (Bjersing and Carstensen 1964) and the corpus luteum is generally accepted as the source of ovarian progesteron (see Appelgren 1967). In the epididymis there are variations of different hydroxysteroid dehydrogenases in different zones (Baillie *et al.* 1966). A high accumulation of 4-iodophenylalanine has been observed in part of the epididymis (Ullberg and Bloomquist 1968). The pancreas is the only additional organ which accumulates any higher concentration of this amino acid analogue, which, like DOPA, is not incorporated into proteins. Normano

(1967) and Kormano and Penttilä (1968) using fluorescence methods, observed fluorescence in the epididymis after the injection of DOPA and dopamine into rats. The accumulation of DOPA in these structures does of course not exclude the possibility that in addition catecholamines are formed. This seems to be the case in ductus deferens, where a higher accumulation of activity could be seen after the injection of DOPA 2 ^{14}C, than after the injection of DOPA 1 ^{14}C. Ductus deferens has been shown to contain a dense network of adrenergic nerve terminals (see Sjöstrand 1965) where *in vitro* a catecholamine formation from DOPA has been shown to occur (Hamberger 1967). After the injection of ^{1} C-5-HTP radioactivity presumably due to serotonin has been shown by autoradiographic techniques to accumulate in the sympathetic neurons of the rat ductus deferens (Taxi and Droz 1966).

The lens accumulated DOPA slowly. This may be put in relation to the slow accumulation of amino acids seen in the lens under *in vitro* conditions (see Brasil and Kern 1968).

The skin accumulated much radioactivity both after DOPA 1 ^{1} C- and DOPA ^{2} ^{14}C-injections. Such an accumulation has been observed earlier with DOPA and 5-HTP (Gey and Pletscher 1964, Ritzén *et al.* 1965). It has been suggested that this accumulation of DOPA might be related to special functions of the skin such as melanin formation, which however has been lost in albino animals (Gey and Pletscher 1964).

The rate limiting step in the endogenous formation of catecholamines in tissues, seems to be the hydroxylation of tyrosine to DOPA (see Bloom and Glarman 1968). Once DOPA is formed it is rapidly converted to catecholamines. DOPA is endogenously present only in very small amounts in tissues (Anton and Sayre 1964, Hempel and Mlinnl 1967). In certain tumours such as phaeochromocytom, neuroblastom and melanom the endogenous DOPA concentration is higher (von Studnitz *et al.* 1963, Cabana *et al.* 1964, Falck *et al.* 1969).

CHAPTER 6

Histochemical demonstration of monoamine oxidase (MAO) and its relation to the *in vitro* uptake of serotonin ^{14}C, studied in whole-body sections of mice

Monoamine oxidase (MAO) catalyzes the oxidative deamination of monoamines in the body. It is widely distributed in the animal kingdom and probably involved in the *in vivo* inactivation of a number of biologically active monoamines of physiological importance, although its precise function has yet to be defined (see Arvy 1963, Gorkin 1966, Collins *et al.* 1970).

To investigate the distribution and activity of MAO several histochemical methods, and quantitative methods based on the disappearance of a substrate, or the formation of deaminated products from a substrate, have been used (*e.g.* Koelle and Valk 1954, Glenner *et al.* 1957, Wernbach *et al.* 1960, Lovenberg *et al.* 1962 b). Lately radiochemical methods for MAO-determination have been developed. (Otsuka *et al.* 1964, Consolo *et al.* 1968, Fellman *et al.* 1969).

Of the histochemical methods for MAO-demonstration the method described by Glenner *et al.* (1957) has been most extensively used. This method is based on a reduction of tetrazolium salts to coloured formazan deposits.

Tissues are incubated in a buffer containing a tetrazolium salt and a suitable substrate for MAO such as tryptamine or serotonin. In connection with the oxidation of the substrate the tetrazolium salt is reduced to form the formazan deposits in the tissues. The mechanism by which tetrazolium salts are reduced in the MAO reaction has been described by Wernbach *et al.* (1957).

In the present investigation whole-body sections from mice have been used for the histochemical demonstration of MAO. In this way it is possible to compare the relative concentration of MAO-activity in the same section in different tissues treated in exactly the same way.

In addition the uptake of ^{14}C-serotonin has been studied in whole-body sections from mice incubated in a buffer under conditions similar to those used in the MAO-investigation.

Material and methods

Whole-body freeze sections 10 μ thick from NMRI mice, were taken on tape (nr 688, Minnesota Mining and Manufacturing Co, USA) according to the

method described earlier (page 54) The sections were dipped in acetone at −10 C for about 15 seconds before they were allowed to reach room temperature in an air tight box. 5 male mice and 5 female mice (one of which was pregnant) were used for the MAO determination. For the experiments with serotonin-^{14}C 2 male mice were used.

The MAO activity was determined according to the method described by Glenner *et al.* (1957) The sections were incubated for one hour at 37 C in a 0 1 M phosphate buffer solution pH 7 6 Tryptamine hydrochloride* (0 05 M) or serotonin creatinine sulphate* (0 05 M) were used as substrates. Nitro-blue tetrazolium* was used as tetrazolium salt. The incubation solution had the following composition.

Tryptamine hydrochloride or Serotonin creatinine sulphate	0 05 M
Sodium sulphate	4 mg
Nitro-blue tetrazolium	5 mg
0 1 M phosphate buffer pH 7 6	5 ml
Distilled water	15 ml

After the incubation the sections were briefly washed in running water They were then fixed in buffered 4 % formaldehyde solution for 24 hours and embedded in glycerol-gelatine. Control sections were incubated without substrate or were pre incubated with the MAO inhibitor nialamide (0 01 M) (Pfizer) for 15 minutes. In addition sections from mice injected i.p. with nialamide 500 mg/kg body weight, 4 hours before they were killed, were used as controls.

In the experiments with serotonin ^{1} C, sections were incubated in a solution with the same composition as described earlier though substituting serotonin-C (5-hydroxytryptamine 2 ^{14}C-binoxalate, spec. act. 18 mCi/mM (68 μCi/mg) New England Nuclear) for tryptamine hydrochloride or serotonin creatinine sulphate as substrate. 2.5 μCi serotonin- C (corresponding to 37 μg 5-hydroxytryptamine ^{2} ^{14}C-binoxalate) was added to each 10 ml of incubation medium The sections were incubated for one hour at 37 C. They were then rinsed for 5 minutes in water and thereafter air-dried. Autoradiograms were made by apposition of the sections against x ray films (Structurix, Gevaert) The exposure time was about 3 weeks. Also in these experiments some sections were pre-incubated fo 15 minutes with nialamide (0.01 M) before the serotonin-^{1} C- ncubation.

Sigma Chemical Company Missouri, USA.

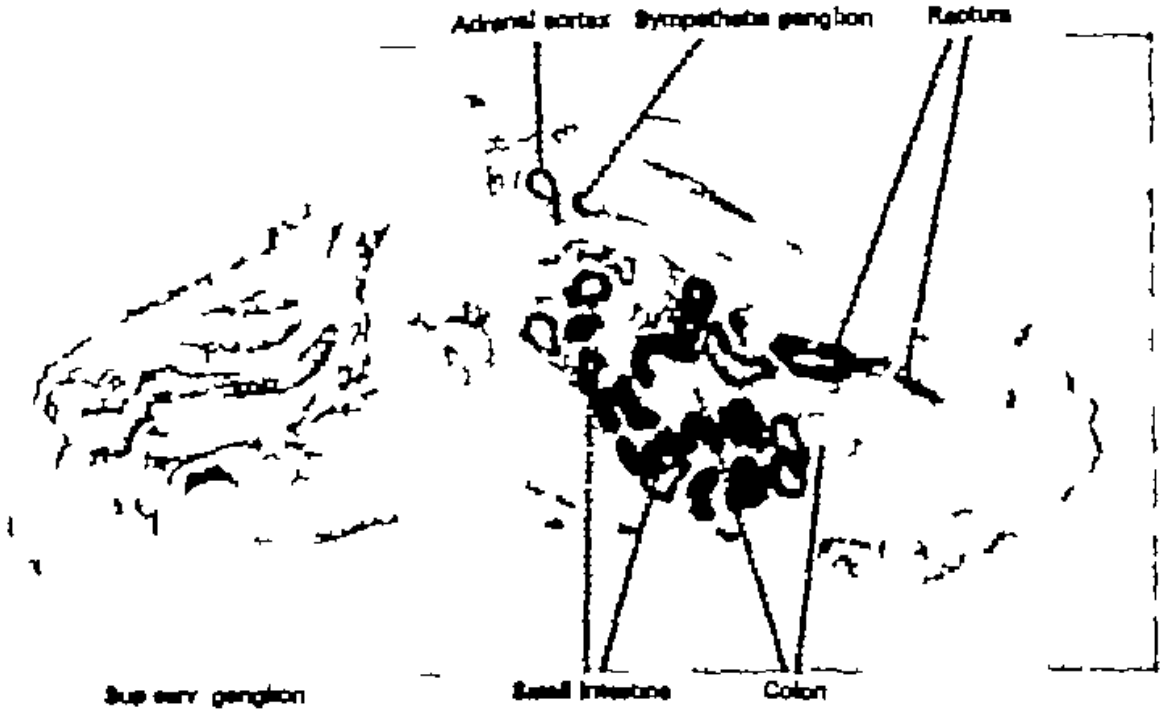

Fig. 37 Whole-body section of a mouse showing the MAO-activity The highest enzyme activity (dark areas) is present in sympathetic ganglia, in the mucosa of the small intestine and rectum, and in the adrenal cortex.

Results

MAO histochemistry

The results obtained with tryptamine hydrochloride and serotonin creatinine sulphate as substrates were similar

The most prominent formazan deposits were seen in sympathetic ganglia followed by the mucosa of small intestine and rectum (Fig 37 and 38) Prominent formazan deposits were also seen in the adrenal cortex (Fig. 37) In other organs except the mentioned and in the fetal tissues the formazan deposits were considerably less prominent.

A rather high enzyme activity could be seen in the liver in the kidneys, in the pancreas, in brown fat and in different parts of the central nervous system. A more detailed description of the enzyme activity in some organs will be presented below

In the sympathetic ganglia most cells showed a strong activity (Fig 39) In spinal ganglia the enzyme activity was low

In the mucosa of the small intestine the activity was most intense at the striated border of the villous epithelium. The epithelial cells of the crypts showed less activity (Fig 40) There was no difference in reaction intensity between duodenum, jejunum, ileum and rectum. In the colon a light activity

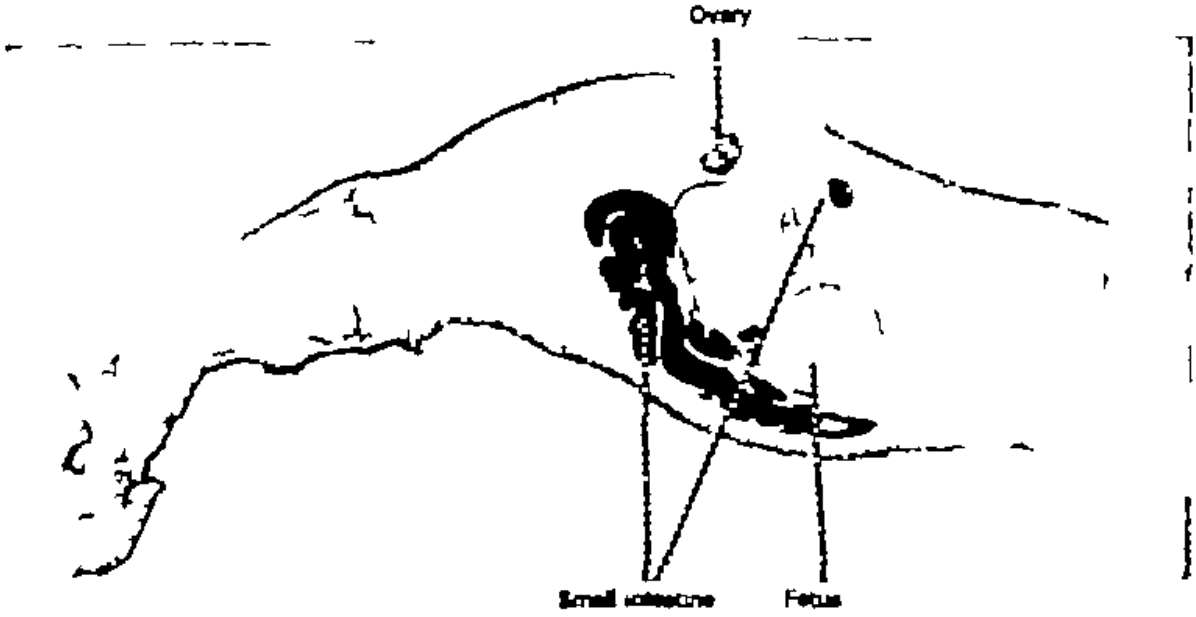

Fig. 38. Whole-body section of a pregnant mouse showing the MAO-activity There is very high enzyme activity (dark areas) in the intestinal mucosa.

was present at the surface epithelium. In the crypts the activity was still weaker In the stomach (Fig 41) a moderate enzyme activity could be seen in the squamous epithelium of the forestomach. In the glandular part of the stomach the strongest enzyme activity was present basally in the glands.

