INTRODUCTION

This study presents a mathematical analysis of the spread of action currents within nerve and muscle fibres and through the volume conductor imbedding the fibres. The notion "action current" was introduced by Hermann (1879) at a time when it was firmly established that the activity of nerve and muscle is accompanied by transient electric currents in the surrounding tissue or fluid. These currents generate a potential field in the surroundings of the active cells. Numerous studies have been devoted to this subject and many attempts made to localize the generators of the action currents and to account for the electrical properties of the nerve and muscle fibres in terms of mathematical or physical models.

In a review of the early history of "animal electricity" Du Bois-Reymond (1848, 1849, 1884) referred to a German mathematician Christian August Hansen as the first to suggest that electricity was the active principle of nervous activity ("Novi prefectus in historia electricitatis", Leipzig 1743). In 1786 Galvani performed his famous experiments on the legs of frogs and attributed his findings to animal electricity stored in the muscles and flowing through the nerves (cf. Luigi Galvani, "De viribus Electricitatis in motu musculari Commentarius", Bologna 1791, English translation Green 1953). This interpretation was rejected by Volta in 1792 who believed the electricity to be "metallic or artificial" and to result from contact between different conductors. Fifty years elapsed before it was demonstrated that a tetanic contraction initiated by repetitive electrical stimulation of a muscle was accompanied by a significant reduction in the demarcation potential, to use modern terminology (Du Bois-Reymond 1849). Bernstein (1871) invented the recording technique with a sensitivity and speed which made it possible to measure the potential change accompanying a twitch contraction.

EXPERIMENTAL STUDIES OF THE SPREAD OF ACTION POTENTIALS IN VOLUME CONDUCTORS When vacuum tube amplifiers and cathode ray tubes were introduced to physiology about fifty years ago by Forbes Adrian Gasser and Erlanger it became possible to reproduce action potentials faithfully and to study their spread (cf Erlanger and Gasser 1937) Craib and Canfield (1927) and Craib (1928) initiated such work with heart and skeletal muscle immersed in salin They demonstrated that the action potential lead off from the volume conductor was triphasic while the potential recorded in air was monophasic Subsequent workers analyzed the distribution of extracellular action potentials in different preparations Lorente de Nó (1947a) used frog s sciatic nerve in situ and in a two dimensional conductor Tasaki and Tasaki (1950) recorded action potentials at different distance from a toad motor nerv fibre immersed in a thin layer of Ringer s solution Håkansson (1957a) compared the potentials from frog single muscle fibres in Ringer s solution and in air and Krnjević and Miledi (1958) studied action potentials of single fibres from rat diaphragm in Ringer Locke solution.

These studies had the limitation that the biological generator was removed from its natural environment. To interpret complex action potential recorded in situ the spread f the action potential under physiol gical conditions must be known to thi purpose small bundles and single fibre of human muscl were studied by Buchthal Guld and Rosenfalck (1957a) Rosenfalck and Buchthal (1962) Buchthal and Rosenfalck (1966) and Ekstedt (1964); single spinal ganglionic cells of frog by Svaetichin (1951) singl motoneurones of cat by Fatt (1957) Freygang and Frank (1958) and Nelson and Frank (1964) th Mauthner cell of the goldfish by Furshpan and Furukawa (1962) and pyramidal cells in the cortex of cat by Rosenthal Woodbury and Patton (1966) Krakau (1958) described the volume conduction of the electroretinogram of the rabbit in the eye ball and extraocularly Recent studies on th surface electrocardiogram notably by Frank and by Nelson are summarized in the report of a conference on the electrophysiology of the heart (Hecht 1957)

RELATIONSHIP BETWEEN INTRACELLULARLY AND EXTRACELLULARLY RECORDED ACTION POTENTIALS The difference in shape and amplitude between muscle or nerve action potentials recorded in air and in Ringer s solution reflects the difference between intracellular and extracellular action potentials single frog muscle fibres were investigated by Håkansson (1957a) Werman (1960 1963) and Murakami Watanabe and Tomita (1961) cardiac muscle fibres of the rabbit by Vaughan Williams (1959); giant axons of the crayfish by Murakami Watanabe and Tomita (1961) and spinal motoneurones by Fatt (1957) Freygang and Frank (1959) and Terzuolo and Araki (1961)

EXPLANATION OF THE SPREAD AND SHAPE OF ACTION POTENTIALS One of the prime questions of electrophysiology was whether the site and size of the electromotive forces of nerve and muscle could be derived from the extracellular current field. More than hundred years ago Helmholtz (1853) treated this problem assuming the electromotive forces to be constant. Under these condition the extracellular field does not specify the distribution of electromotive forces unequivocally Infinitely many distributions of fictive generators can be derived which produce the same potential field extracellularly According to Helmholtz (1853) the potential field satisfy Laplace s equation. Later investigators (Craib 1928 Wilson McLeod and Barker 1933 Benoit 1937 etc) assume that the equation is valid also for the potential field produced by action currents On this basis Craib (1928) explained the triphasic shape of the muscle action potential in terms of two dipole generators of opposite direction both propagating along the fibres Dipole and multipole generators were introduced to account for the spread of cardiac action currents through the body (Wilson McLeod and Barker 1933 Hecht 1957 Yeh Martin and Beaumont 1958 Yeh 1961) and a linear distribution of sources and sinks described the shape and radial decline of the action potential of a bullfrog sciatic nerve (Lorente de Nó 1947a)

In this classical account of extracellular potential fields of active nerve Lorente de Nó derived an expression for the extracellular

action potential in terms of the second derivative of the surface action potential in air or oil and the distance from the axis of the nerve. Tasaki (1953) accounted for the radial decline of the action potential around a node of Ranvier by considering the node a point sink of current, i.e. the amplitude decreases in inverse proportion to the distance in a three-dimensional conductor and linearly with the logarithm of the distance in a two-dimensional external medium.

Qualitative accounts of the triphasic shape of extracellular action potentials in terms of the theory of local circuits have been given by Bishop (1937), Offner (1954) and Mauro (1960). Bishop (1937) objected to a dipole model whose axis coincided with the axis of the muscle or nerve. In view of the existence of polarized surface membranes he found it more correct to consider the dipoles as oriented transversely to the surface of the fibres.

In an attempt to apply the mathematical model developed by Lorente de Nó (1947a) to the extracellular action potentials of single muscle fibres I used the intracellular action potential as a basis for the calculations (Rosenfalck 1957). Thereby conclusions could be drawn regarding the radial decline of action potentials and its dependence on the diameter of the generator and the area of depolarization (Buchthal, Guld and Rosenfalck 1957a). Krakau (1957, 1959) used Lorente de Nó's model and Fourier transforms and found good agreement between the theoretical radial decline in amplitude of different Fourier components of an action potential and the decline calculated from the action potentials recorded at different distances from a muscle fibre of frog (Håkansson 1957a).

Plonsey (1964) reformulated the theory of Lorente de Nó in greater detail than did my note of 1957. His calculations were based on quantities available from in situ measurements: the density of the membrane current and the action potential recorded just outside the generator. An alternative formulation (Plonsey 1965) involving integration over a solid angle was based on the intracellular action potential and the extracellular surface action potential, the difference between the internal and external conductivity being taken into account (see also Geselowitz 1967). Recently Clark and Plonsey (1966) presented rigorous mathematical expressions for the extracellular

action potentials of a cylindrical generator simulating an unmyelinated nerve fibre this formulation was used to evaluate the core conductor model of nerve and muscle fibres (Hermann 1872 1879) These models are discussed on p 25 and 115

In a short note G selowitz (1966) derived an elaborate expression for the membrane current of a cylindrical fibre in terms of the trans membrane potential using the model developed by Clark and Plonsey A simpler expression might have been obtained if the intracellular ac tion potential had been used instead of the transmembrane potential (p 23) Geselowitz (1967) suggested a more general derivation of the multipole components of the model of the heart than that of Yeh Martinek and Beaumont (1958)

The first ttempt to interpret the spread of the action potentials around cell bodies was made by Lorente de Nó (1947b) he analyzed qualitatively the spread f action currents in pools of motoneurones in the cat and the rabbit in terms of the activity of the individual cells and their anatomical arrangement. A emi quantitative treat ment of the potential field around a single neurone in the cortex of cat arrived at a potential which declined inversely with the distance from the center of the cell body (Tasaki Polley and Orrego 1954) Th field of potential around the motoneurone obeyed this relation to good approxim tion (Fatt 1957) Rall (1962) calculated the distribution of the extracellular potential around a dendritic neurone model consisting of a spherical soma (active) and seven cylindrical dendrites (passive) He showed that th shape of the action potential the de crement of its amplitude with radial distance and the increase of its spike latency with distance could be predicted to good approxi mation. The voltage versus distance curves of action potentials' from pyramidal neurone in the cortex of cat were accounted for by a dipole mod l by Rosenthal Woodbury and Patton (1966)

Krakau (1958) described the volume conduction of the electro-retinogram of the rabbit in the eye and extraocularly with the eye immersed in NaCl solution in terms of an electric double layer of source and sinks in the wall of th eye the moment of the double layer increasing towards the posterior pole of the eye

AIMS OF THE PRESENT STUDY: The main object of this study was to account for the extracellular action potentials recorded from isolated frog muscle fibres in Ringer s solution and in air (Håkanson 1956 1957a) in terms of the intracellular action potential. To this purpose action potentials of a cylindrical fibre were treated mathematically to determine (i) the relationship betw n the intracellular and the extracellular action potentials (ii) the duration amplitude shape and radial decline of the extracellular action potential and (iii) the relationship betwee the thickness of the fibre and the amplitude of the extracellular action potential. The calculati ns were based on the intracellular action potential just beneath the surface of the fibre I considered the case of an unlimited extracellular fluid and that of a thin layer of fluid the latter being treated as equivalent to the linear core conductor model An attempt will be made in thi study to take into account anisotropy of the volume conductor surrounding the fibre when the extracellular action potentials are calculated.

The results derived from the linear core conductor model and from the three-dimensional model will be compared to the results of Clark and Plonsey (1966) and will amplify them The validity of the approximation Lorente de Nó (1947a) made u e of to derive the external action potentials will be examined

My calculations will be based p rtly on simulated intracellular action potentials i.e analytical expre sions which reproduce the appearance of action potential of nerve and mu cle fibres to good approximation partly on measured muscle action potentials The question as to whether spike potentials of high voltage in normal and denervated human muscle arise from singl fibre or from a small group of fibres (Buchthal Guld and Rosenfalck 1957a Krnjević and Mil di 1958 Rosenfalck and Buchthal 1962 Ekstedt 1964 Buchthal and Rosenfalck 1966) will be dealt with

The paper is divided int three parts Part 1 contains the formal mathematical deduction Part 2 contains the numerical analysis of the mathematical model in terms of simulated and recorded intracellular action potentials The results and their relation to the findings of others are discussed in Part 3

PART 1

THE MATHEMATICAL THEORY

Section 1

The Maxwell field equations within conducting media

The electromagnetic field in a conducting medium such as muscle or nerve tissue is governed by Maxwell s equations:

(1) $\operatorname{curl}\vec{H} \quad \frac{4\pi}{c}\,\vec{i} + \frac{1}{c}\,\dot{\vec{D}}$

(2) $\operatorname{curl}\vec{E} \quad -\frac{1}{c}\,\dot{\vec{B}}$

(3) $\operatorname{div}\vec{D} \quad 4\pi\rho$

(4) $\operatorname{div}\vec{B} \quad 0$

$\vec{E}$ is the strength of the electric field and $\vec{D}$ the electric displacement $\vec{H}$ the strength of the magnetic field and $\vec{B}$ the magnetic induction $\vec{i}$ the current density and ρ the charge density c is the velocity of light all measured in c. g. s. electrostatic units. These quantities are furthermore related by

(5) $\vec{i} \quad \sigma\,\vec{E}$

(6) $\vec{D} \quad \xi\,\vec{E}$

(7) $\vec{B} \quad \mu\,\vec{H}$

where σ is the conductivity and ξ the capacitivity both of which may be tensors. μ is the magnetic permeability. It is a prerequisite for (5) that no currents from external generators interfere. The

tissue in which the action currents flow is inhomogeneous hence ε σ and μ vary in space As a first approximation the tissue is assumed to be homogeneous and isotropic The significance of an isotropy is considered in Section 9

Combining (1) and (3) gives the equation of continuity:

(6) $$\mathrm{div}\vec{I} + \rho \quad 0$$

From (3) (5) (5) and (6) we obtain

$$\rho \quad \frac{4\pi\sigma}{\varepsilon} \rho$$

and hence

$$\rho \quad \rho_0(x\ y\ z) \exp\left(\frac{4\pi\sigma}{\varepsilon} t\right)$$

The capacitivity (dielectric constant) ε of muscle tissue at 1 10 kHz is about 10^5 times that of empty space (Spector 1956) This high value reflects mainly the capacity of the muscle fibre membranes (Schwan and Cole 1950) The capacitivity of the intracellular and extracellular fluids is of the same order as that of water i.e $\varepsilon \approx 10^2$ (electrostatic units)

The conductivity σ of the intracellular fluid of muscle is about 0 4 mho/m 3 6 10^9 e s.u (Katz 1948) Hence the time constant τ with which the charg density ρ decays is

$$\tau \quad \frac{\varepsilon}{4\pi\sigma} \approx 2\ 10^{-9} \text{ sec}$$

Therefore an accumulated charge disappears in a time which is negligible as compared with the duration of action potentials and we can assume

(8) $$\rho \quad 0$$

To solve the field equations (1) (4) the scalar (φ) and the vector potential ($\vec{A}$) are introduced

PART 1

THE MATHEMATICAL THEORY

Section 1

The Maxwell field equations within conducting media

The electromagnetic field in a conducting medium such as muscle or nerve tissue is governed by Maxwell s equations

(1) $\operatorname{curl} \vec{H} \quad \frac{4\pi}{c} \vec{i} + \frac{1}{c} \vec{D}$

(2) $\operatorname{curl} \vec{E} \quad \frac{1}{c} \vec{B}$

(3) $\operatorname{div} \vec{D} \quad 4\pi\rho$

(4) $\operatorname{div} \vec{B} \quad 0$

$\vec{E}$ is the strength of the electric field and $\vec{D}$ the electric displacement $\vec{H}$ the strength of the magnetic field and $\vec{B}$ the magnetic induction $\vec{i}$ the current density and ρ the charge density c is the velocity of light all measured in c g s electrostatic units These quantities are furthermore related by:

(5) $\vec{i} \quad g \vec{E}$

(6) $\vec{D} \quad \xi \vec{E}$

(7) $\vec{B} \quad \mu \vec{H}$

where g is the conductivity and ξ the capacitivity both of which may be tensors μ is the magnetic permeability It is a prerequisite for (5) that no currents from external generators interfere The

tissue in which the action currents flow is inhomogeneous; hence ε σ and μ vary in space As a first approximation the tissue is assumed to be homogeneous and isotropic The significance of anisotropy is considered in Section 9

Combining (1) and (3) gives the equation of continuity

(5) $\quad \operatorname{div} \vec{i} + \dot{\rho} \quad 0$

From (3) (5) (6) and (8) we obtain

$$\rho \quad \frac{4\pi\sigma}{\varepsilon} \rho$$

and hence

$$\rho \quad \rho_0(x\ y\ z) \exp\left(\frac{4\pi\sigma}{\varepsilon} t \right)$$

The capacitivity (dielectric constant) ε of muscle tissue at 1 10 kHz is about 10^8 times that of empty space (Spector 1956) This high value reflects mainly the capacity of the muscle fibre membranes (Schwan and Cole 1960) The capacitivity of the intracellular and extracellular fluids is of the same order as that of water i e $\varepsilon \approx 10^2$ (electrostatic units)

The conductivity σ of the intracellular fluid of muscle is about 0 4 mho/m 3 6 10^9 e s u (Katz 1948) Hence the time constant τ with which the charge density ρ decays is

$$\tau \quad \frac{\varepsilon}{4\pi\sigma} \approx 2\ 10^{-9} \text{ sec}$$

Therefore an accumulated charge disappears in a time which is negligible as compared with the duration of action potentials and we can assume

(9) $\quad \rho \quad 0$

To solve the field equations (1) (4) the scalar (φ) and the vector potential ($\vec{A}$) are introduced

(10) $\vec{B}$ curl $\vec{A}$

(11) $\vec{E}$ grad φ $\frac{1}{c}$ $\vec{A}$

From (3) (6) (8) and (11) we obtain:

(12) $\Delta\varphi$ $\frac{1}{c}$ div $\vec{A}$

where Δ is the Laplacian operator The definitions (10) and (11) do not determine φ and $\vec{A}$ uniquely Therefore to simplify equation (12) the following condition is imposed on φ and $\vec{A}$:

(13) div $\vec{A}$ $\frac{\varepsilon\mu}{c}$ φ

Thereby (12) becomes

(14) $\Delta\varphi$ $\frac{\varepsilon\mu}{c^2}$ φ

The action potentials to be considered are propagated at constant velocity U along the fibre Let us introduce cylindrical coordinates (x θ):

(15) φ $\varphi(r$ $+U$ t $\theta)$

(16) $\vec{A}$ $\vec{A}(r$ x+U t $\theta)$

and therefore

(17) φ U $\frac{\partial\varphi}{\partial x}$

(18) φ U^2 $\frac{\partial^2\varphi}{\partial x^2}$

(19) $\vec{A}$ U $\frac{\partial\vec{A}}{\partial}$

Inserting (18) and (14) we get:

$$\Delta\varphi \quad \frac{\varepsilon\mu U^2}{c^2} \quad \frac{\partial^2\varphi}{\partial z^2} \tag{20}$$

In estimating the size of the right hand term we assume

$$\mu \approx 1 \quad \varepsilon \leq u$$

The conduction velocity U in striated mammalian and amphibian muscle fibres is of the order of 100-500 cm/sec (Hâkansson 1956 1957a b Buchthal and Rosenfalck 1958) and in unmyelinated giant nerve fibres the maximum velocity is 3500 cm/sec (Spector 1956) The maximum velocity of 3500 cm/sec gives:

$$\frac{\varepsilon\mu U^2}{c^2} \approx 1 \; 4 \; 10^{9}$$

Hence the right hand term of (20) can be disregarded so that the scalar potential φ can be assumed to satisfy Laplace s equation

$$\Delta\varphi \quad 0 \tag{21}$$

According to (11) the significance of the vector potential $\vec{A}$ as regards the strength of the electric field $\vec{E}$ can be estimated from the ratio

$$\alpha \quad \frac{1}{\omega} \left| \frac{\partial A_z}{\partial t} \right| / \left| \frac{\partial \varphi}{\partial z} \right|$$

From (17) and (19) we obtain.