Formazan deposits could also be seen at the location of the myenteric plexus both in the stomach and in the intestine (Fig. 41)

In the adrenal cortex (Fig 4) the highest activity was present in the zona fasciculata. In the zona glomerulosa the activity was somewhat less intense and in the zona reticularis and the x zone even weaker In the adrenal medulla the activity was low

In the testicles the strongest enzyme activity was seen in the interstitial cells (Fig 43) The epithelial lining of the epididymal duct and of ductus deferens, showed a relatively high activity

Fig. 39 Detail of whole-body section of mouse showing the MAO-activity in sympathetic ganglion. A strong enzyme activity is present in all cells in the ganglion. (×20)

Fig. 40. Detail of whole-body section of mouse showing the MAO-activity in the mucosa of the small intestine. A high enzyme activity can be seen at the striated border of the villous epithelium. The epithelial cells of the crypts show a less intense activity (×60)

In the ovary the interstitial cells showed the strongest activity (Fig 44)

In the thyroid the highest enzyme activity was seen in cells scattered between the follicles (Fig. 45) The cells had a localization similar to the parafollicular cells.

In the skin the hair follicles showed a strong enzyme activity

In control sections, obtained by either of the three mentioned methods, the deposition of formazan was low and evenly distributed (Fig. 46)

Serotonin ^{14}C-incubations

A strong accumulation of radioactivity could be seen in the adrenal cortex. In the adrenal medulla the activity was low (Fig 47 a)

Sympathetic ganglia and the intestinal mucosa were other instances where a strong radioactivity could be seen.

A relatively high activity could be seen in the bone marrow the red pulp of the spleen and the epithelium of ductus deferens. A rather high radioactivity was also seen in the central nervous system and in brown fat.

In sections pre incubated with nialamide there was only a low radioactivity in the adrenal cortex. Other organs accumulated a similar amount of activity as without the MAO inhibition (Fig 47 b)

Fig. 41 Detail of whole-body section of mouse showing the MAO-activity in the wall of the stomach at the junction between the forestomach (to the left in the picture) and the fundic gland area (to the right in the picture). The highest enzyme activity can be seen in the squamous epithelium of the forestomach and at the base of the fundic glands. Formazan deposits can also be seen in the picture at the location of Auerbach plexus. (×40)

Fig. 42. Detail of whole-body section of a mouse showing the MAO-activity in the adrenal gland. There is high enzyme activity in the adrenal cortex, especially in the zona fasciculata. In the adrenal medulla the enzyme activity is low (×20)

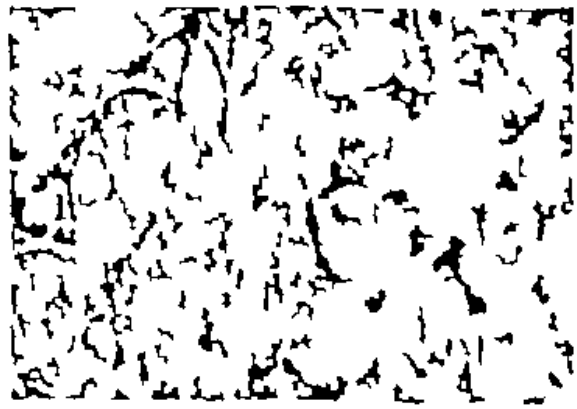

Fig. 43. Detail of whole-body section of mouse showing the MAO-activity in testicle. The highest enzyme activity is present in the interstitial cells. (×70)

Fig. 44 Detail of a whole-body section of mouse showing the MAO-activity in an ovary The highest enzyme activity is present in the interstitial cells. (×50)

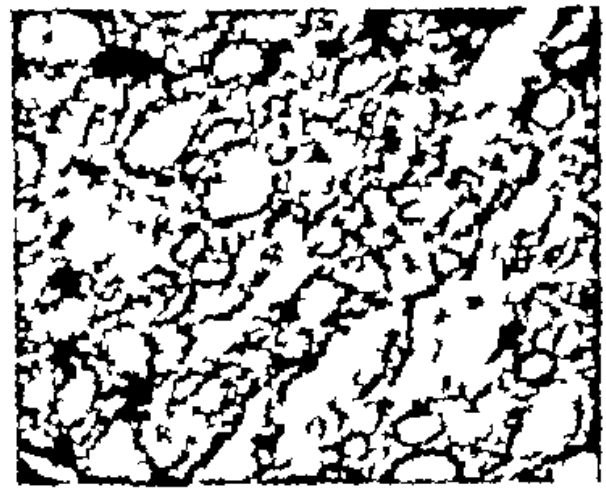

Fig. 45. Detail of a whole-body section of a mouse showing the MAO-activity in the thyroid. The highest enzyme activity can be seen in cells scattered between the follicles, probably the parafollicular cells. (×50)

Discussion

The use of whole-body sections for the demonstration of MAO-activity as in the present investigation allows a direct comparison of the enzyme activity in different organs treated in exactly the same way

In the cells the mitochondria contain the greatest part of the MAO-activity (see Gorkin 1966) The formazan precipitations have with a histochemical method for MAO localization in the electron microscope, also been shown to be localized in association to the outer mitochondrial membrane (Boadle and Bloom 1969)

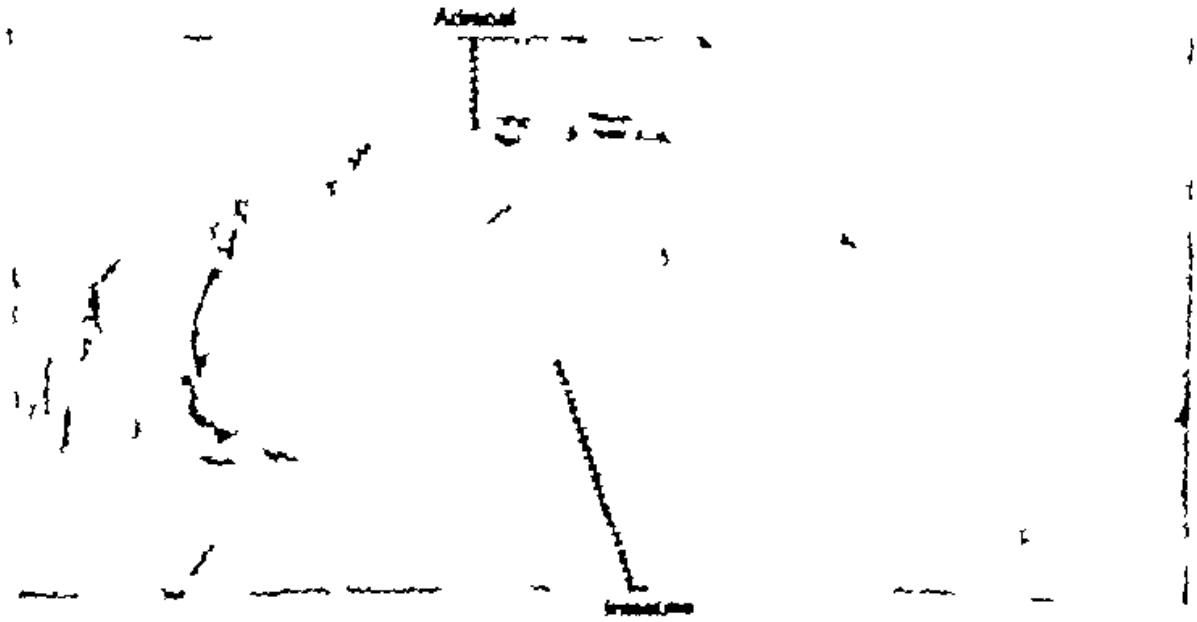

Fig. 4. Whole-body section of mouse which has been pre-treated with the MAO-inhibitor nialamide 500 mg/kg i.p. 4 hours before was killed. The section has been treated for MAO-histochemistry. The enzyme reaction is weak in all tissues

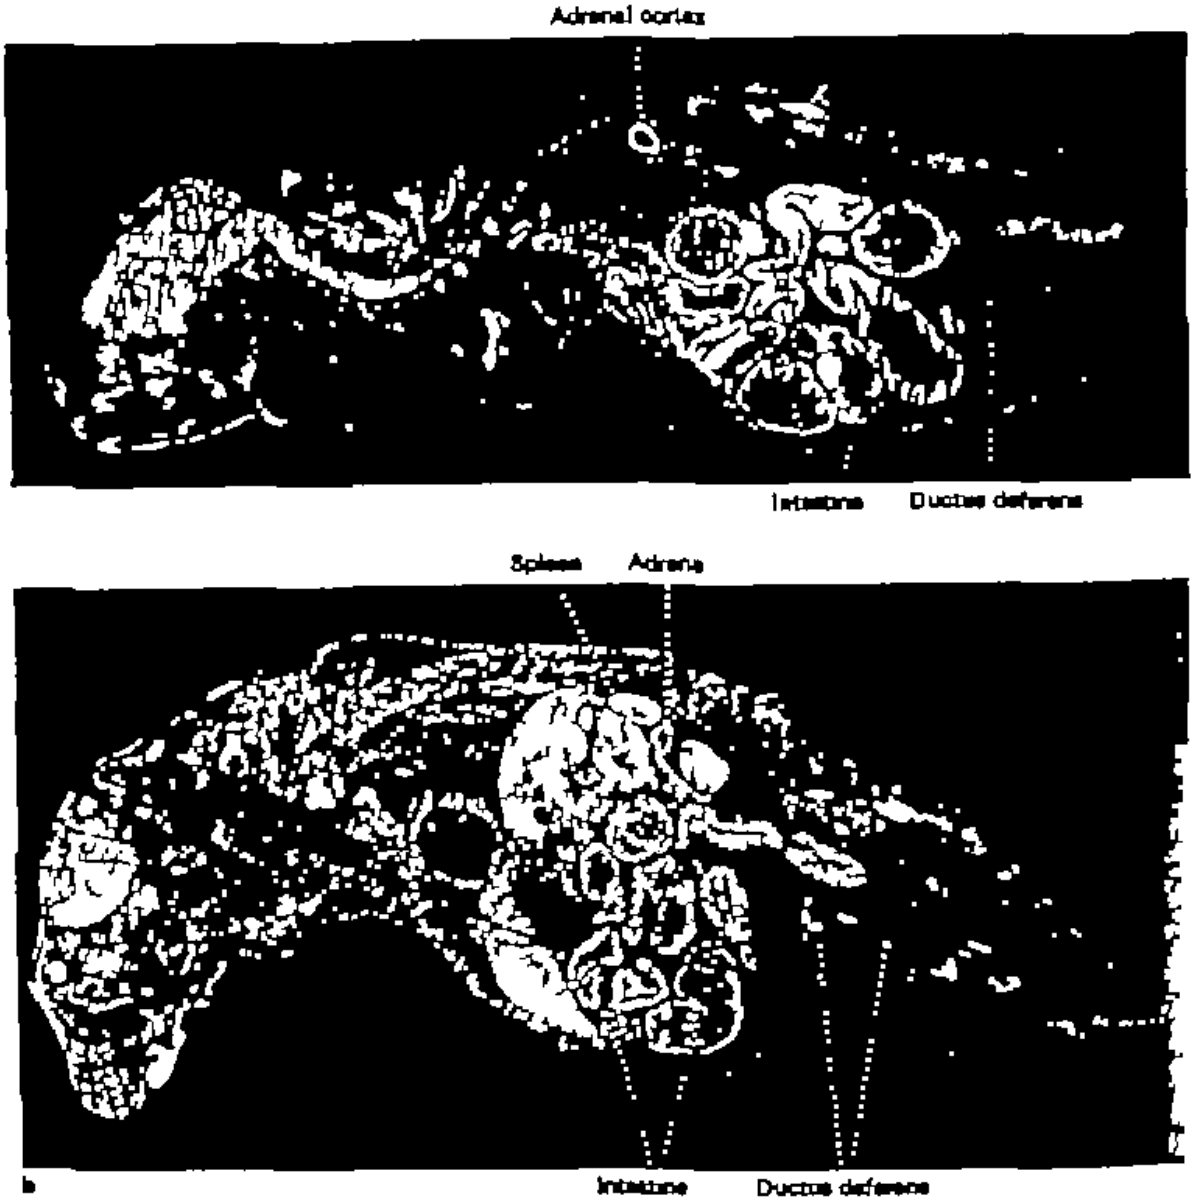

Fig. 47 a. Autoradiogram of whole-body section of mouse. The section has been incubated in buffer containing serotonin- ^{14}C.