$$\alpha \quad \frac{U^2}{c} \left| \frac{\partial A_z}{\partial z} \right| / |\varphi|$$

Replacing $\frac{\partial A_z}{\partial}$ by $\operatorname{div}\vec{A}$ α is according to (13) estimated from

$$\alpha \approx \frac{\varepsilon\mu U^2}{c^2} \quad 1 \; 4 \; 10^{9}$$

Thus the lectric field is characterized by the scalar potential φ the vector potential $\vec{A}$ being negligible

Section 2

The variation of the action potential within a fibre

The fibre is assumed to be an infinitely long circular cylinder of radius a. The electric potential φ_i inside the fibre is then determined by Laplace's equation (21). In view of the axial symmetry the equation can be written:

$$\frac{\partial^2 \varphi_i}{\partial r^2} + \frac{1}{r}\frac{\partial \varphi_i}{\partial r} + \frac{\partial^2 \varphi_i}{\partial z^2} = 0 \qquad (22)$$

Furthermore we assume that the action potential V_i is recorded from just under the surface membrane of the fibre. Considering V_i a function of z the boundary condition is

$$\varphi_i(a, z) = V_i(z) \qquad (23)$$

(22) and (23) uniquely determine $\varphi_i(r, z)$; this is an example of Dirichlet's problem of potential theory (Kellogg 1929). The solution could be obtained numerically by replacing the partial differential equation (22) by a set of finite difference equations solved by matrix methods (Karlqvist 1952).

Particular solutions of Laplace's equation (22) are found by separation of variables (e.g. Bland 1961). Formal solutions which satisfy (22) and the boundary condition (23) can be obtained by means of integral transforms (Tranter 1951). For the purposes of this study the Fourier transform was most appropriate. We therefore introduce

$$\Phi_i(r, p) = \int_{-\infty}^{\infty} \varphi_i(r, z) \exp(ipz)\,dz \qquad (24)$$

with the inversion:

$$\varphi_i(r, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \Phi_i(r, p) \exp(-ipz)\,dp \qquad (25)$$

Transforming the individual terms of (22) we are lead to:

$$(26) \qquad \frac{\partial^2 \Phi_1}{\partial r^2} + \frac{1}{r}\frac{\partial \Phi_1}{\partial r} \quad p^2 \Phi_1 \quad 0$$

if the potential φ_1 is measured relative to the resting potential. Similarly the boundary condition (23) leads to:

$$(27) \qquad \Phi_1(a\ p) = \int_{-\infty}^{\infty} V_1(z)\ \exp(i\,p\,z)dz$$

The complete solution of (26) is:

$$(28) \qquad \Phi_1(r\ p) \quad A(p)\ I_o(r\,p) + B(p)\ K_o(r|p|)$$

where I_o and K_o are modified Bessel functions (Jahnke and Emde 1948 Carslaw and Jaeger 1959) Since $K_o(r|p|) \to \infty$ for $r \to 0$ the solutions which are physically possible have the form

$$(29) \qquad \Phi_1(r\ p) \quad A(p)\ I_o(r\,p)$$

Introducing (29) in (27) we obtain:

$$A(p) \quad \frac{1}{I_o(a\,p)} \int_{-\infty}^{\infty} V_1(z)\ \exp(i\,p\,z)dz$$

and hence

$$\Phi_1(r\ p) \quad \frac{I_o(r\,p)}{I_o(a\,p)} \int_{-\infty}^{\infty} V_1(z)\ \exp(i\,p\,z)dz$$

Inverting the transform we obtain

$$(30) \qquad \varphi_1(r\ z) \quad \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{I_o(r\,p)}{I_o(a\,p)}\ \exp(\ i\,p\,z)\ \left\{\int_{-\infty}^{\infty} V_1(u)\ \exp(i\,p\,u)du\right\} dp$$

which can be written as:

$$(31) \qquad \varphi_1(r\ z) \quad \frac{1}{\pi} \int_{0}^{\infty} \frac{I_o(r\,p)}{I_o(a\,p)}\ \left\{\int_{-\infty}^{\infty} V_1(u)\cos p(z\ u)du\right\} dp$$

or

$$(32) \qquad \varphi_1(r\ z) \quad \frac{1}{\pi} \int_0^{\infty} \frac{I_0(r\,p)}{I_0(a\,p)} \left\{ \int_0^{\infty} [V_1(z\ u) + V_1(z+u)] \cos up\, du \right\} dp$$

This solution was arrived at by purely formal deductions diare garding the additional conditions which have to be satisfied by V_1 and $\varphi_1(r\ z)$ How far these deductions are justified is evaluated by means of simulated intracellular action potentials (Part 2)

Section 3

The density of the membrane current

The radial current density $i_r(r\ x)$ is given by

$$i_r \quad \sigma_i \frac{\delta \varphi_i}{\delta r}$$

where σ_i is the conductivity of the interior of the fibre Using (30) and $I_o \quad I_1$ w obtain:

$$i_r(r\ ) \quad \frac{\sigma_i}{2\pi}\int_{\infty}^{\infty} \frac{p I_1(rp)}{I_o(ap)} \exp(\ ipx) \left\{ \int_{\infty}^{\infty} V_i(u)\ \exp(ipu)du \right\} dp$$

Therefore the density of the current i_m passing outwards through the membran is

$$(33) \quad i_m(x) \quad \frac{\sigma_i}{2\pi} \int_{\infty}^{\infty} \frac{p I_1(ap)}{I_o(ap)} \exp(\ ipx) \left\{ \int_{-\infty}^{\infty} V_i(u)\ \exp(ipu)du \right\} dp$$

This may also be written

$$(34) \quad i_m(\ ) \quad \frac{\sigma_i}{\pi} \int_{0}^{\infty} \frac{p I_1(ap)}{I_o(ap)} \left\{ \int_{0}^{\infty} [V_i(x\ u)+V_i(x+u)]\ \cos up\, du \right\} dp$$

since $p\ I_1(ap) \quad |p|\ I_1(a|p|)$

The current density i_x in the fibre direction is

$$i \quad \sigma_i \frac{\delta \varphi_i}{\delta}$$

or according to (30)

$$(35) \quad i\ (r\ ) \quad \frac{\sigma_i}{2\pi} \int_{\infty}^{\infty} \frac{ip I_o(rp)}{I_o(ap)} \exp(\ ip\ ) \left\{ \int_{\infty}^{\infty} V_i(u)\ \exp(ipu)du \right\} dp$$

Expressed in t rms of second derivatives the radial current density i_r is according to (22)

$$i_r \quad \sigma_i\ r \left\{ \frac{\delta^2 \varphi_i}{\delta r^2} + \frac{\delta^2 \varphi_i}{\delta x^2} \right\}$$

Then the density of the membrane current i_m is

$$(36) \qquad i_m \quad \sigma_i a \left\{ \left. \frac{\partial^2 \varphi_i}{\partial r^2} \right|_{r\ a} + \frac{d^2 V_i}{dx^2} \right\}$$

From (30) we obtain since $I_i \quad \frac{1}{2}(I_o + I_2)i$

$$\frac{\partial^2 \varphi_i}{\partial r^2} \quad \frac{1}{4\pi} \int_{-\infty}^{\infty} p^2 \frac{(I_o(rp)+I_2(rp))}{I_o(ap)} \exp(ipx)$$

$$\cdot \left\{ \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du \right\} dp$$

and

$$(37) \qquad \frac{\partial^2 \varphi_i}{\partial x^2} \quad \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{p^2 I_o(rp)}{I_o(ap)} \exp(ipx)$$

$$\left\{ \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du \right\} dp$$

Therefore:

$$(38) \qquad \left. \frac{\partial^2 \varphi_i}{\partial r^2} \right|_{r\ a} \quad \frac{1}{2} \frac{d^2 V_i}{dx^2} + \frac{1}{4\pi} \int_{-\infty}^{\infty} \frac{p^2 I_2(ap)}{I_o(ap)} \exp(ipx)$$

$$\left\{ \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du \right\} dp$$

which in (36) gives

$$(38) \qquad i_m(x) \quad \frac{\sigma_i}{2} \frac{d^2 V_i}{dx^2} + \frac{\sigma_i a}{4\pi} \int_{-\infty}^{\infty} \frac{p^2 I_2(ap)}{I(ap)} \exp(ipx)$$

$$\left\{ \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du \right\} dp$$

This can also be written:

$$(40)\quad i_m(x) \quad \frac{\sigma_i a}{2}\,\frac{d^2V_i}{dx^2} + \frac{\sigma_i a}{2\pi}\int_0^{\infty} \frac{p^2 I_2(ap)}{I_0(ap)} \left\{ \int_0^{\infty} [V_i(x\ u) + V_i(x+u)] \cos up\, du \right\} dp$$

since $I_2(ap) \quad I_2(a|p|)$

If the integral term of (39) and (40) can be neglected the density of the membrane current is proportional to the second derivative of the intracellular action potential. An evaluation of the integral term is given on p 78

Section 4

The core conductor model

To clarify the origin of the electrical phenomena of resting and of stimulated nerves and muscles detailed studies were made of the passive response of these tissues to electric currents which were too weak to act as a stimulus (e g Pflüger 1859) Such studies lead Matteucci (1863) and Hermann (1872) to analyse the electric properties of a model consisting of a metal wire covered by a polarizable surface layer Weber (1873) and Weinberg (1941) calculated the potential field generated by stationary currents flowing through this core conductor model. They assumed the core to be a perfect conductor and hence its potential was constant along the axis of the model. This implies that these analyses contribute little to the understanding of the potential fields in and around active nerve and muscle fibres surrounded by a large volume of conducting fluid

In Hermann s (1879) core conductor model (Fig 1) the interior of the fibre and the external medium are characterized by the resistance per unit length (r_i and r_e respectively) The properties of the polarized surface membrane of the fibre are disregarded in the following analysi of this model.

The following notation is used:

$V_e(\ )$ potential in external fluid

$V_i(x)$ intracellular potential

$i_e(x)$ total longitudinal current in external fluid

$i_i(\ )$ total longitudinal current in the fibre

$2\pi a\, i_m(\ )$ membrane current per cm length of fibre

r_e resistance of external fluid per cm length

r_i resistance of intracellular fluid per cm length.

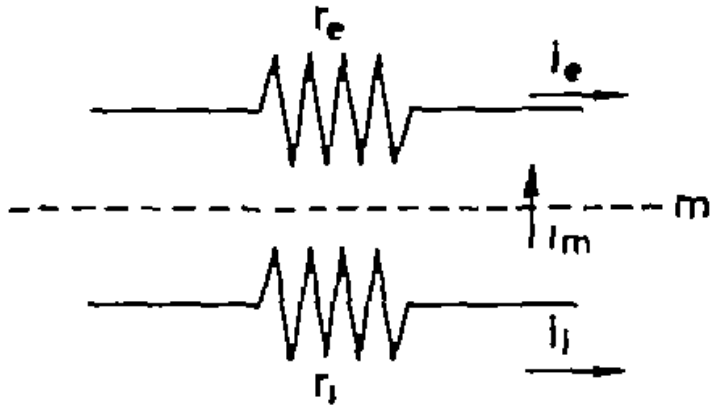

Fig 1 Element of the core conducto mod l
(Hermann 1879)
m surface membrane
r_i resistor representing 1 cm length of the intra ellular fluid (the core)
r resistor repre enting 1 cm length of the external conductor
i_f longitudinal current in the core
$_e$ longitudinal current in the external conductor
i_m density of the current leaving the core through the membrane

From Ohm law we get

(41) $\frac{dV}{dx}$ r_e $_i$

(42) $\frac{dV}{d}$ $_i$

Sin e no charge accumulat we furthermore have

(43) 2π $_m$ $\frac{d}{dx}$

(44) $i(\ )$ $_e(\ )$

As to the rel tion between V_i and V_e we get from (41) (42) and (44)

$$\frac{1}{r_e}\frac{dV_e}{d} + \frac{1}{r_i}\frac{dV_i}{dx} \quad 0$$

and hence

$$(45) \qquad V_e(x) \quad \frac{r_e}{r_i} \; V_i(x)$$

V_i being measured from the resting level
Let us consider the density of the membrane current i_m:
From (42) and (43) we obtain

$$2x \; i_m \quad \frac{1}{r_i}\frac{d^2V_i}{d^2}$$

Introducing the conductivity and radius of the fibre we have

$$(46) \qquad \frac{1}{r_i} \quad \sigma_i \; xa^2$$

and h nce

$$(47) \qquad i_m \quad \frac{\sigma_i a}{2}\frac{d^2V_i}{d^2}$$

Comparing thi expression with that derived for the three dimensional model (39) and (40) it is seen that the two models differ by the term

$$(48) \quad \frac{\sigma_i a}{4\pi}\int_{-\infty}^{\infty}\frac{p^2 I_2(ap)}{I_0(ap)}\exp(\;ip\;)\left\{\int_{-\infty}^{\infty} V_i(u)\exp(ipu)du\right\}dp$$

o in th real domain

$$(49) \quad \frac{\sigma_i a}{2\pi}\int_0^{\infty}\frac{p^2 I_2(ap)}{I_1(ap)}\left\{\int_0^{\infty}[V_i(\;\;u)+V_i(\;+u)]\;\cos up\,du\right\}dp$$

The density of th membrane current can also be related to the xtracellular potential V_e

From (47) (45) and (46) we obtain:

$$(50) \qquad i_m(\;) \quad \frac{1}{2\pi a\; r_e}\frac{d^2V_e}{dx^2}$$

Section 5

The extracellular action potentials in an unlimited conductor

Considering again the three dimensional model of a fibre we assume the external medium to extend infinitely in all directions As shown in Section 1 the potential φ_e in the external medium is determined by Laplace s equation

$$\frac{\partial^2 \varphi_e}{\partial r^2} + \frac{1}{r}\frac{\partial \varphi_e}{\partial r} + \frac{\partial^2 \varphi_e}{\partial z^2} = 0 \tag{51}$$

The boundary condition which φ_e has to s tisfy is that the current density through the fibre membrane is given by (33) (34) With

$$i_m = \sigma_e \left.\frac{\partial \varphi_e}{\partial r}\right|_{r=a} \tag{52}$$

where σ_e is the conductivity of the external medium (33) implies

$$\left.\frac{\partial \varphi_e}{\partial r}\right|_{r=a} = \frac{\sigma_i}{2\pi\sigma_e}\int_{-\infty}^{\infty} \frac{p I_1(ap)}{I_0(ap)} \exp(ipz) \left\{\int_{-\infty}^{\infty} V_1(u)\exp(ipu)du\right\} dp \tag{53}$$

Hence φ_e is a solution to the Neumann problem of potential theory (Kellogg 1929) Introducing the Fourier transform

$$\Phi_e(r,p) = \int_{-\infty}^{\infty} \varphi_e(r,z)\exp(ipz)dz \tag{54}$$

(51) leads to

$$\frac{\partial^2 \Phi_e}{\partial r^2} + \frac{1}{r}\frac{\partial \Phi_e}{\partial r} - p^2 \Phi_e = 0$$

which has the general solution

$$\Phi_e(r,p) = A(p) I_0(rp) + B(p) K_0(r|p|)$$

Since $I_o \to \infty$ for $r \to \infty$ we need only consider solutions of the form:

$$\Phi(r\ p) \quad B(p)\ K_o(r|p|)$$

which by inversion gives

$$(55) \qquad \varphi_e(r\ z) \quad \frac{1}{2\pi} \quad \int_{-\infty}^{\infty} B(p)\ K_o(r|p|)\ \exp(\ ipz)dp$$

With $K_o \quad K_1$ this implies:

$$(56) \qquad \left.\frac{\partial \varphi_e}{\partial r}\right|_{r=a} \quad \frac{1}{2\pi} \int_{-\infty}^{\infty} |p|\ B(p)\ K_1(a|p|)\ \exp(\ ipz)dp$$

Hence (55) is satisfied when

$$B(p) \quad \frac{\sigma_1}{\sigma_e}\ \frac{I_1(a|p|)}{I_o(ap)K_1(a|p|)} \quad \int_{-\infty}^{\infty} V_1(u)\ \exp(ipu)du$$

Inserting this in (55) we obtain

$$(57) \quad \varphi(r\ z) \quad \frac{\sigma_1}{2\pi\sigma_e} \int_{-\infty}^{\infty} \frac{I_1(a|p|)K_o(r|p|)}{I_o(ap)\ K_1(a|p|)}\ \exp(\ ipz)$$

$$\left\{ \int_{-\infty}^{\infty} V_1(u)\ \exp(ipu)du \right\} dp$$

An alternative form of this expression is

$$\varphi_e(r\ ) \quad \frac{\sigma_1}{\pi\sigma_e} \quad \int_0^{\infty} \frac{I_1(ap)\ K_o(rp)}{I_o(ap)\ K_1(ap)}$$

$$\left\{ \int_{-\infty}^{\infty} V_1(u)\cos p(\sigma-)du \right\} dp$$

and hence

$$(58) \quad \varphi_e(r\ z) \quad \frac{\sigma_1}{\pi\sigma_e} \quad \int_0^{\infty} \frac{I_1(ap)\ K_o(rp)}{I_o(ap)\ K_1(ap)}$$

$$\left\{ \int_0^{\infty} [V_1(\quad u) + V_1(z+u)]\cos pu\, du \right\} dp$$

The potential $\varphi_e(a\ z)$ just outside the fibre is

$$(59)\qquad \varphi_e(a\ z) \quad \frac{\sigma_i}{\pi\sigma_e} \int_0^{\infty} \frac{I_1(ap)\ K_0(ap)}{I_0(ap)\ K_1(ap)} \left\{ \int_{-\infty}^{\infty} V_1(u)\cos p(u\ z)du \right\} dp$$

The extracellular potential can also be expressed in terms of the density of the membrane current $i_m(z)$ From (52) and (56) we get

$$i_m(z) \quad \frac{\sigma_e}{2\pi} \int_{-\infty}^{\infty} |p|\ B(p)\ K_1(a|p|)\ \exp(\ ipz)dp$$

Considering this an inversion of a Fourier transform we obtain

$$B(p) \quad \sigma_e\ |p|\ K_1(a|p|) \int_{-\infty}^{\infty} i_m(s)\ \exp(ips)ds$$

which in (55) gives

$$\varphi_e(r\ z) \quad \frac{1}{2\pi\sigma_e} \int_{-\infty}^{\infty} \frac{K_0(r|p|)}{|p|\ K_1(a|p|)}\ \exp(\ ipz) \left\{ \int_{-\infty}^{\infty} i_m(s)\ \exp(ips)ds \right\} dp$$