b A toradiogram of a section, which has been pre incubated with the MAO-inhibitor nialamide before it was incubated with serotonin- C. A strong accumulation of radioactivity (light areas) can be seen in the adrenal cortex in the section, which has not been pre incubated with nialamide ( ) In the pre-incubated section the radioactivity in the adrenal cortex is low (b)

The highest MAO-activity could be observed in the sympathetic ganglia A high activity in sympathetic ganglia has also been shown in other species (Koelle and Valk 1954 Glenner *et al* 1957 Klingman and Klingman 1966, Consolo *et al.* 1968 Giacobini and Kerpel Fronius 1970) In spinal ganglia the MAO-activity was low Similar is the case in the cat (Giacobini and Kerpel-Fronius 1970)

The MAO-content in different ganglia has been correlated to the number of adrenergic neurons in the ganglia (Consolo *et al.* 1968)

A high MAO-activity could be observed in the myenteric plexa of the stomach and the intestine. This has also been observed in other species (see Glenner *et al.* 1957 Ruckebuch and Santini 1968)

In the mucosa of the small intestine and the rectum the enzyme activity was very high. The results are in agreement with an earlier investigation in the mouse (Iwai 1969) Also in other species a high activity has been shown in various parts of the intestine, although there are some species variations (Koelle and Valk 1954 Glenner *et al* 1957 Klingman *et al.* 1964 Penttilä 1968 Iwai 1969 Murali and Radhakrishnan 1970) The enterochromaffin cells in the intestine are mainly localized basally in the mucosa (see Penttilä 1966) where the MAO-activity is lowest. In the stomach the highest activity is present basally in the glands. The situation has been shown to be the same in the guinea pig and in the rat (Eder 1957 Håkanson *et al.* 1967 a) In this case the strongest MAO-activity is present in the area where most enterochromaffin and enterochromaffin-like cells are found (see Chapter 3) In the gastrointestinal tract most of the endogenous serotonin stores are present in the enterochromaffin cells (Penttilä 1966, Vialli 1966) The storage of serotonin thus seems to be in accordance with the occurrence of MAO in the stomach, but not in the intestine.

In connection with this the side effects observed in patients receiving MAO-inhibitors for treatment of depressive states can be pointed out (Sjöqvist 1967 Mayer 1968 Hammer *et al.* 1969) Hypertensive symptoms could be observed after the consumation of certain food stuffs, especially cheese. Tyramine is the principal pressor substance in cheese. When the MAO was inhibited, the tyramine was not destroyed and the hypertensive symptoms occurred. MAO thus has a detoxifying function in the gastrointestinal tract.

The observation that a high MAO-activity is present in cells of the thyroid which might correspond to the parafollicular cells is in agreement with an earlier investigation (Larsson *et al.* 1966)

A surprisingly high MAO-activity was found in the adrenal cortex, while the adrenal medulla showed a low activity Earlier reports of the MAO-activity in the adrenal gland show great variations.

Using the tetrazolium method Glenner *et al.* (1957) found a moderate activity in the cortex in guinea pig and rabbit. No activity could be observed in the medulla.

In a series of investigations Rosenkrantz and collaborators (Rosenkrantz 1959 Rosenkrantz and Laferte 1960 Connors and Rosenkrantz 1962) observed a substance in the cortex capable of nitro-blue tetrazolium reduction in the adrenal cortex of rabbit, guinea pig, rat, dog and cow after incubations with serotonin

They concluded that serotonin had a direct effect on the adrenal cortex, but they were unable to identify the reducing substance. It seems possible that the nitro-blue tetrazolium reduction was due to MAO-activity

Koelle and Valk (1954) observed an intense MAO-activity especially in the zona fasciculata of the adrenal cortex of the cat. The method used gave however an unspecific if considerably lower activity in control sections. Francis (1954) found an intense activity in singular medullar cells, possibly corresponding to ganglion cells in the guinea pig. The activity in the cortex was intense, but with the method used not specific. Langemann (1951) found MAO-activity in both cortex and medulla of the adrenal of the ox. Martinez and Toledano (1968) observed MAO-activity in the adrenal cortex of the cat, but no activity in the medulla.

In the testis the highest MAO-activity was found in the interstitial cells. Also the epithelium of the epididymal duct and ductus deferens showed a rather high activity. The results are in agreement with investigations in the rat (Penttilä and Kormano 1968, Spano *et al.* 1968). The uptake of DOPA in these structures has been discussed in Chapter 5.

In the ovary the highest MAO-activity was present in the interstitial cells. Adrenergic nerves are rather numerous in and restricted to the interstitial tissue of the ovary (see Sjöberg 1967). The uptake of injected DOPA is highest in the follicle walls and corpora lutea (see Chapter 5), where the MAO-activity is lowest.

Put together, there seems to be no correlation between the storage of monoamines or the uptake of DOPA and the occurrence of MAO in the steroid hormone producing organs. The same applies to the gastrointestinal tract. It is, however, obvious that monoaminergic mechanisms are present in the steroid hormone producing organs.

Effects of monoamines in the release of steroid hormones have also been observed. These have however in some cases been shown to be mediated via the release of the hormones in the hypophysis and the hypothalamus, but direct effects of monoamines on the steroid hormone producing organs have also been reported. Thus serotonin has been shown to stimulate the secretion of hydrocortisone by a direct effect on the adrenal gland (Verdesca *et al.* 1961). Direct effects of monoamines in the production of testosterone from the testis have also been reported (see Ellis 1969, Eik-Nes 1969). Reserpine inhibits ovulation (see Meyerson and Sawyer 1968). This effect, which is blocked by MAO-inhibitors, has earlier been proposed to be mediated via the hypophysis. Recently however it has been reported that the effect, at least to some extent must be produced via a direct action on the ovary (France 1970). Several MAO-inhibitors have been shown to depress the weight and function of the reproductive system. This action appears to be mediated both via the hypo-

physis and via a direct effect on the sex organs (see Zor *et al.* 1966, Forbes 1970)

In the incubations with serotonin- ^{14}C, there was a strong accumulation of radioactivity in the adrenal cortex. After pre-incubation with nialamide the uptake of serotonin- ^{14}C was considerably lower in the adrenal cortex. It might therefore be possible that in this case MAO is responsible for the binding of the serotonin to the tissue. The histochemical MAO-method in fact involves a binding of the substrate to the MAO-containing tissues, where the substrate is then oxidatively deaminated. The uptake of serotonin- ^{14}C may therefore partly be due to MAO in the tissues. In such tissues as the sympathetic ganglia the intestinal mucosa, the epithelium of ductus deferens the bone marrow and the spleen the activity was high, independent of MAO-inhibition. In these cases additional factors are obviously of importance for the *in vitro* binding of serotonin. It must be observed that incubations in the present investigation have been performed with sections, which have been frozen and dipped in acetone. It is impossible to make comparison between the uptake of substances in the tissues under these conditions and the uptake under *in vivo* conditions. *In vivo* injected serotonin is strongly accumulated in the adrenal medulla (see Ritzén *et al.* 1965) When whole-body sections from mice are incubated with DOPA- ^{14}C, there is no accumulation of radioactivity in the adrenal cortex (Fig 48) (Tjälve, unpublished) DOPA does not serve as a substrate for MAO (see Chapter 5) The tissues accumulating the highest radioactivity in this case are the bone marrow and the intestinal mucosa.

one hour. The fluorescence was however a little weaker and the islet cells with stronger fluorescence were fewer after two hours than after one hour (Fig. 51).

In the pieces incubated with DOPA *in vitro* there was a strong fluorescence in both the exocrine and endocrine pancreas (Fig. 52). In the islets all cells showed the same high fluorescence. In the exocrine pancreas a stronger fluorescence was seen in the zymogen granules than in the rest of the cells.

Part 2 Chromatographic investigation of the in vitro metabolism of DOPA 2 ^{14}C in the rabbit pancreas

Material and methods

Pieces of pancreas, weighing 20 mg each from two untreated Havanna rabbits were incubated for 30 minutes in 2 ml of the same buffer solution and under the same conditions as has been described in Part 1. Instead of non-labelled DOPA, DOPA ^{14}C was added to the incubation solution. The isotope (DL-3(3,4-dihydroxyphenyl)alanine 2 ^{14}C, specific activity 261 μCi/mg (52 mCi/mM) (The Radiochemical Centre Amersham, England) was added in a concentration of 2.5 10^{-3} M corresponding to 2.6 μCi in 2 ml buffer solution.

After the incubation the pieces were rinsed for some seconds in a buffer solution not containing DOPA. They were then immediately homogenized in a Potter Elvehjem homogenizer extracted twice with acid ethanol (1 ml conc. HCl/1000 ml ethanol) and filtered. The acid ethanol extracts were evaporated in N_2. Small amounts of the extracts were spotted on paper (What

They concluded that serotonin had a direct effect on the adrenal cortex, but they were unable to identify the reducing substance. It seems possible that the nitro-blue tetrazolium reduction was due to MAO-activity

Koelle and Valk (1954) observed an intense MAO-activity especially in the zona fasciculata of the adrenal cortex of the cat. The method used gave however an unspecific if considerably lower activity in control sections. Francis (1954) found an intense activity in angular medullar cells, possibly corresponding to ganglion cells in the guinea pig The activity in the cortex was intense but with the method used, not specific. Langemann (1951) found MAO-activity in both cortex and medulla of the adrenal of the ox. Martinez and Toledano (1968) observed MAO-activity in the adrenal cortex of the cat, but no activity in the medulla.

In the testis the highest MAO-activity was found in the interstitial cells. Also the epithelium of the epididymal duct and ductus deferens showed a rather high activity The results are in agreement with investigations in the rat (Penttilä and Kormano 1968 Spano *et al* 1968) The uptake of DOPA in these structures has been discussed in Chapter 5

In the ovary the highest MAO-activity was present in the interstitial cells. Adrenergic nerves are rather numerous in and restricted to the interstitial tissue of the ovary (see Sjöberg 1967) The uptake of injected DOPA is highest in the follicle walls and corpora lutea (see Chapter 5) where the MAO-activity is lowest.

Put together there seems to be no correlation between the storage of monoamines or the uptake of DOPA and the occurrence of MAO in the steroid hormone producing organs. The same applies to the gastrointestinal tract. It is however obvious that monoaminergic mechanisms are present in the steroid hormone producing organs.

Effects of monoamines in the release of steroid hormones have also been observed. These have however in some cases been shown to be mediated via the release of the hormones in the hypophysis and the hypothalamus, but direct effects of monoamines on the steroid hormone producing organs have also been reported. Thus serotonin has been shown to stimulate the secretion of hydrocortisone by a direct effect on the adrenal gland (Verdesca *et al.* 1961) Direct effects of monoamines in the production of testosterone from the testis have also been reported (see Ellis 1969 Eik Nes 1969) Reserpine inhibits ovulation (see Meyerson and Sawyer 1968) This effect, which is blocked by MAO-inhibitors, has earlier been proposed to be mediated via the hypophysis. Recently however it has been reported that the effect, at least to some ex must be produced via a direct action on the ovary (France 1970) Si MAO-inhibitors have been shown to depress the weight and function reproductive system. This action appears to both via the

physis and via a direct effect on the sex organs (see Zor *et al.* 1966, Forbes 1970)

In the incubations with serotonin-^{14}C, there was a strong accumulation of radioactivity in the adrenal cortex. After pre-incubation with nialamide the uptake of serotonin-^{14}C was considerably lower in the adrenal cortex. It might therefore be possible that in this case MAO is responsible for the binding of the serotonin to the tissue. The histochemical MAO-method in fact involves a binding of the substrate to the MAO-containing tissues, where the substrate is then oxidatively deaminated. The uptake of serotonin-^{14}C may therefore partly be due to MAO in the tissues. In such tissues as the sympathetic ganglia, the intestinal mucosa, the epithelium of ductus deferens the bone marrow and the spleen, the activity was high, independent of MAO inhibition. In these cases additional factors are obviously of importance for the *in vivo* binding of serotonin. It must be observed that the incubations in the present investigation have been performed with sections which have been frozen and dipped in acetone. It is impossible to make comparison between the uptake of substances in the tissues under these conditions and the uptake under *in vivo* conditions. *In vivo* injected serotonin strongly accumulated in the adrenal medulla (see Ritzén *et al.* 1965) When whole-body sections from mice are incubated with DOPA-2-^{14}C, there is no accumulation of radioactivity in the adrenal cortex (Fig. 48) (Tjälve unpublished) DOPA does not serve as a substrate for MAO (see Chapter 5) The tissues accumulating the highest radioactivity in this case are the bone marrow and the intestinal mucosa.