Interchanging the order of integration we find:

$$\varphi_e(r\ z) \quad \frac{1}{2\pi\sigma_e} \int_{-\infty}^{\infty} i_m(s) \left\{ \int_{-\infty}^{\infty} \frac{K_0(r|p|)}{|p|\ K_1(a|p|)} \exp(ip(s\ z))dp \right\} ds$$

This can also be written as

$$(60)\qquad \varphi_e(r\ z) \quad \frac{1}{\pi\sigma_e} \int_{-\infty}^{\infty} i_m(s) \left\{ \int_0^{\infty} \frac{K_0(rp)}{pK_1(ap)}\ \cos p(s-z)dp \right\} ds$$

An approximate expression for the inner integral can be obtained from the series expansion of $K_1(ap)$ (Carslaw and Jaeger 1959 Appendix III) which gives:

$$ap\ K_1(ap) \to 1 \quad \text{for} \quad ap \to 0$$

From the tables of K_1 (e g Dwight 1958) it is seen that $ap\ K_1(ap)$ decreases with increasing values of ap However in Part 2 Section 4 it is shown that in the calculations of action potentials we need not consider values of ap exceeding 0 4 For ap 0 4 one has $ap\ K_1(ap)$ 0 874 and the following approximation is justified:

$$(61) \qquad \int_0^\infty \frac{K_0(rp)}{pK_1(ap)} \cos p(s-x)dp \approx a \int_0^\infty K_0(rp) \cos p(s-x)dp$$

$$\frac{a}{r} \int_0^\infty K_0(u) \cos(u \frac{s}{r})du$$

This integral is evaluated in Watson (1966 p 388):

$$\int_0^\infty K_0(u) \cos(u \frac{s}{r})du \quad \frac{\pi}{2\sqrt{1 + (\frac{x}{r})^2}}$$

which by insertion in (61) gives

$$\int_0^\infty \frac{K_0(rp)}{pK_1(ap)} \cos p(s-x)dp \approx \frac{a\pi}{2\sqrt{r^2 + (s-x)^2}}$$

and hence (60) may be approximated by

$$(62) \qquad \varphi_e(r\ s) \approx \frac{a}{2\sigma} \int_{-\infty}^{\infty} \frac{i_m(s)}{\sqrt{r^2 + (s-x)^2}} ds$$

An alternative formulation of (60) can be obtained by using

$$(63) \qquad \frac{1}{ap} \quad I_0(ap)\ K_1(ap) + K_0(ap)\ I_1(ap)$$

(Carslaw and Jaeger 1959 Appendix III) From (63) we get.

$$\frac{1}{p\,K_1(ap)} \quad a\left\{I_o(ap)+K_o(ap)\,\frac{I_1(ap)}{K_1(ap)}\right\}$$

Introducing this in (60) we get

$$\varphi_e(r\ z) \quad \frac{a}{\pi\sigma_e} \int_{-\infty}^{\infty} i_m(s)\left\{\int_0^{\infty} K_o(rp)\left[I_o(ap)+K_o(ap)\,\frac{I_1(ap)}{K_1(ap)}\right]\right.$$
$$\left.\cos p(s\ z)dp\right\} ds$$

For small values of ap the term $K_o(ap)\,I_1(ap)/K_1(ap)$ is small as compared to $I_o(ap)$ Thus for ap 0 4 $K_o\,I_1/K_1$ amounts to 10 per cent of $I_o(ap)$ This leads to the approximate expression for $\varphi_e(r\ z)$

$$(64) \quad \varphi_e(r\ z) \approx \frac{a}{\pi\sigma_e} \int_{-\infty}^{\infty} i_m(\ ) \left\{\int_0^{\infty} K_o(rp)\ I_o(ap)\right.$$
$$\left.\cos p(s-z)dp\right\} ds$$

The inner integral is given in Watson (1966 p 389)

$$(65) \quad \int_0^{\infty} K_o(rp)\ I_o(ap)\cos p(s-z)dp$$
$$\int_0^{\frac{\pi}{2}} \frac{d\theta}{\sqrt{(s-z)^2+(s+r)^2 \quad 4ar\sin^2\theta}}$$
$$\frac{1}{2}\int_0^{\pi} \frac{du}{\sqrt{(s\ z)^2+s^2+r^2 \quad 2ar\cos u}}$$

where $u \quad \pi \quad 2\theta$

Introducing (65) in (64) we get

$$(66) \quad \varphi_e(r\ z) \approx \frac{1}{4\pi\sigma_e} \int_{-\infty}^{\infty}\int_{\pi}^{\pi} \frac{i_m(s)\ a\,du\,ds}{\sqrt{(s-z)^2+s^2+r^2 \quad 2ar\cos u}}$$

Thus whereas the first approximation (62) was a line integral the present approximation is a surface integral The denominator represents the distance R between (r z) and the point (s s) located

on the surface of the fibre and in plane t an angle u from the plane through (r z) and the fibre axi Thus

$$\varphi_e(r\ z) \approx \frac{1}{4\pi\sigma_e} \int_S \frac{i_m(s)}{R}\, dS \tag{67}$$

where S is the surface of the fibre and dS an element of its area

Integrating (66) after u one obtains

$$\varphi_e(r\ z) \approx \frac{s}{\pi\sigma_e} \int_{-\infty}^{\infty} \frac{i_m(s)}{\sqrt{(z\ s)^2+(r+s)^2}}\, K\left(\sqrt{\frac{4sr}{(z\ s)^2+(s+r)^2}}\right) ds \tag{68}$$

where K denotes the complete elliptic integral of the first kind The integrand of (68) and (62) are nearly the same for most values of r and z s th deviations occurring near the singularity of (68) i.e r s s z (Table 1)

Table 1

Percentage difference between the integrands of (62) and (68) at various axial and radial positions

axial position	radial position		
z s	r=a	r 3a	r 7a
0	(100)	2.9	0 4
2a	7	0 1	0 2
4a	2 5	0 8	0
6a	1 4	0 7	0 3
8a	0 8	0 6	0
10a	0 6	0 6	0
12a	0 4	0 4	0
14	0 4	0	0
16a	0	0	0

The xtracellular potential can be expressed in still more general terms than in (58) and (60) Considering the region of space out xld r b where b ≥ a and assuming the radial gradient of the potential to be known at r b we obtain in analogy to (60):

$$(69) \qquad \varphi_e(r\ z) \quad \frac{1}{\pi} \int_{-\infty}^{\infty} \left.\frac{\partial \varphi_e(r\ s)}{\partial r}\right|_{r=b} \left\{ \int_0^{\infty} \frac{K_0(r\,p)}{p\,K_1(b\,p)} \cos p(s \quad) dp \right\} ds$$

Section 6

A fibre surrounded by a thin layer of conductor

In this Section the external conductor is assumed to be limited to a circular cylinder of radius b which is only slightly larger than the radius a of the fibre. The action potential in the external fluid is then determined by (51) and (53) together with the additional condition

$$\left.\frac{\partial \varphi_e}{\partial r}\right|_{r\,b} \qquad 0 \tag{70}$$

The general solution of (51) is

$$\varphi_e(r\ z) \quad \frac{1}{2\pi} \int_{-\infty}^{\infty} \left\{ (A(p)\ I_0(rp) + B(p)\ K_0(r|p|) \right\} \exp(\ ipz)dp$$

With $I_0 \quad I_1$ and $K_0 \quad K_1$ we have

$$\frac{\partial \varphi_e}{\partial r} \quad \frac{1}{2\pi} \int_{-\infty}^{\infty} \left\{ p\,A(p) I_1(rp) \quad |p| B(p) K_1(r|p|) \right\} \exp(\ ipz)dp$$

The boundary condition (70) is fulfilled if:

$$p\,A(p)\ I_1(bp) \quad |p|\ B(p)\ K_1(b|p|) \tag{71}$$

Similarly the condition (53) is satisfied if

$$A(p)\ I_1(ap) \quad \frac{|p|}{p}\ B(p)\ K_1(a|p|) \tag{72}$$

$$\frac{\sigma_i}{\sigma_e} \quad \frac{I_1(ap)}{I_0(ap)} \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du$$

From (71) and (72) we obtain

$$A(p) \quad \frac{\sigma_i}{\sigma_e} \quad \frac{\dfrac{I_1(ap)}{I_0(ap)}\ K_1(b|p|) \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du}{I_1(\ p)\ K_1(b|p|) \quad K_1(a|p|)\ I_1(bp)}$$

$$B(p) \quad \frac{\sigma_i}{\sigma_e} \frac{p}{|p|} \frac{I_1(ap)}{I_0(ap)} \frac{I_1(bp)}{I_1(ap)\, K_1(b|p|) - K_1(a|p|)\, I_1(bp)} \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du$$

and hence

$$(73) \quad \varphi_e(r\ ) \frac{\sigma_i}{2\pi\sigma_e} \int_{-\infty}^{\infty} \frac{K_1(b|p|)\, I_0(rp) + \frac{|p|}{p} I_1(bp)\, K_0(r|p|)}{I_1(ap)\, K_1(b|p|) - K_1(a|p|) I_1(bp)} \frac{I_1(ap)}{I_0(ap)} \exp(ipz) \left\{ \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du \right\} dp$$

Let us consider the potential on the surface of the thin conducting layer $\varphi_e(b\ z)$