They concluded that serotonin had a direct effect on the adrenal cortex, but they were unable to identify the reducing substance. It seems possible that the nitro-blue tetrazolium reduction was due to MAO-activity

Koelle and Valk (1954) observed an intense MAO-activity especially in the zona fasciculata of the adrenal cortex of the cat. The method used gave however an unspecific if considerably lower activity in control sections. Francis (1954) found an intense activity in singular medullar cells, possibly corresponding to ganglion cells in the guinea pig. The activity in the cortex was intense, but with the method used, not specific. Langemann (1951) found MAO-activity in both cortex and medulla of the adrenal of the ox. Martinez and Toledano (1968) observed MAO-activity in the adrenal cortex of the cat but no activity in the medulla.

In the testis the highest MAO activity was found in the interstitial cells. Also the epithelium of the epididymal duct and ductus deferens showed a rather high activity. The results are in agreement with investigations in the rat (Penttilä and Kormano 1968, Spano *et al.* 1968). The uptake of DOPA in these structures has been discussed in Chapter 5.

In the ovary the highest MAO-activity was present in the interstitial cells. Adrenergic nerves are rather numerous in and restricted to the interstitial tissue of the ovary (see Sjöberg 1967). The uptake of injected DOPA is highest in the follicle walls and corpora lutea (see Chapter 5), where the MAO-activity is low est.

Put together, there seems to be no correlation between the storage of monoamines or the uptake of DOPA and the occurrence of MAO in the steroid hormone producing organs. The same applies to the gastrointestinal tract. It is, however, obvious that monoaminergic mechanisms are present in the steroid *hormone producing organs*.

Effects of monoamines in the release of steroid hormones have also been observed. These have however in some cases been shown to be mediated via the release of the hormones in the hypophysis and the hypothalamus, but direct effects of monoamines on the steroid hormone producing organs have also been reported. *Thus serotonin has been shown to stimulate the secretion of hydro*cortisone by a direct effect on the adrenal gland (Verdesca *et al.* 1961). Direct effects of monoamines in *the production of testosterone from the testis* have also been reported (see Ellis 1969, Eik Nes 1969). Reserpine inhibits ovulation (see Meyerson and Sawyer 1968). This effect, which is blocked by MAO-inhibitors, has earlier *been proposed to be mediated via the hypophysis*. Recently however it has been reported that the effect, at least to some extent must be produced via a direct action on the ovary (France 1970). Several MAO-inhibitors have been shown to depress the weight and function of the reproductive system. This action appears to be mediated both via the hypo-

physes and via a direct effect on the sex organs (see Zor *et al.* 1966, Forbes 1970)

In the incubations with serotonin ^{14}C, there was a strong accumulation of radioactivity in the adrenal cortex. After pre-incubation with nialamide the uptake of serotonin-^{14}C was considerably lower in the adrenal cortex. It might therefore be possible that in this case MAO is responsible for the binding of the serotonin to the tissue. The histochemical MAO-method in fact involves a binding of the substrate to the MAO-containing tissues, where the substrate is then oxidatively deaminated. The uptake of serotonin-^{14}C may therefore partly be due to MAO in the tissues. In such tissues as the sympathetic ganglia, the intestinal mucosa, the epithelium of ductus deferens, the bone marrow and the spleen, the activity was high independent of MAO-inhibition In these cases additional factors are obviously of importance for the *in vitro* binding of serotonin. It must be observed that the incubations in the present investigation have been performed with sections, which have been frozen and dipped in acetone. It is impossible to make a comparison between the uptake of substances in the tissues under these conditions and the uptake under *in vivo* conditions. *In vivo* injected serotonin is strongly accumulated in the adrenal medulla (see Rutzén *et al* 1965) When whole-body sections from mice are incubated nh DOPA-2 ^{4}C, there is no accumulation of radioactivity in the adrenal cortex (Fig. 48) (Tjälve, unpublished) DOPA does not serve as a substrate for MAO (see Chapter 5) The tissues accumulating the highest radioactivity in this case are the bone marrow and the intestinal mucosa.

Studies on the uptake and metabolism of DOPA in the rabbit pancreas

As has been shown and discussed in Chapter 1 the injection of DOPA and 5-HTP into mice leads to a monoamine formation in the pancreatic islets. In the exocrine pancreas monoamines are formed in the zymogen granules (Alm *et al.* 1969 Alm 1969)

The present study was performed in order to investigate whether these circumstances are the same in the rabbit as in the mouse. The *in vitro* uptake and metabolism of DOPA in the rabbit pancreas was also studied. The reason for this investigation was the fact that rabbits were used as experimental animals in Chapter 8 where the *in vitro* effect of monoamines and monoamine precursors on the insulin release was studied

The investigation is divided into two parts. In the first part fluorescence microscopy is employed to study an eventual endogenous occurrence of monoamines, and the *in vivo* and *in vitro* uptake of DOPA in the rabbit pancreas. In the second part DOPA 2 ^{1}C is used for a chromatographic investigation of the *in vitro* metabolism of DOPA in the rabbit pancreas. Separate descriptions of the experiments in the two parts will be given followed by a common discussion for the two parts.

Part 1 Fluorescence microscopic investigation of the in vivo and in vitro uptake of DOPA in the rabbit pancreas.

Material and methods

Male pigmented rabbits of the Havanna strain, weighing about 2 kg were used. The rabbits were kept on a diet consisting of carrots, Swedish turnips and cabbage *ad lib* and were given free access to water

Six rabbits were used for the *in vivo* DOPA investigation and two were used for the *in vitro* DOPA investigation. In addition two rabbits were used for control of eventual endogenous fluorescence.

For the *in vivo* experiments L-DOPA (Sigma) was dissolved in physiological saline (100 mg/6 ml physiological saline) and immediately injected intravenously in an ear vein. The dose injected corresponded to 100 mg L-DOPA/kg body weight. Two rabbits were killed respectively 10 minutes, 1 hour and 2

hours after the injection by a sharp blow on the back of the head. They were then bled by decapitation and small pieces of the tail and the body of the pancreas were quickly removed and frozen in isopentane cooled with liquid nitrogen. The pieces were then freeze-dried, treated according to the Falck-Hillarp fluorescence method and subjected to fluorescence microscopy as has been described in Chapter 1

In the *in vitro* experiments pieces of the pancreas, weighing about 20 mg each, were taken from untreated rabbits, killed as described above. Each piece was put in 2 ml of a buffer solution, pH 7.4 of a composition which is described in Chapter 8 (p. 88) L-DOPA was added to the buffer to give a concentration of 10^{-4} M. The buffer was also supplemented with 3 mg/ml of glucose.

The pieces were then incubated for 30 minutes at 37.5 C in a Dubnoff shaker The incubations were gassed with O_2+CO_2 (95.5) After the incubation the pieces were rinsed for some seconds in a buffer solution not containing DOPA. They were then blotted on a filter paper freeze dried and treated for fluorescence microscopy as described (Chapter 1)

For control of endogenous fluorescence pancreatic pieces of two untreated animals were taken and handled for fluorescence microscopy

For identification of β-cells in the pancreatic islets the sections were stained with aldehyde fuchsin, as described by Jennings (1965) after they had been submitted for fluorescence microscopy

Results

In untreated animals a weak fluorescing network of varicose adrenergic nerve terminals could be observed in the islets (Fig 49) Fluorescing islet cells could not be observed. Adrenergic nerves could also be observed in connection to vessels.

10 minutes after the injection of DOPA there was a distinct green fluorescence in both, the endocrine and exocrine pancreas. In the endocrine pancreas all cells emitted a fluorescence of similar intensity In the exocrine pancreas there was a slightly stronger fluorescence over zymogen granules in the cells than over the rest of the cells.

One hour after the injection most cells in the islets showed a moderate cytoplasmic fluorescence (Fig 50) There were, however some cells which showed a stronger fluorescence. On the aldehyde fuchsin staining showed that these cells were B cells. In the exocrine pancreas the fluorescence was confined to zymogen granules and pancreatic ducts.

Two hours after the injection was essentially the same as after

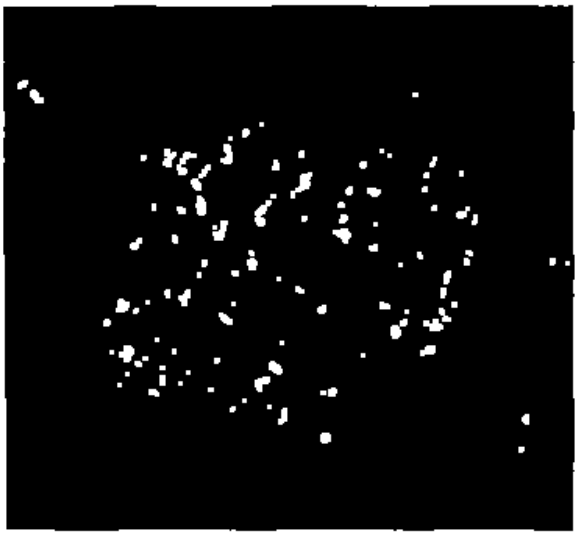

Fig. 19 Fluorescence photomicrograph of pancreatic islet of an untreated rabbit. A twork of varicose adrenergic nerv terminals can be seen in the islet. (×130)

one hour The fluorescence was, however a little weaker and the islet cells with stronger fluorescence were fewer after two hours than after one hour (Fig 51)

In the pieces incubated with DOPA *in vitro* there was a strong fluorescence in both the exocrine and endocrine pancreas (Fig 52) In the islets all cells showed the same high fluorescence. In the exocrine pancreas a stronger fluorescence was seen in the zymogen granules than in the rest of the cells.

Part 2. Chromatographic investigation of the in vitro metabolism of DOPA-2-^{14}C in the rabbit pancreas

Material and methods

Pieces of pancreas, weighing 20 mg each from two untreated Dutch rabbits were incubated for 30 minutes in 2 ml of the same buffer solution and under the same conditions as has been described in Part 1. In addition from labelled DOPA, DOPA-2-^{14}C was added to the incubation solution. The substance (DL-3(3,4-dihydroxyphenyl)alanine-2-^{14}C, specific activity 50–60 μC mg/5–6 mCi/mM) (The Radiochemical Centre Amersham, England) was added in a concentration of $2.5 \cdot 10^{-4}$ M corresponding to 6 μCi in the buffer solution.

After the incubation the pieces were rinsed for some seconds in a buffer solution not containing DOPA. They were then immediately homogenized in a Potter Elvehjem homogenizer extracted twice with acid ethanol (1 ml conc. HCl/1000 ml ethanol) and filtered. The acid ethanol extracts were evaporated in N_2. Small amounts of the extract were spotted on paper (What

man no 1) Descent chromatograms were run for 20 hours in phenol-0 1 N HCl (85 15 w/v) The front was at this time about 40 cm from the origin. Reference substances were chromatographed parallelly with the tissue extracts.

The radioactivity of the chromatograms was detected with the aid of a radiochromatogram scanner (Packard) and by autoradiography The x ray film used for the autoradiography was Structurix (Gevaert) The non radioactive reference substances used were visualized by spraying the chromatograms with a diluted solution of Folin-Ciocalteau phenol reagent, which produced blue spots on the exposure of the paper with ammonia fumes.

The extraction procedure was controled by measurement of the radioactivity of the residues on the filters in a liquid scintillation counter (Packard) For this purpose the residues were dissolved in 1 ml Soluene 100 (Packard) and transferred to liquid scintillation vials containing 15 ml of 0,5 % PPO and 0,05 % POPOP in toluene The activity in the residues was found to be very low

Results

Four radioactive spots were seen in the chromatograms with R_f-values corresponding to DOPA (0 09) noradrenaline (0 14) dopamine (0.30) and dihydroxyphenylacetic acid (0 49) (Fig. 53) Quantitation of the spots, other than estimation of the peaks obtained in the radiochromatogram scanner and by estimation of the blackening of the films, was not tried. From these estima-

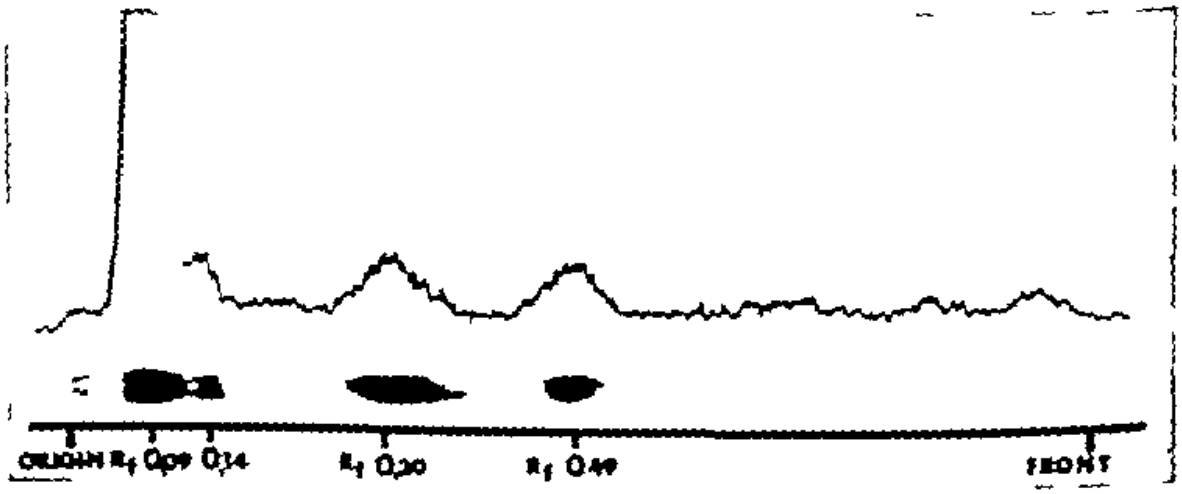

Fig 53 Diagram of radioactive paper chromatogram scanned in a radiochromatogram scanner (Packard) and autoradiogram of the same chromatogram. Tissue extract from pieces of rabbit pancreas incubated in buffer containing DOPA-2 ^{14}C was chromatographed in phenol-0.1 N HCl (85 15 w/) Four radioactiv spots with Rf-values corresponding to DOPA (0 09) noradrenaline (0 14) dopamine (0.30) and dihydroxyphenylacetic acid (0 49) ere egistered

tions, it as, however obvious that the DOPA-spot dominated, while the amounts of noradrenaline, dopamine and dihydroxyphenylacetic acid were of a smaller magnitude

Discussion

The results of the fluorescence microscopic investigation show that the *in vitro* uptake of DOPA in the rabbit pancreas is essentially the same as has been described in the mouse (see Chapter 1) In the islets an initial catecholamine formation takes place in all islet cells. The catecholamines then disappear first from the β-cells, leaving the α-cells with the highest catecholamine concentration.

In untreated rabbits a network adrenergic nerves could be observed within the islets. Cegrell (1968) showed similar networks in the golden hamster dog and cat, but could not demonstrate them in the rabbit. The reason for this discrepancy might be that the fluorescence as it was observed in the present investigation, is weak and is only visible under optimal fluorescence conditions. The islets of the rabbits have also been shown to be richly innervated with hollinergic nerves (Coupland 1958, Lihman and Sutherland 1965)

The results from the *in vitro* fluorescence microscopic investigation indicate that the monoaminergic mechanisms observed *in vivo* also function *in vitro* Fluorescence was observed in all islet cells. In the exocrine pancreas a stronger fluorescence was seen over the zymogen granules than in the rest of the cells. The parafollicular cells of the thyroid and the enterochromaffin-like cells of the stomach have similarly been shown *in vitro* to possess functioning monoaminergic mechanisms when the tissues are incubated with the monoamine precursors (Owman and Sundler 1967 Håkanson *et al.* 1969 b)

The results from the *in vitro* chromatographic investigation show that both dopamine and noradrenaline are formed. Apart from the fluorescence methods, the catecholamine formation *in vitro* has also been studied with chromatographic methods. *In vitro* the injection of DOPA into mice has thus been shown to give a dopamine formation in the pancreas (Rosell *et al* 1963) and the injection of dopamine into rats has been shown to give a formation of noradrenaline (Symchowicz *et al* 1968 The formation of noradrenaline from dopamine probably takes place in the adrenergic nerves as has been shown to be the case in rat adrenal gland Jonason 1969)

The dihydroxyphenylacetic acid is formed as a result of the action of MAO on dopamine. As has been shown (Chapter 1) MAO is present in the parenchymal cells of both the exocrine pancreas. Dopamine is a better substrate for MAO than (Weiner 1960) The *in vivo*

catabolism of dopamine has also been shown to proceed at a higher rate than the catabolism of noradrenaline in rat salivary glands and in rabbit brain *in vitro* (Jonason and Rutledge 1968 Jonason 1969) In the rat salivary glands the extraneuronal MAO seems to be of greatest importance in the catabolism (Jonason 1969) The same should be the case in the pancreas.

The catabolism through the action of COMT seems in the present investigation to be of lesser importance than the catabolism through the action of MAO This was also the case in the rat salivary glands and the rabbit brain *in vitro* (Jonason and Rutledge 1968 Jonason 1969)

In the present investigation radioactive DL-DOPA was used. Dopamine is not obtained from the D-form and therefore the radioactive DOPA-spot on the chromatograms should contain more D- than L-DOPA.

CHAPTER 8

Radioimmunological studies on the effect of catechol and indolamines and of their precursors on the insulin secretion from rabbit pancreas *in vitro*

The capability of the pancreatic islets, the parafollicular cells of the thyroid and the enterochromaffin cell system of the gastrointestinal tract, to form and store biogenic amines, has led to the mentioned assumptions that the biogenic amines might be of importance in the formation storage and/or release of the hormones formed in these cell systems. Effects of monoamines on the release of insulin have also been shown (see Chapter 1 and Discussion). This has been possible with the use of radioimmunological methods for hormone estimation.

The introduction of methods for the estimation of insulin levels by means of radioimmunoassay was made by Yalow and Berson (1960). The method allows a precise and reliable estimation of insulin secretion *in vivo* and *in vitro*. Several investigations of the effect of a variety of substances on the insulin secretion have been performed. Radioimmunological methods for the estimation of hormones other than insulin have also been developed, but these methods are still difficult to use and the number of such investigations few as yet.

In the present work a radioimmunological method (Hales and Randle 1963) has been used to study some parameters of the monoamine and the monoamine precursor influence on the insulin release.

The investigation has been performed on rabbit pancreas *in vitro*. The *in vitro* method used is the one described by Coore and Randle (1964). The rabbit pancreas has been shown to be especially suitable for *in vitro* studies of this type, mainly due to the high concentration of insulin in the pancreas relative to that of other species (Marks and Young 1960). An *in vitro* preparation has been chosen to avoid influences on the insulin secretion of other organs which might occur *in vivo* upon injections of monoamines or monoamine precursors.

Material and methods

Procedure

Male pigmented rabbits of the Havanna strain were used. The weight of the animals was about kg and they were kept under the same conditions as described in Chapter 7. Approximately 30 animals were used.

The rabbits were killed by a sharp blow on the back of the head and then bled by decapitation. The tail and the body of the pancreas were rapidly removed and dropped into a Petri dish containing an ice-chilled medium of the same composition as in the incubations (see below). After trimming the pancreas of blood vessels and mesentery it was divided into 10—16 pieces, weighing about 20 mg each. Each piece was placed in an Erlenmeyer flask in 2 ml of the buffer (see below). They were then incubated in a Dubnoff shaker at 37.5° C for 30 minutes before the incubation used for the radioimmunoassay commenced. This pre-incubation was found to be necessary to establish a steady rate of insulin secretion.

After the pre-incubation each piece was transferred with forceps to new flasks and was taken individually through a series of three incubations of 30 minutes duration each. The first of these flasks contained 2 ml of the same medium as in the pre-incubation-flasks. The flasks used for the second and the third incubations were supplemented with substances, the effects of which on the insulin release were to be investigated. These flasks contained an, between themselves, identical medium. Between each individual incubation period the pieces were rinsed for 15 seconds in a small quantity of the medium in which they were to be incubated. At least four pieces of pancreas were treated identically for each substance during a series of incubations.

Insulin which had been secreted into the medium was measured after removal of the pancreas from the flask. The insulin content in the first medium was used as a control. The insulin content in the second and the third incubation solution was then compared with that in the first solution. The amount of insulin in these solutions was expressed as percentage of the content in the first solution. This was done in order to avoid errors caused by the variation in insulin-output between different pieces, depending on their varying number of islets. This variation in turn is caused by an irregular distribution of the islets dispersed among the cells of the exocrine pancreas. In spite of the fact that the islets only form a small proportion of the total pancreatic mass, the preparation used has been found to be very useful for *in vitro* studies of insulin release (see Discussion and Results).

Incubation medium

The medium used for all incubations was a bicarbonate-buffered salt solution pH 7.4 (Krebs 1950) of the following composition (m-equiv/l): Na^+ 141.0 K^+ 5.9 Ca^{2+} 5.1 Mg^{2+} 2.4 PO_4^{3-} 2.2 SO_4^{2-} 2.4 HCO_3^- 24.9 Cl^- 109.6 pyruvate 4.9 glutamate 4.9 and fumarate 5.4. This composition was obtained by mixing the following chemicals with distilled water to a volume of one liter:

$MgSO_4$ 144 4 mg CaCl 283 3 mg KCl 440.3 mg Na pyruvate 538.9 mg Na-glutamate 468.1 mg Na fumarate 437.3 mg Na_2PO_4 12 H_2O 279.5 mg NaHCO 2090.8 mg and NaCl 5763 0 mg The buffer was supplemented with 1 mg/ml of bovine albumin, fraction V (Sigma) The albumin serves the double purpose of preventing adhesion of insulin to the walls of the vessels used and of diminishing the breakdown of insulin caused by the enzymes of the exocrine pancreas (see Candela and Coore 1967) The media were also supplemented with glucose in the concentration of 3 mg/ml for most incubation series and 0 6 mg/ml for some other incubation series. The incubations were gassed with $O_2 + CO_2$ (95 5)

Substances investigated

The effects on the insulin secretion of the following substances (in the concentrations given in the figures in the results) were studied* L-DOPA, D-DOPA, dopamine noradrenaline, L-5-HTP serotonin (serotonin creatinine sulphate) L-tyrosine, L tryptophan, dihydroxyphenylacetic acid (DOPAc) L-DOPA + the DOPA-decarboxylase inhibitor MK 485 (DL-α-hydrazino-α-methyl-3 4-dihydroxyphenylpropionic acid) L DOPA + the dopamine β-hydroxylase inhibitor DDTC (Na-diethyldithiocarbamate, Fluka AG Buchs, Switzerland) L-DOPA + the α-receptor blocking substance phenoxybenzamine (phenoxybenzamine hydrochloride, (Dibenyline) Smith Kline and French Labs, Ltd Herts, England) L-DOPA + the β-receptor blocking substance H56/28 (1 (o-allylphenoxy) 3-isopropylamino-2 propanol hydrochloride (Aptin) AB Hässle, Mölndal Sweden) L-DOPA + the β-receptor blocking substance propanolol (propanolol hydrochloride, ICI Macclesfield England) 5-HTP + MK 485 noradrenaline + phenoxybenzamine adrenaline, adrenaline + phenoxybenzamine and adrenaline + H56/28. The effects of MK 485 DDTC phenoxybenzamine, H56/28 and propanolol were also investigated separately in the concentrations which were used in the combinations with the monoamines and the monoamine precursors.

The effects of L-DOPA and noradrenaline on the insulin secretion were also studied as described, using pancreatic pieces from two rabbits treated with 6-hydroxydopamine (6OH-dopamine) (100 mg/kg intravenously) 1 hours before they were killed. 6OH-dopamine has been shown to cause a selective destruction of adrenergic nerve terminals (Thoenen and Tranzer 1968) with rapidly occurring and long lasting inability of storage and uptake of noradrenaline (Jonsson and Sachs 1970)

* The substances were obtained from Sigma Chemical Co, USA, unless otherwise stated

Measurement of insulin

The concentration of insulin in the incubation medium was measured by radioimmunoassay according to the double antibody technique described by Hales and Randle (1963) The radioimmunoassay was initiated immediately after the incubations. The method is based on the competition of insulin in the sample to be assayed and of radioactive insulin for reaction with an antibody which is specific to insulin. The amount of radioactive insulin bound to antibody therefore varies inversely with the concentration of insulin in the assay sample. In the present method the complex of insulin and anti insulin is rendered insoluble by a second antibody The precipitate obtained is separated from free insulin by filtration. The concentrations of insulin in the samples were found by referring to standard curves prepared from measurements on pure rabbit insulin. Twice crystallized rabbit insulin was used (supplied by Novo Research Institute, Copenhagen, Denmark) The antibodies (insulin binding reagent) and the ^{125}I insulin, which were used, were supplied by the Radiochemical Centre Amersham, England.