Using $I_0(rp) \quad I_0(-rp) \quad I_1(ap) \quad I_1(-ap)$ and

$$K_1(b|p|)\, I_0(b|p|) + I_1(b|p|)\, K_0(b|p|) \quad \frac{1}{b|p|}$$

(Carslaw and Jaeger 1959 Appendix III) we get

$$(74) \quad \varphi_e(b\ z) \frac{\sigma_i}{2\pi\sigma_e b} \int_{-\infty}^{\infty} \frac{1}{I_1(ap)\, K_1(b|p|) - K_1(a|p|)\, I_1(bp)} \frac{I_1(ap)}{|p|\, I_0(ap)} \exp(ipz) \left\{ \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du \right\} dp$$

An alternative expression is obtained by using the symmetry properties of I_0 and I_1

$$\varphi_e(b\ ) \frac{\sigma_i}{\pi\sigma_e b} \int_{0}^{\infty} \frac{1}{I_1(ap)\, K_1(bp) - K_1(ap)\, I_1(bp)} \frac{I_1(ap)}{p\, I_0(ap)} \left\{ \int_{-\infty}^{\infty} V_1(u) \cos p(u\ z)du \right\} dp$$

which can be written as

(75) $$\varphi_e(b\ z) \quad \frac{\sigma_i}{\pi \sigma_e b} \int_0^\infty I_1(ap)\ K_1(bp)^{1}\ K_1(ap)\ I_1(bp)$$

$$\frac{I_1(ap)}{pI_0(ap)} \left\{ \int_0^\infty [V_i(\ \ u) + V_i(z+u)] \cos pu\, du \right\} dp$$

With $b-a \ll a$ we can derive an approximate and simpler expression for $\varphi_e(b\ )$ Using the Taylor s series of $K_1(bp)$ and $I_1(bp)$ and the relations connecting I_1 and K_1 we get

(76) $$I_1(ap)\ K_1(bp) \quad K_1(\ p)\ I_1(bp)$$

$$\approx I_1(ap)\ \{K_1(ap) + (b-a)\cdot p\ K_1'(ap)\}$$

$$K_1(ap)\ \{I_1(\ p) + (b-a)\ p\ I_1(ap)\}$$

$$(b-a)\ p\ \{I_1(ap)\ K_1'(ap) \quad K_1(ap) I_1'(ap)\}$$

$$(b\ a)\ p\ (\ \frac{1}{ap}) \qquad \frac{b-a}{a}$$

A still bette approxim tion i

(77) $$I_1(ap)\ K_1(bp) \quad K_1(\ p)\ I_1(bp)$$

$$\approx (b-a)p\ \{I_1(\ p)\ K_1(\ p) \quad K_1(ap)\ I_1'(ap)\}$$

$$+ \tfrac{1}{2}(b-a)^2 p^2\ \{I_1(ap)\ K_1(ap) \quad K_1(ap)\ I_1(ap)\}$$

$$\frac{b-a}{a} + \tfrac{1}{2}(b-a)^2 p^2\ \frac{1}{a}\frac{d}{dp}$$

$$\{I_1(\ p)\ K_1(ap) - K_1(ap)\ I_1(ap)\}$$

$$\frac{b-a}{} + \frac{(b\ a)^2}{2}\ p^2\ \frac{d}{dp}(\ \frac{1}{ap})$$

$$\frac{b-a}{} + \frac{(b\ a)^2}{2a^2}$$

$$B(p) \quad \frac{\sigma_i}{\sigma_e} \frac{\frac{p}{|p|} \frac{I_1(ap)}{I_0(ap)} I_1(bp)}{I_1(ap)\, K_1(b|p|) - K_1(a|p|)\, I_1(bp)} \int_{-\infty}^{\infty} V_1(u)\, e$$

and hence

$$(73) \quad \varphi_e(r\ z) \quad \frac{\sigma_i}{2\pi\sigma_e} \int_{-\infty}^{\infty} \frac{K_1(b|p|)\, I_0(rp) + \frac{|p|}{p} I_1(bp)\, K_0(}{I_1(ap)\, K_1(b|p|) - K_1(a|p|) I_1(bp)} -$$

$$\frac{I_1(ap)}{I_0(ap)} \exp(ipz) \left\{ \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du \right\} dp$$

Let us consider the potential on the surface of the thin conducting layer $\varphi_e(b\ z)$

Using $I_0(rp) \quad I_0(rp) \quad I_1(ap) \quad I_1(ap)$ and

$$K_1(b|p|)\, I_0(b|p|) + I_1(b|p|)\, K_0(b|p|) \quad \frac{1}{b|p|}$$

(Carslaw and Jaeger 1959 Appendix III) we get

$$(74) \quad \varphi_e(b\ z) \quad \frac{\sigma_i}{2\pi\sigma_e b} \int_{-\infty}^{\infty} I_1(ap)\, K_1(b|p|) \frac{1}{} K_1(a|p|)\, I_1(bp)$$

$$\frac{I_1(ap)}{|p|\, I_0(ap)} \exp(ipz) \left\{ \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du \right\} dp$$

An alternative expression is obtained by using the symmetry properties of I_0 and I_1

$$\varphi_e(b\ z) \quad \frac{\sigma_i}{\pi\sigma_e b} \int_{0}^{\infty} I_1(ap)\, K_1(bp) \frac{1}{} K_1(ap)\, I_1(bp)$$

$$\frac{I_1(ap)}{p\, I_0(ap)} \left\{ \int_{-\infty}^{\infty} V_1(u) \cos p(u\ z)du \right\} dp$$

which can be written as

(75) $$\varphi_e(b\ z)\quad \frac{\sigma_l}{\pi\sigma_e b}\quad \int_0^{\infty} I_1(ap)\ K_1(bp)^{1}\ K_1(ap)\ I_1(bp)$$

$$\frac{I_1(ap)}{pI_0(ap)}\ \left\{\int_0^{\infty}[V_1(z\ u)+V_1(z+u)]\cos pu\,du\right\}\,dp$$

With b-a a w can derive an approximate and simpler expression for $\varphi_e(b\ z)$ Using th Taylo a series of $K_1(bp)$ and $I_1(bp)$ and the relations connecting I_1 and K_1 we get

(76) $$I_1(ap)\ K_1(bp)\quad K_1(ap)\ I_1(bp)$$

$$\approx I_1(ap)\ \{K_1(ap)+(b-a)\ p\ K_1'(ap)\}$$

$$K_1(ap)\ \{I_1(ap)+(b-a)\ p\ I_1'(ap)\}$$

$$(b\ \ )\ p\ \{I_1(ap)\ K_1(\ p)\quad K_1(ap)I_1(ap)\}$$

$$(b-a)\ p\ (\ \ \frac{1}{ap})\qquad \frac{b-a}{a}$$

A still bett approximation s

(77) $$I_1(\ p)\ K_1(bp)\quad K_1(ap)\ I_1(bp)$$

$$\approx (b\ a)p\ \{I_1(ap)\ K_1(ap)\quad K_1(ap)\ I_1(ap)\ \}$$

$$+\tfrac{1}{2}(b\ a)^2p^2\ \{I_1(ap)\ K_1''(\ p)\quad K_1(ap)\ I_1(ap)\}$$

$$\frac{b-a}{a}+\tfrac{1}{2}(b-\ \ )^2p^2\ \ \frac{1}{a}\ \frac{d}{dp}$$

$$\{I_1(\ p)\ K_1(ap)\ K_1(ap)\ I_1(ap)\}$$

$$\frac{b-a}{}+\frac{(b-\ \ )^2}{2a}\ \ p\ \ \frac{d}{dp}\ (\ \ \frac{1}{ap})$$

$$\frac{b-a}{a}+\frac{(b-a)^2}{2a^2}$$

Taking the third derivatives into account we get

(77) $$I_1(ap)\,K_1(bp) - K_1(ap)\,I_1(bp) \approx \frac{b-a}{a} + \frac{(b-a)^2}{2a^2} - \frac{(b-a)^3}{6a^3}\{3+(ap)^2\}$$

Considering p values for which $a|p| < 0.4$ (p. 83) $(ap)^2$ can be neglected in (78) and

$$I_1(ap)\,K_1(bp) - K_1(ap)\,I_1(bp) \approx \frac{b-a}{a} + \frac{(b-a)^2}{2a^2} - \frac{(b-a)^3}{2a^3}$$

Introducing the first approximation (78) in (74) and (75) we get

$$\varphi_e(b,x) \approx \frac{\sigma_i a}{2\pi\sigma_e b(b-a)} \int_{-\infty}^{\infty} \frac{I_1(ap)}{pI_0(ap)} \exp(ipx) \left\{\int_{-\infty}^{\infty} V_1(u)\exp(ipu)du\right\} dp$$

This expression can be reformulated using:

(79) $$I_1(ap) - \frac{ap}{4}[I_0(ap) - I_2(ap)]$$

and Fourier's integral formula

(80) $$V_1(x) - \frac{1}{2\pi}\int_{-\infty}^{\infty} \exp(ipx)\left\{\int_{-\infty}^{\infty} V_1(u)\exp(ipu)du\right\} dp$$

We get.

(81) $$\varphi_e(b,x) \approx \frac{\sigma_i a^2}{2\sigma_e b(b-a)}\left[V_1(x) - \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{I_2(ap)}{I_0(ap)} \exp(ipx) \left\{\int_{-\infty}^{\infty} V_1(u)\exp(ipu)du\right\} dp\right]$$

where V_i is measured from the resting level. The proportionality factor in (81) represents the ratio between the external (r_e) and intracellular longitudinal resistance (r_i) since for b-a $\ll$ a:

(82) $$r_e \quad \frac{1}{\sigma_e \, 2\pi b(b-a)}$$

(83) $$r_i \quad \frac{1}{\sigma_i \, \pi a^2}$$

and hence

$$\frac{r_e}{r_i} \quad \frac{\sigma_i a^2}{2\sigma_e b(b-\ )}$$

Therefore the first term in (81) represents the extracellular potential expected from the linear core conductor model (45) in Part 2 Section 3 it is shown that the second term can be neglected.

The second derivative of the surface action potential $\varphi_e(b,z)$ given in (74) is

$$\frac{\partial^2 \varphi_e(b,\ )}{\partial z^2} \quad \frac{\sigma_i}{2\pi \ \sigma_e b} \int_{-\infty}^{\infty} |p| \, \frac{I_1(\ p)}{I_0(\ p)} \exp(\ ipz)$$

$$I_1(ap)\, K_1(b|p|)\ K_1(\ |p|)\, I_1(\ ap)$$

$$\left\{ \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du \right\} dp$$

Using the approximation (78) we get

(84) $$\frac{\partial^2 \varphi_e(b,\ )}{\partial z^2} \approx \frac{\sigma a}{2\pi\sigma\ b(b-\ )} \int_{-\infty}^{\infty} p I_1(ap) \, \frac{}{I_0(ap)} \exp(\ ipz)$$

$$\left\{ \int_{-\infty}^{\infty} V_1(u) \exp(ipu)du \right\}$$

Comparing this expression with that derived for the membrane current density $i_m(\ )$ (33) we obtain

$$\frac{\partial^2 \varphi_e(b\ x)}{\partial x^2} \approx \frac{a}{\sigma_e b(b-a)}\ i_m(x)$$

or

$$(85)\qquad i_m(x) \approx \frac{\sigma_e b(b-a)}{a}\ \frac{\partial^2 \varphi_e(b\ x)}{\partial x^2}$$

Introducing the longitudinal extracellular resistance r_e given by (82) this can be written:

$$(86)\qquad i_m(x) \approx \frac{1}{2\pi a\ r_e}\ \frac{\partial^2 \varphi_e(b\ x)}{\partial x^2}$$

which represents the density of the membrane current as expected from the core conductor model (50)

The variation in potential through the thin conducting layer $\varphi_e(a\ x)\ \ \varphi_e(b\ )$ can be estimated by using a Taylor expansion of $\varphi_e(a\ x)$:

$$\varphi_e(a\ x)\ \ \varphi_e(b\ ) + (a\ b)\left.\frac{\partial \varphi_e}{\partial r}\right|_{r=b} + \frac{(a\ b)^2}{2}\left.\frac{\partial^2 \varphi_e}{\partial r^2}\right|_{r\ b} +$$

Using (70) and Laplace s equation (51) we get the following approxi mation

$$\varphi_e(a\ x)\ \ \varphi_e(b\ x) \approx \frac{(b\ x)^2}{2}\ \frac{\partial^2 \varphi_e(b\ x)}{\partial x^2}$$

Introducing (84) and (79) we obtain

$$(87)\qquad \varphi_e(a\ x)\ \ \varphi_e(b\ x) \approx \frac{\sigma_1 a^2(b\ a)}{4\pi\sigma_e b}\int_0^{\infty} p^2\left(1\ \ \frac{I_2(ap)}{I_0(ap)}\right)$$

$$\left\{\int_0^{\infty} [V_1(\ \ u) + V_1(\ +u)]\cos pu\, du\right\} dp$$

From (80) follow that:

$$\frac{d^2V_1}{dx^2} \quad \frac{1}{\pi}\int_0^{\infty} p^2 \left\{\int_0^{\infty} [V_1(x\ u)+V_1(x+u)]\cos up\,du\right\} dp$$

Therefore (87) can be written

$$(88) \quad \varphi_e(a\ x)\ \varphi_e(b\ x) \approx \frac{\sigma_1 a^2(b-a)}{4\sigma_e b}$$

$$\left\{\frac{d^2V_1}{dx^2} + \frac{1}{\pi}\int_0^{\infty} \frac{p^2 I_2(ap)}{I_o(ap)} \left\{\int_0^{\infty} [V_1(x\ u)+V_1(x+u)]\right.\right.$$

$$\left.\left.\cos pu\,du\right\} dp\right\}$$

In Part 2 Section 2 it is shown that the integral term can be neglected.

Se tion 7

The theory of Lorente de Nó

Lorente de Nó (1947a) analyzed mathematically th spread in volume conductors of action currents from nerves (recently revi wed by Plonsey 1964) The analysis was based on theorems of potential theory (cf Kellogg 1829) as derived by Helmholtz (1853) Lorente de Nó showed that the nerve action potential in a volume conductor having th same conductivity as the nerve can be calculated from the surf ce action potential of a nerve surrounded by oil or air He assumed that the internal electromotive forces f the nerve fibre do not depend on the resistance of th external conductor More specifically Lorente de Nó found that the action potential could be considered to arise from an electric double l yer lo ated just outside the nerve with a moment of $\frac{1}{4\pi}$ times the surface action potential V_e in oil or air

$$(89) \qquad \varphi(P) \quad \frac{1}{4\pi} \int_S V_e(P) \frac{\partial \frac{1}{R}}{\partial n} \, dS$$

where th integration extends over the surface S of the nerve; dS denotes a surface element $\frac{\partial}{\partial n}$ the normal d rivative on S and R ip the distanc between the point P and P Considering the nerve to be a right circular cylinder Lorente de Nó transformed the surface integral (89) to one more suited for num rical evaluation:

$$(90) \qquad \varphi_e(r\ z) \quad \frac{1}{4\pi} \int_\tau \frac{\partial^2 V_e(\ )}{\partial\ ^2} \frac{d\tau}{R}$$

wh re τ is the volum of the nerve and $d\tau$ a volume element. His calculations were based on d ta from the alpha fibres of bullfrog cistic nerves They lead to triphasic action potential and account ed for the decline in amplitud with increasing distance from the nerve

Lorent d Nó (1947a) also expre sed the action potentials in terms of th current passing th surface of the nerve This was obtained by using the relation (50) between the density of the mem

brane current $i_m(z)$ and the surface action potential $V_e(z)$ as derived from the core conductor model

$$(91) \qquad \varphi_e(r\ z) \quad \frac{r_e a}{2} \int_{\tau} \frac{i_m(\ )}{R}\ d\tau$$

Lorente de Nó repl ced the volume integrals (90) and (91) by line integrals e g

$$(92) \qquad \varphi_e(r\ z) \quad \frac{\pi r_e a^3}{2} \int_{-\infty}^{\infty} \frac{i_m(s)}{R}\ ds$$

where R is the distance between (r z) and the line element ds on the axis of the nerve

Lorente de Nó derived th line int grals by considering the potential at distances large as compared to the radius of the nerve The line integrals can be obtained from the volume integrals without this restriction. Thus (91) can be written:

$$\varphi_e(r\ z) \quad \frac{r_e a}{2} \int_{-\infty}^{\infty} ds \int_0^a dr_1 \int_0^{2\pi} r_1 d\theta\ \frac{i_m(s)}{R}$$

where

$$R^2 \quad (\ \ s)^2 + \ ^2 + r_1^{\ 2} \quad 2rr_1 \cos\theta$$

Introducing the expansion (M rse and F shbach H 1953)

$$\frac{1}{R} \quad \sum_{m=0}^{\infty} \varepsilon_m \cos m\theta \quad \int_0^{\infty} J_m(kr)J_m(kr_1) \exp(-k|\ \ s|)dk$$

where

$$\varepsilon_m \quad \begin{cases} 1 & \text{for } m = 0 \\ 2 & \text{for } m > 0 \end{cases}$$

we get by integrating after θ

$$\varphi_e(\ \ ) \quad \pi r_e a \int_{-\infty}^{\infty} ds \int_0^a dr_1 \int_0^{\infty} dk\ r_1\ i_m(\ )$$

$$J_o(kr) J_o(kr_1) \exp(-k|\ \ s|)$$

Integration after r_1 (cf Carslaw and Jaeger 1959) leads to

$$(93)\quad \varphi_e(r\ \ ) \quad x r_e a^2 \int_{-\infty}^{\infty} i_m(s) \left\{ \int_0^{\infty} J_1(ka)\, J_o(kr)\, \exp(\ k|\, z-s|\ )/k\, dk \right\} ds$$

An approximate expression can be found by assuming

$$J_1(ka) \approx \frac{ka}{2}$$

This approximation i valid for small valu of ka the deviation is 3 % for ka 0 5 8 % for ka 0 8 and 17 % for ka 1 2 Hence as long as the xponential term of (93) does not decline too slowly with increasing k i e a long as $|z\ s| \gtrsim a$

$$\int_0^{\infty} J_1(ka) J_o(kr)\, \exp(\ k|\quad\ |) \frac{dk}{k}$$

$$\approx \frac{a}{2} \int_0^{\infty} J_o(kr)\, \exp(\ k|\quad\ |)\, dk$$

$$\frac{a}{2\sqrt{(z\ s)^2 + r^2}}$$

according to th tabl s of Laplace transforms (e g McLachlan and Humbert 1950) Introducing this evaluation in (93) we get

$$(94)\quad \varphi\ (r\ \ ) \approx \frac{x r_e a^3}{2} \int_{-\infty}^{\infty} \frac{i_m(s)}{\sqrt{(z\ \ )^2 + r^2}}\, ds$$