The precipitates in the solutions were collected by filtration through Milli pore cellulose acetate membrane filter discs (Oxoid Ltd, England) The radioactivity in the filter discs was measured by liquid scintillation counting After the filtration the filters were transferred to empty counting vials and dried 20 ml of a scintillant of the following composition was then added to each vial ethanol 150 ml, dioxan 300 ml, naphtalene 50 g, POP 5 g toluene to 1 litre. The vials were then transferred to a liquid scintillation counter (Packard) for determination of radioactivity For each sample the filter discs in the immunoassay clean filters for background count rate determination and unfiltered samples of iodinated insulin for total count-rate determination were counted.

The filter discs in the immunoassay were obtained from the unknown insulin solutions, the standard insulin solutions and from samples to which no unlabelled insulin was added (Zero for control of the total insulin binding capacity of the antibodies) The filtration procedure was controlled by the counting of filters from samples to which no insulin binding reagent had been added. The assays were always performed in duplicate samples.

Calculation and expression of result

The count rate for each determination was expressed in counts per minute. Computation of the mean count rates for replicates was then made. The amount of bound iodinated insulin (as given by the observed count rate) at each concentration of insulin in the standards and for the Zero was plotted

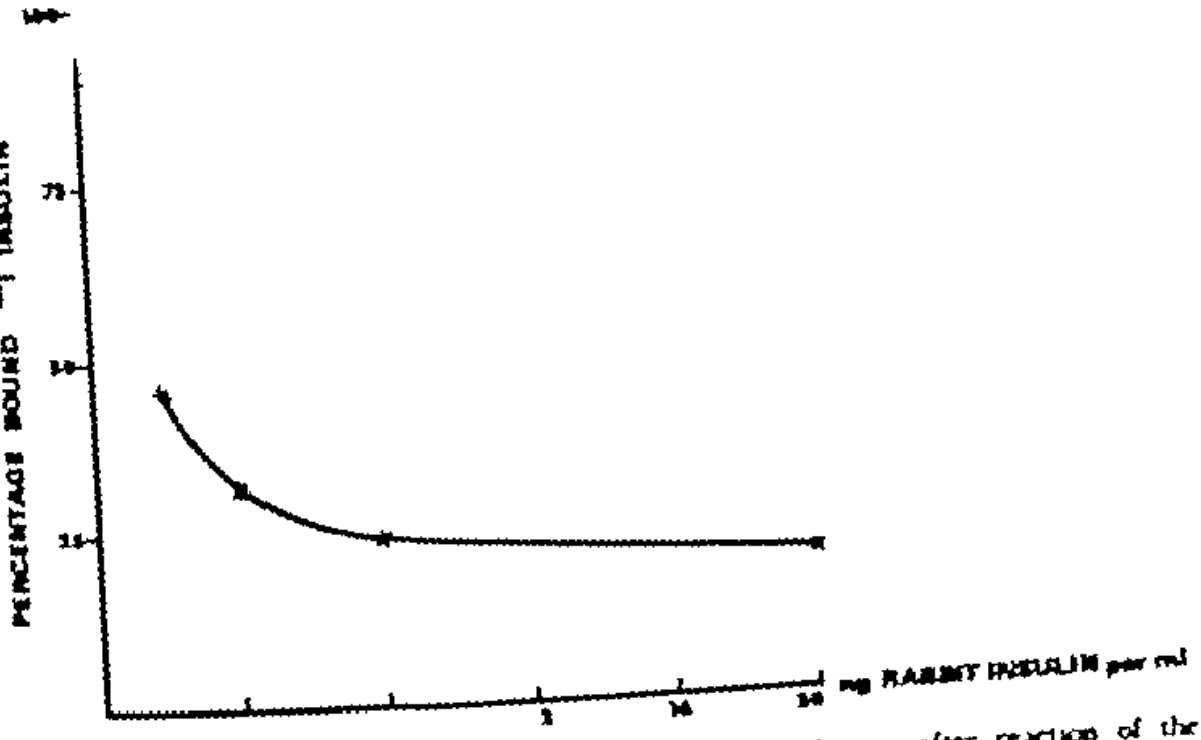

Fig. 54 Binding of ^{125}I-insulin in insulin-antibod precipitate after reaction of the insulin-antibodies with solutions containing differen amounts of rabbit insulin (the antibodies for this curv were from batch N 9996, /The Radiochemical Centr /)

on a graph. The concentration of insulin in each of the unknowns could then be read directly from th graph (see Fig 54)

The effect of the substances on the insulin secretion was calculated as follows

The mean concentration of insulin in the second and the third incubation solution compared with the insulin concentration of the first incubation solution The differences were expressed as percentage of insulin in the second and th ird solution in relation to the first solution. Student t test was used for the tistical evaluat on of the differences

Ve erification of the reliabil ty of th method incubations of pancreatic piece er performed in suc cessiv 30 minut periods in media containing in- er a e amount of glucose which is known to be the major stimulus of in- sulin sec etion. An increase of glucose f rm 0.6 mg/ml to 3.0 mg ml caused an rease in the radioimmunologically measurabl ins lin of a magnitude of abo t seven times. When panc e tic pieces were incubated for consecutive 30 m tr periods w th th same glucose content in the incubation solutions, the

L-DOPA-effect. Both phenoxybenzamine and H56/28 inhibit the secretion of insulin to some extent (Fig. 59). The β-receptor blocking substance propanolol strongly stimulates the insulin secretion and this effect is still observable in the presence of L-DOPA (Fig. 59).

As was the case for L-DOPA, noradrenaline inhibits the insulin secretion also in the presence of phenoxybenzamine (Fig. 60).

Adrenaline was found to inhibit the insulin secretion (Fig. 60). This effect

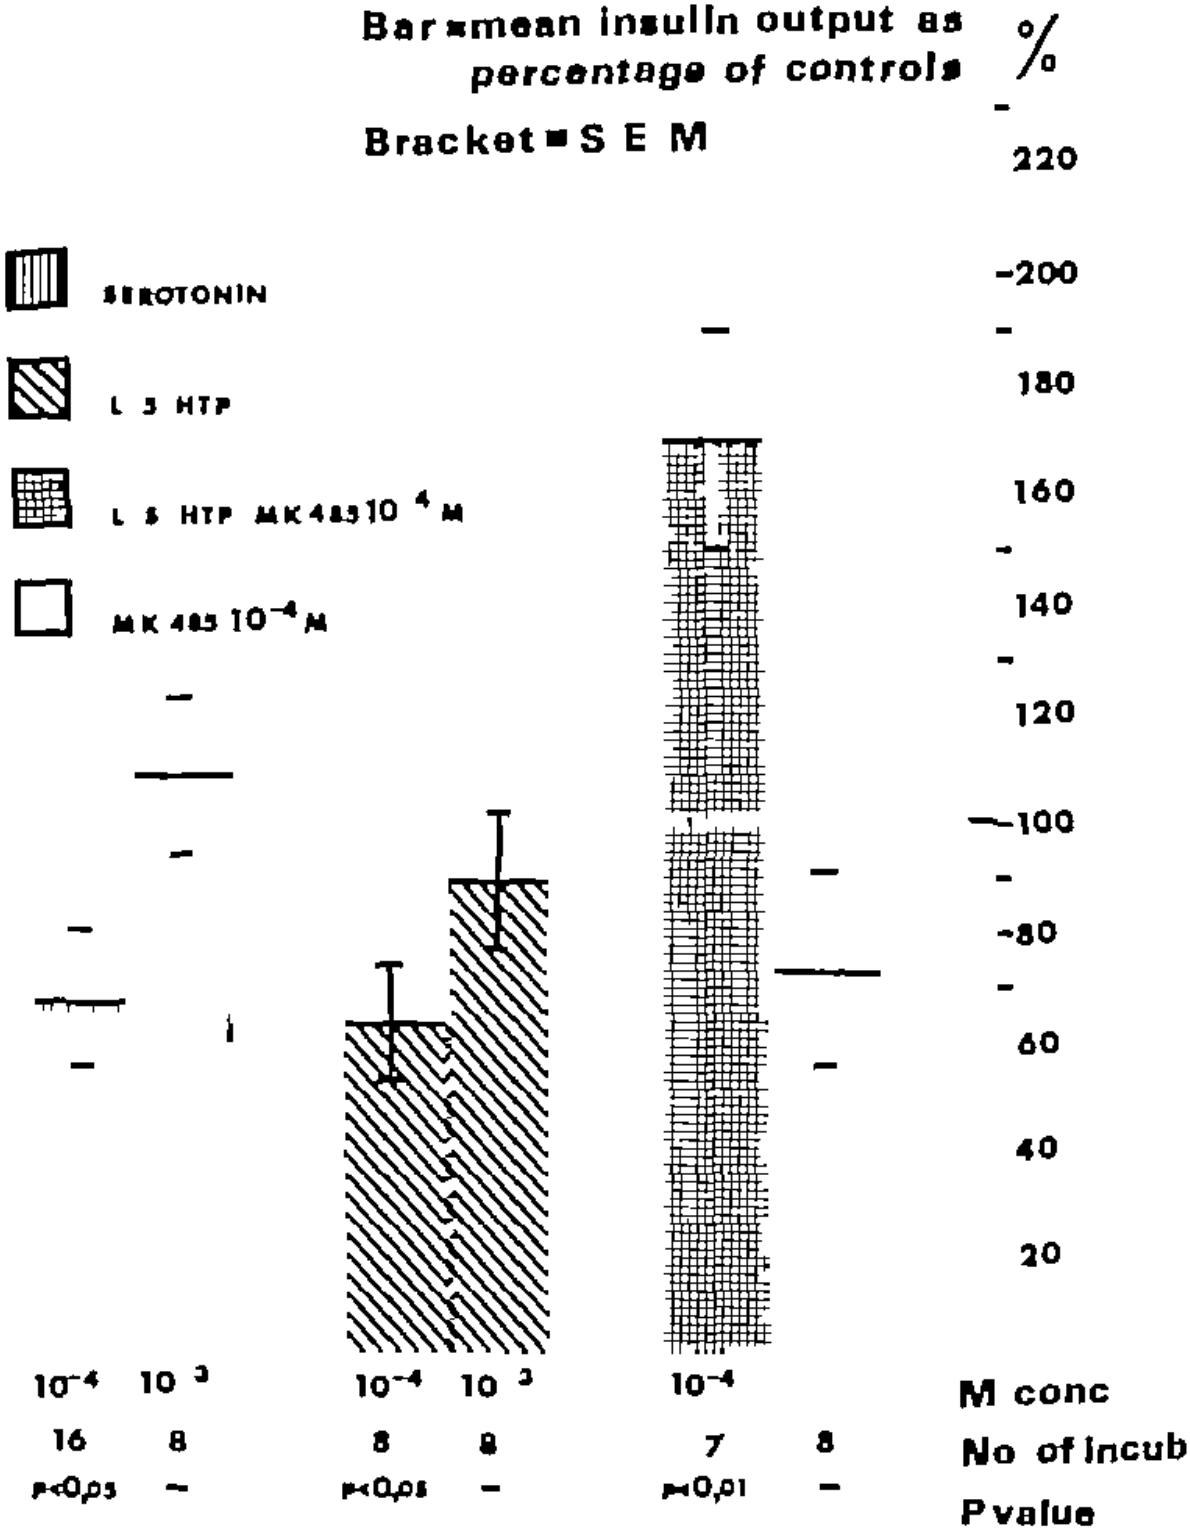

Fig. 61 *Effect of* different concentrations of serotonin and L-5-HTP in the incubation solutions and of L 5-HTP in combination with 10 M Mk 485 in the incubation solutions on the insulin release from pieces of rabbit pancreas *in vitro* The effect of 10^{-4} M Mk 485 (DOPA-decarboxylase inhibitor) on the insulin release is also given. substances had no effect on the insulin secretion. When L-5-HTP in a concentration of 10 M was incubated together with MK 485 the inhibiting effect observed on the insulin secretion without MK 485 had changed to a stimulating effect (Fig. 61).

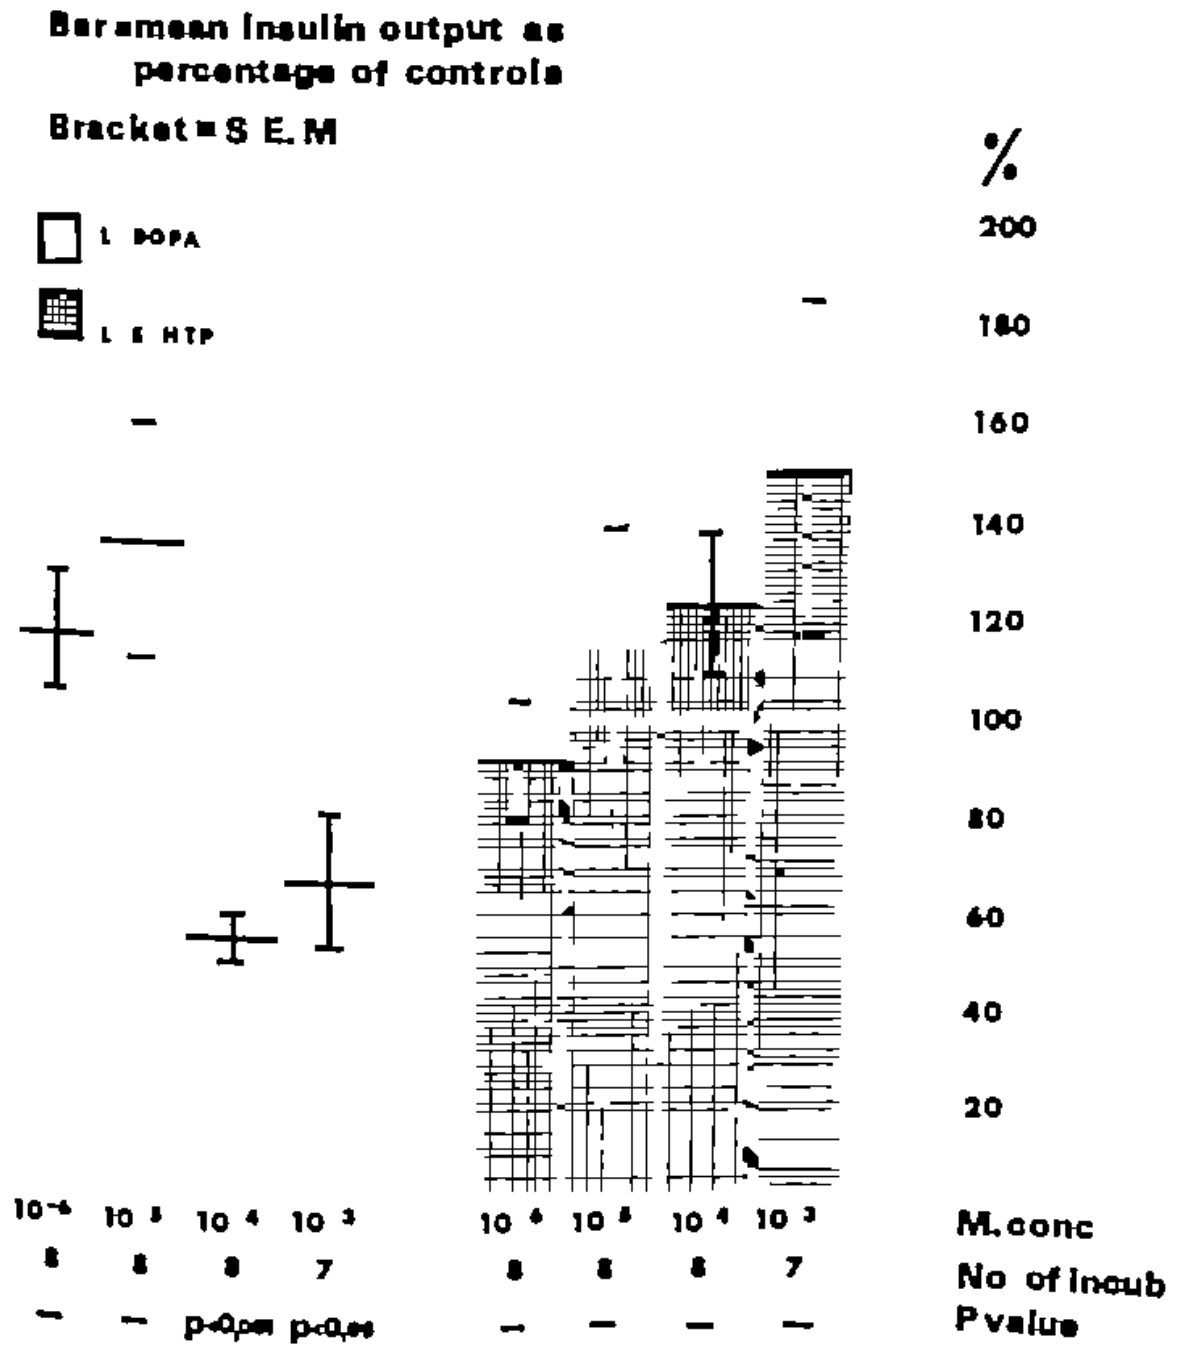

Fig. 64. Effect of different concentrations of L-DOPA and L-5-HTP in the incubation solutions on the release of insulin from pieces of rabbit pancreas *in vitro*. Glucose-concentration in the incubation solutions 0.6 mg/ml.

L-tyrosine in a concentration of 10^{-4} M had no effect on the insulin secretion. In a concentration of 10^{-3} M and 10^{-2} M, it stimulated the insulin secretion (Fig. 62). L-tryptophan in a concentration of 10^{-4} M and 10^{-3} M inhibited the insulin secretion to some extent (Fig. 62).

Dihydroxyphenylacetic acid (DOPAc) was found to have no effect on the insulin secretion in a concentration of 10^{-4} M (Fig. 62).

The results of the incubations performed on the 60H-dopamine pre treated rabbits are shown in Fig 63 As can be seen both L-DOPA and noradrenaline in the concentrations tried, inhibit the insulin secretion also in this case.

Glucose concentration 0.6 mg/ml

In the concentrations of 10^{-4} M and 10^{-3} M L-DOPA also had an inhibiting effect when the glucose concentration was 0 6 mg/ml (Fig 64) The incubations with L-5-HTP on the other hand indicated a small stimulating effect on the insulin secretion, although this effect was not statistically significant (Fig. 64)

Discussion

The preparation used in the present investigation has been shown to be very useful for the study of the *in vitro* release of insulin. This preparation, which was originally introduced by Coore and Randle (1964) has been used in several investigations. Telib and Pfeiffer (1970) especially studied the dynamics of insulin secretion using this *in vitro* preparation. They found a constant insulin secretion for five hours when pancreatic pieces were incubated in consecutive periods in solutions containing the same substances. When the effect of certain substance on the insulin secretion has been studied, it has been found to be most reliable to use the first incubation as a control and compare the obtained insulin secretion with the secretion in the following incubations, where the substance is present (see Coore and Randle 1964 Hales and Milner 1968 Telib and Pfeiffer 1970) This is the most appropriate way to express the results, because variation in the number of islet per piece causes variation in the absolute amount of insulin secreted by the different pieces. When, as in the present investigation, insulin is measured in an incubation medium, the immunological reaction between insulin and antibody has been found to be remarkably robust in tolerating without alteration in reaction considerable changes in the composition of the incubation medium (see Hunter 1968)

From the results it is obvious that the incubation of pancreas in the presence of L-DOPA causes a strong inhibition in the secretion of insulin. As was shown in Chapter 7 both dopamine and noradrenaline are formed in the pancreas under these circumstances. D-DOPA, which is not decarboxylated, does not inhibit the insulin secretion.

When the DOPA-decarboxylase inhibitor MK 485 is present in the incubation solution, the inhibitory effect of L-DOPA is blocked. This indicates that dopamine or noradrenaline are responsible for the effect. Both dopamine

and noradrenaline were also found in the pre
inhibiting effect on the insulin secretion.

Injections of L-DOPA into mice and rabb t
hyperglycaemia, which has been proposed to be
son *et al.* 1967 b Hayashi *et al.* 1968) When the
inhibited, the hyperglycaemia was abolished The
findings in the present investigation.

In the presence of MK 485 L-DOPA actually
tion to some extent. This might be explained by
L-DOPA. Most amino acids are known to have a
insulin secretion (Floyd *et al.* 1966 Edgar *et al.* 1969 M
1970)

When L-DOPA was incubated in the presence of the dopamine β-hydroxylase inhibitor DDTC, the inhibitory effect of L-DOPA persisted. This indicates that the formation of noradrenaline is not necessary for the inhibition of the insulin secretion. A dopamine formation occurs in the pancreas both *in vivo* and *in vitro* after the administration of L-DOPA and this probably takes place both in the islets and in the exocrine pancreas, while a formation of noradrenaline only seems to occur in the adrenergic nerves (see Chapter 1 5 and 7) In line with the assumption that a formation of noradrenaline is not necessary for the inhibitory effect of L-DOPA, is the observation that this effect was not influenced by the prior administration of 6OH-dopamine to the rabbits. 6OH-dopamine is known to specifically abolish the capability of the adrenergic nerves to form and store catecholamines (Thoenen and Tranzer 1968, Jonsson and Sachs 1970) The inhibitory effect of noradrenaline was also present after 6OH-dopamine-pre treatment. 6OH-dopamine, however does not affect the adrenergic receptor sites (Thoenen *et al.* 1970) and the effect of exogenous noradrenaline therefore persists also after 6OH-dopamine pre-treatment.

Adrenaline was in the present investigation also shown to cause an inhibition of the insulin secretion.

The inhibitory effect of catecholamines on the insulin secretion has been observed earlier Coore and Randle (1964) observed an inhibitory effect of adrenaline in the rabbit. Porte and co-workers ha studied the inhibitory effect of adrenaline and noradrenaline in man (see Port *et al.* 1965 Porte and Williams 1966 Port 1969) The inhibitory effect of adrenaline and noradrenaline has also been shown in rat and mouse (see Malaisse *et al.* 1967 Loubatières *et al.* 1967 Lernmark and Hellman 1970) Wong *et al.* (1967) showed an inhibitory effect of dopamine, noradrenaline and adrenaline in the rabbit.

In the present investigation L-5-HTP and serotonin were found to inhibit

the insulin secretion in a glucose concentration of 3 mg/ml in the medium. This effect could be observed in a concentration of 10^{-4} M of L-5-HTP and serotonin, but not in a concentration of 10^{-4} M. When MK 485 was present in the medium L-5-HTP stimulated the insulin secretion. It thus seems probable that the effect of L-5-HTP is due to an inhibitory effect of serotonin formed in the pancreas from L-5-HTP. The stimulatory effect of L-5-HTP in the presence of MK 485 might, as with L-DOPA, be an amino acid-effect of L-5-HTP. In a glucose concentration of 0.6 mg/ml L-5-HTP in a concentration of 10^{-3} M had a small stimulating effect on the insulin secretion.

The effect of serotonin on the insulin secretion has earlier been studied in the rabbit and the golden hamster (Telib *et al.* 1968, Feldman and Lebovitz 1970 a, b, c). Telib *et al.* (1968) who studied the insulin secretion from rabbit pancreas *in vitro* found that when the glucose concentration was 3 mg/ml, serotonin, in one concentration, corresponding to 10^{-4} M in the present investigation, inhibited the insulin secretion, while it had a stimulating effect in a higher concentration. In the absence of glucose in the medium serotonin had a stimulating effect on the insulin secretion. In *in vitro* experiments in golden hamster serotonin, in a concentration of 10 M and with a glucose concentration of 3 mg/ml in the medium, had an inhibitory effect on the insulin secretion (Feldman and Lebovitz 1970 a). The results of these investigations thus largely support the findings in the present investigation.

It is interesting to notice that dopamine probably in itself inhibits the insulin secretion.

The observation that dopamine not only is a precursor of noradrenaline and adrenalin but also might have a function of its own, was first clearly expressed by Blaschko (1957). There is now considerable evidence that dopamine has a specific function, both in the central nervous system and in the periphery (see Klawans 1968). Serotonin has also been demonstrated to have many functions separate from the functions of catecholamines (see Garong and Lorenzen 1967).

The capability of the cells of the pancreatic islets to store and form dopamine and serotonin together with the observation that dopamine and serotonin affect the insulin secretion might indicate that these two amines play a role in the intrinsic regulation of the hormone production by these cells.

As has been demonstrated in the present investigation and in several earlier investigations, noradrenaline and adrenaline, however also affect the insulin secretion. As has been shown in Chapter 7 the islets of the rabbit in addition are richly innervated with adrenergic nerves. Also in other species, such as golden hamster cat and dog the islets are richly innervated with adrenergic nerves (Cegrell 1968).

Besides the adrenergic innervation, the islets of cat, rat, rabbit, golden hamster and guinea pig have been shown to be richly innervated with cholinergic nerves (Coupland 1958, Libman and Sutherland 1965). Stimulation of the vagus nerve and administration of parasympathomimetic agents have been shown to cause a stimulation of the insulin secretion (Kaneto *et al.* 1967, 1968; Malaisse *et al.* 1967; Mayhew *et al.* 1968).

It thus seems probable that the sympathetic and parasympathetic nervous systems also may influence the insulin secretion.

Another interesting fact is that the islet cells of the rabbit have been demonstrated to have a strong positive reaction for both true and pseudocholinesterase (Coupland 1958). True or pseudocholinesterase have also been demonstrated in the parafollicular cells and the enterochromaffin cells in many species (see Pearse 1968). Pearse correlates these findings with high levels of phospholipid synthesis in the cells. Another possibility is that acetylcholine plays a role in the intrinsic regulation of the polypeptide hormone production in these cells.

In addition injected atropine has been shown to be accumulated in the pancreatic islets, the parafollicular cells and the enterochromaffin cell system in mice (Albanus *et al.* 1968; Slanina and Tjälve, in preparation).

Since the actions of monoamines and acetylcholine in connection with neuronal functions are assumed to be based on the changes they induce in the permeability of membranes, a similar function might be present also in extraneuronal tissues. Dopamine, serotonin and acetylcholine might be functionally integrating with each other within the cells. The possibility of a synergistic effect of several biogenic amines in these cells has been discussed by Ullberg and Hammarström (1969). The possible role of acetylcholine in regulation of membrane permeability and active transport has been discussed by Koelle (1963).

It is interesting to notice that dopamine and serotonin have been shown to affect the release of the hypothalamic releasing factors such as FSH-releasing factor, LH releasing factor and luteinizing hormone releasing factor (see Kamberi *et al.* 1970, Schneider and McCann 1969 a, b, 1970). Dopamine and serotonin have also been reported to affect the release of ACTH from the hypophysis (Gromova *et al.* 1967; King and Thomas 1968, King 1969).

The inhibitory effect of adrenaline and noradrenaline on the insulin secretion has been shown to be affected by α- and β-receptor blocking substances. In most cases the α-receptor blocking agents have been reported to abolish the inhibitory effects, while in the presence of β-receptor blocking agents, the inhibitory effects persist (see Malaisse *et al.* 1967; Porte 1969).

As adrenaline and noradrenaline are known to affect the generation of 3'5' cyclic AMP (adenosine-3'5' cyclic phosphate), it has also been proposed that

their effects on the insulin secretion might be mediated via this mononucleotide (see Robison *et al.* 1968) Exogenous 3 5 cyclic AMP and substances, such as theophylline, which increase the endogenous content of 3 5 cyclic AMP have been shown to stimulate the insulin secretion in the rat (Sussman and Vaughn 1967 Turtle *et al.* 1967) A lowering effect of adrenaline on the endogenous 3'5 cyclic AMP level in pancreatic islets of the rat, has been shown to be blocked by phenoxybenzamine (α-blocker) (Turtle and Kipnis 1967) Phenoxybenzamine was also shown to prevent the inhibitory effect of adrenaline on the insulin secretion. In conclusion, these findings might indicate that the effect of adrenaline and noradrenaline on the insulin secretion are mediated via generation of 3 5 cyclic AMP which in turn takes place via an action of adrenaline and noradrenaline on α and β-receptors.

Recently data have been presented on the inhibitory mechanism of action of adrenaline and serotonin on the insulin secretion, which indicate that these substances act rather via a specific receptor site on the islet β-cells, than via a generating action on 3 5 cyclic AMP (Feldman and Lebovitz 1970 c)

In the present investigation it was found that the inhibitory effect of L-DOPA and catecholamines on the insulin secretion was blocked by H56/28 (β-blocker) but was not affected by phenoxybenzamine (α-blocker) Propanolol was found to be a potent stimulator of the insulin secretion in itself

The effects reported of β-receptor blocking agents are very divergent. In some investigations in the rat, propanolol has been reported as in the present investigation, to cause a stimulation of the insulin release (Sussman *et al* 1967 Mariani *et al.* 1969 a) In studies in intact mouse, dog and man an impairment in the insulin secretion has been reported after the administration of β-receptor blocking agents (Bressler *et al.* 1969 Sirek *et al.* 1969 Cerasi *et al.* 1969) The hypoglycaemic effect of tolbutamide has been reported to persist after block of the β-receptors in rabbit, but not in man and mouse (Erill 1969 de Divitis *et al.* 1968 Bressler *et al.* 1969) In man there are several reports of hypoglycaemia as a result of the administration of propanolol (Kotler *et al.* 1966, Abramson *et al.* 1966, Simpson 1967 Machintosh 1967) In the rabbit propanolol has been shown to cause hypoglycaemia and to increase the hypoglycaemic response to insulin (Calvey and Summerill 1968)

In the present investigation it was observed that phenoxybenzamine blocked the inhibitory effect of L-DOPA and catecholamines. Phenoxybenzamine was also in itself observed to have a small inhibitory effect on the insulin secretion. An inhibitory effect of phenoxybenzamine has also been reported on an isolated perfused rat pancreas preparation (Mariani *et al.* 1969 b) In intact man and mouse α-receptor blocking agents have been reported to cause a stimulation of the insulin secretion (Cerasi *et al* 1969 Bressler *et al.* 1969) In the rabbit

the α-receptor blocking substance phentolamine has been shown to cause hyperglycaemia, while in rat, dog and man it has been shown to cause hypoglycaemia (Trapold *et al.* 1950 Sherif *et al.* 1957 Salvador *et al.* 1968, Calvey and Summerill 1968) In the rabbit phentolamine also reduces the hypoglycaemic response to insulin (Calvey and Summerill 1968)

A possible explanation for the varying results reported by different authors on the effects of adrenergic blocking agents on the insulin secretion may be, that if their effects are truly manifestations of adrenergic blocking actions, the types of adrenergic receptors, which mediate the insulin release, vary from species to species. It is also possible that the results reported from intact organisms are due to metabolic effects, which secondarily may affect the insulin secretion.

L-tyrosine was in the present investigation found to have a stimulatory effect on the insulin secretion, while L-tryptophan inhibited the insulin secretion to some extent. As has been mentioned most amino acids have been reported to stimulate the insulin secretion (Floyd *et al.* 1966 Edgar *et al.* 1968 Milner 1970 Feldman and Lebovitz 1970 b) In *in vitro* investigations a condition precedent for the effects of amino acids on the insulin secretion has been shown to be the presence of glucose in the incubation medium (Edgar *et al.* 1969 Milner 1970) There seems to be some species variation in the insulin response to amino acids. Tryptophan has been shown to cause a stimulation of the insulin secretion in golden samster (Feldman and Lebovitz 1970 b) an effect which could not be demonstrated in the present investigation, nor in another investigation in the rabbit (Milner 1970) In the rabbit phenylalanine has been shown to have an inhibitory effect on the insulin secretion (Milner 1970)

Summary

In recent years the interest has been focused on extraneuronal localizations and functions of catechol- and indolamines. Special attention has been paid to the ability of some endocrine cell systems, such as the pancreatic islets, the para follicular cells of the thyroid and the enterochromaffin cell system of the gastrointestinal tract, to form and store dopamine and serotonin. It has been assumed that catechol and indolamines might play a role in the regulation of the polypeptide hormones, which are known to be or assumed to be produced by these cell systems.

The present work has been performed to elucidate some of the extraneuronal localizations and functions of catechol and indolamines and then especially the localization and function in the mentioned endocrine cell systems.

The formation of dopamine and serotonin in the pancreatic islets, the parafollicular cells of the thyroid and the mucosa of the stomach after administration of the monoamine precursors dihydroxyphenylalanine (DOPA) and 5-hydroxytryptophan (5-HTP) into mice was studied with microautoradiography fluorescence microscopy and combined microautoradiography fluorescense microscopy (Chapter 1—3) The combination of microautoradiography and fluorescence microscopy allowed a concomitant demonstration of catechol- and indolamines in the cells.

It was found that there was a good correspondence between the localization of dopamine and serotonin in these cell systems.

The monoamines were rapidly formed in the cells after the injection of the precursors.

In the islets all cells contained monoamines shortly after the injection. Later the monoamines disappeared first from the β-cells. Some α-cells contained more monoamines than others. The enzyme monoamine oxidase (MAO) which was demonstrated by a histochemical method appeared to have the strongest activity in the cells from which the monoamines first disappeared. In the stomach endogenous fluorescence was present in mast cells in the fundic gland area and in enterochromaffin cells in the pyloric gland area. After injection of the precursors, monoamines seemed to be formed in these two cell types as well as in the so called enterochromaffin-like cells of the fundic gland area.

The combination of microautoradiography and fluorescence microscopy showed that the same cells in the pancreatic islets, in the thyroid and in the stomach formed catechol and indolamines after the injection of the precursors.

With electron microscope autoradiography it was shown that the incorporation in the fundic gland area took place in enterochromaffin cells of two types (Chapter 4). The silver grains were found predominantly over the specific granules in the cytoplasm of the cells.

Whole-body autoradiography was used to compare the distribution patterns obtained after the injection of DOPA 2-^{14}C and DOPA 1-^{14}C before and after the inhibition of DOPA-decarboxylase (Chapter 5). When DOPA 1-^{14}C is decarboxylated, $^{14}CO_2$ is formed and exhaled. Comparison of the distribution patterns allows a conception of the places, where catecholamines are formed. In the adrenal medulla catecholamines were very rapidly formed. DOPA in itself was not accumulated in the medulla. The condition was the same in the pancreatic islets and in the parafollicular cells. DOPA in itself was moderately accumulated in the exocrine pancreas. A relatively strong accumulation could also be seen in parts of the caput epididymidis and in structures of the ovary such as follicle walls and corpora lutea. In ganglia DOPA in itself was accumulated to some extent, although catecholamines were formed much less in sympathetic than in spinal ganglia.

A histochemical method was used to study MAO in whole-body sections of mice (Chapter 6). The highest enzyme activity was found in sympathetic ganglia, the intestinal mucosa and the adrenal cortex. Serotonin-^{14}C incubated with whole-body sections of mice, was shown to be accumulated in the adrenal cortex. This binding could not be observed when MAO was inhibited, thus MAO in this case might be responsible for the binding.

Fluorescence microscopy was used to show that the formation of dopamine in the pancreatic islets of the rabbit after the administration of DOPA occurred in a similar way as in the mouse (Chapter 7). The uptake-storage mechanisms appeared to function also *in vitro*. By means of chromatography dopamine, noradrenaline and dihydroxyphenylacetic acid were demonstrated to be formed from DOPA *in vitro* in the rabbit pancreas (Chapter 7).

The effects of monoamines and monoamine precursors on the insulin secretion from rabbit pancreas were studied *in vitro* with a perifusion technical method (Chapter 8). The results indicated that dopamine, noradrenaline and DOPA *in vitro* inhibited the insulin secretion. Noradrenaline and adrenaline also inhibited the insulin secretion. The effects of catecholamines were like those of a β-receptor blocking substance, but not by an α-receptor blocking substance. The results also indicated that serotonin formed from 5-HTP in vitro inhibited the insulin secretion in a high glucose concentration. In low glucose concentration it seemed to have a small stimulating effect on the insulin secretion. Tyrosine had a stimulating, and tryptophan a depressing effect on the insulin secretion.

My sincere thanks are due to

Professor Sven Ullberg, Head of the Department of Toxicology University of Uppsala, who has been my teacher and under whose guidance it has been my privilege to work. His personal interest has greatly supported this work.

Professor Carl G Schmiterlöw Dean of the Royal Veterinary College and Head of the Department of Pharmacology for his interest in and encouragement of my work.

Professor Lennart Nicander for his valuable advice in the electron microscopical part of this work and for placing the facilities of the Department of Anatomy and Histology Royal Veterinary College, at my disposal.

Dr Lars-Erik Appelgren for much valuable advice and many stimulating discussions.

Dr Premysl Slamma for fruitful co-operation and stimulating discussions.

Drs Sven-Erik Sjöstrand and Dimitr Popov for valuable advice and stimulating discussions.

Other colleagues in the Department of Pharmacology for stimulating discussions and encouraging interest.

Dr Leif Ploen and Mrs Birgitta Ivarsson for valuable help during the electron microscopical work.

Mrs Else Stålfelt, Mr Anders Nilsson and Mrs Gun Mabo for valuable technical assistance.

Mrs Birgitta Hagtorn for skilful preparation of the illustrations.

Miss Helena Nordin and Mrs Ulla Sunnberg for their skill and care in the preparation of the manuscripts

Miss Ingvild Halbig for correcting the English.

A. S Novo Copenhagen, Denmark for supplying me with rabbit insulin

This investigation was supported by the American Medical Association-Education and Research Foundation, The Swedish Medical Research Council grant no. 12X 713-01 Anslaget till främjande a ograduerade forskares vetenskapliga verksamhet id Veterinarhögskolan" "Knut & Alice Wallenbergs Stiftelse and Ragnar & Torsten Söderbergs Stiftelse