Thus the lin integral (92) obtained by Lorente d Nó (1947a) by concentrating the fictive source and sinks of the action potential on the axis of the nerve (94) is identical with (62) which was d rived from the rigorous model in Section 5 if the ext rnal con ductor act s if ts cros se tion were equal to that of the nerve Thi implies

$$r_e \quad \frac{1}{\sigma_e\ \pi^{\ 2}}$$

An evaluation of the error introduced by replacing the volume integral of (91) by the line integral of (94) is given in Appendix 2 The calculations indicate that the error is small even for points (r z) near the surface of the nerve

The action potentials as given by the approximation (94) satisfy Laplace's equation Let us consider to what extent (94) gives the *correct density of the current which passes the surface of the nerve* The current density $i_{m\,1}(z)$ corresponding to (94) is

$$i_{m\,1}(z) \quad \sigma_e \frac{\partial \varphi_e}{\partial r}\Big]_{r\,a} \quad \frac{\pi \sigma_e r_e a^4}{2} \int_{-\infty}^{\infty} \frac{i_m(s)}{\{(\quad s)^2 + a^2\}^{3/2}}\, ds$$

Assuming r_e given by (95) we get

$$(96) \qquad i_{m\,1}(z) \quad \frac{a^2}{2} \int_{-\infty}^{\infty} \frac{i_m(\ )}{\{(z\ s)^2 + a^2\}^{3/2}}\, ds$$

This integral can be transformed so that the difference between $i_{m\,1}(z)$ and $i_m(z)$ is easier to assess To this end we u

$$(97) \qquad \frac{a^2}{2} \int_{-\infty}^{\infty} \frac{i_m(\ )}{\{(z-s)^2 + a^2\}^{3/2}}\, d \quad i_m(z)$$

as is shown by introducing the variabl u $1 + \dfrac{a^2}{(z\ s)^2}$

On account of the rapid increase of the denominator with $|z\ s|$ the major contribution to the integral (97) comes from values of s which deviate only slightly from z i.e 90 per cent from z 2a ≤ s ≤ +2a and 98 per cent from z 3a ≤ s ≤ z+3a.

From (96) and (97) it follows that

$$(98) \quad i_{m\,1}(\ ) \quad i_m(\ ) + \frac{a^2}{2} \int_{-\infty}^{\infty} \frac{i_m(s)\ i_m(\ )}{\{(z\ )^2 + a^2\}^{3/2}}\, ds$$

where the integral represents the difference between the density of the *current* $i_m(\ )$ *which passes the surface of* the nerve and the

current density $i_{m\ 1}(x)$ as calculated from the approximation to the external field given by (84) and (85) Because of the rapid increase of the denominator with $|x\ s|$ the integral of (98) can be neglected if $i_m(s)$ varies little in the range $x\ 2a < s < x+2a$ Under this condition the approximation (94) gives the correct current density at the surface of the nerve (see Section 4 of Part 2)

Section 8

The radial decline of the extracellular action potential

According to (57) the potential $\varphi_e(r\ z)$ can formally be given as

$$(99)\qquad \varphi_e(r\ z) \qquad \int_{-\infty}^{\infty} C(p)\ K_o(r|p|)\ \exp(\ ip\ )dp$$

where

$$C(p) \qquad \frac{\sigma_i}{2\pi\sigma_e}\ \frac{I_1(a|p|)}{I_o(ap)\ K_1(a|p|)}\ \int_{-\infty}^{\infty} V_1(u)\ \exp(ipu)du$$

To evaluate the significance of (99) time is introduced as a variable in addition to the space variables For this purpose z is replaced by $z + U\ t$ where U is the conduction velocity of the action potential (cf p 17) Thus

$$\varphi_e(r\quad t) \qquad \int_{\infty}^{\infty} C(p)\ \exp(\ ip\ )\ K_o(r|p|)\ \exp(\ ipUt)dp$$

Introducing

$$\omega \quad p\ U$$

we get

$$(100)\quad \varphi_e(r\quad t) \qquad \frac{1}{U}\ \int_{-\infty}^{\infty} C(\tfrac{\omega}{U})\ \exp(\ i\omega\ \tfrac{z}{U})\ K_o(\tfrac{|\omega|}{U})\ \exp(\ i\omega t)d\omega$$

(100) represent the Fourier expansion of the action potential. The different frequency components of the action potential differ with respect to their radial decline the highest frequencies being attenuated close to the fibre (Fig 2) In Table 2 are given the distances at which the amplitudes of components of various frequencies have declined to one tenth of its value at the surface of the fibre For frequencies of 4000 5000 Hz the distance is 8–10 times shorter than for frequencies of 250 300 Hz To further

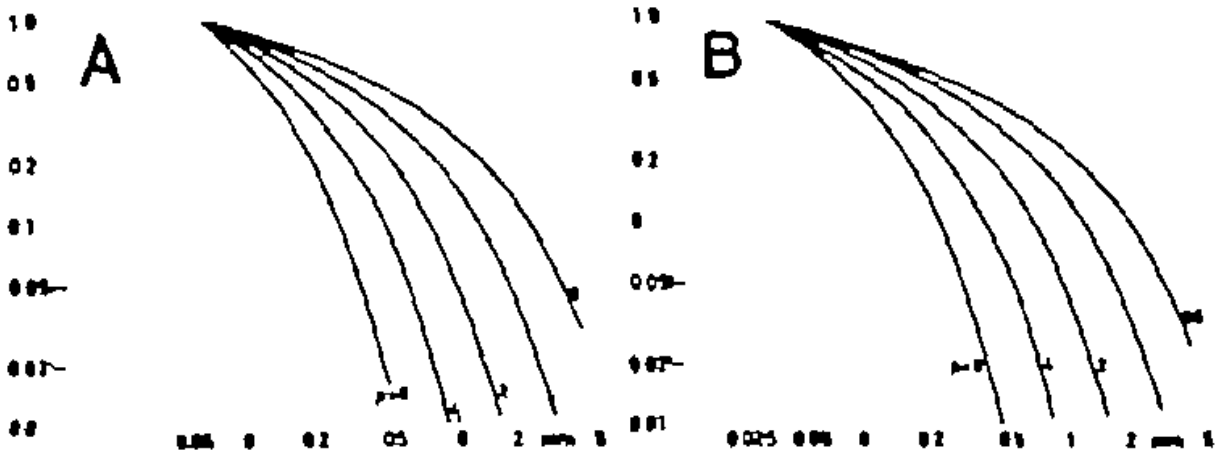

Fig 2 Radial decline in amplitude of different Fourier components of an action potential calculated for a fibre in an unlimited isotropic conductor The curves represent $K_0(rp)/K_0(ap)$ for different values of p; r is the radial distance from the axis of the fibre and a the radius of the fibre

A a 0 05 mm
conduction velocity (U) 3 m/sec
Fourier frequencies 240 3800 Hz

B a 0 025 mm
U 4 m/sec
Fourier frequencies 320 5100 Hz

characterize the radial declin the slope of the curves of Fig 2 is given in Table 2 For high frequency components the slope doubles within few radii from the fibre

With K_0 K_1 we obtain from (100)

$$(100a) \qquad \frac{\delta \varphi_e}{\delta r} \frac{1}{U^2} \int_{-\infty}^{\infty} C(\frac{\omega}{U}) \; |\omega| \exp(i\omega x/U) \; K_1(r|\omega|/U) \exp(i\omega t) d\omega$$

This expression can be used to estim te the radial variation of the gradient $\frac{\delta \varphi_e}{\delta r}$ and hence of the current flowing radially in the volume conductor

) $\frac{\sigma}{\sigma_x} \quad \frac{1}{5}$

Section 9

A fibre surrounded by an anisotropic conductor

In the preceding sections the medium surrounding the fibre was assumed to be homogeneous and isotropic In fact in muscle nerve and brain conditions are more complicated The membrane impedance of inactive fibres and cells is so high that the action currents of an active fibre or cell passes mainly through the extracellular space (cf Buchthal Guld and Rosenfalck 1955b) As a result the conductivity of whole muscle and of white and grey matter of the brain is only about 1/10 of that of Ringer s solution (Burger and van Dongen 1960 61 Buchthal and A Rosenfalck 1966 Geddes and Baker 1967) Furthermore the tight parallel arrangement of the muscle and nerve fibres cause a significant difference in conduction properties in the direction of th fibres and perpendicular to it. Hermann (1879) found the transverse resistance of frog nerves to be 5 times the longitudinal resistance a similar difference was deduced for skeletal muscle (Geddes and Baker 1967) Considering the fibre to have a quadratic cross section and the extracellular space to be small the effective conductivity in a direction perpendicular to the fibres is half that in the direction of the fibres (Buchthal Guld and Ro enfalck 1955b) A larger anisotropy is indicated by a model f closely packed circular fibres *)

An estimate of the anisotropy can be obtained from the following considerations Let β denote the ratio between the distance through which a current flows to traverse the muscle and th short st distance

Then we have

$$\frac{1}{\beta} \quad \frac{1}{x} \quad \int_{\frac{x}{2}}^{\frac{x}{2}} \cos\theta d\theta \quad \frac{2}{x}$$

assuming the path of the current to consist of randomly orient ed elements. Let α denote the fraction of the muscle which is extracellular space If σ denotes the conductivity of the extra

*) Calculations performed by Professor Lottrup Knudsen in personal discussions concerning the range of conduction velocities in a muscle (Buchthal Guld and Rosenfalck 1955b)

cellular fluid and if $\alpha \ll 1$ the effective conductivity of the muscle in the transverse direction is:

$$\sigma_r \quad c \; \frac{\alpha}{\beta} \; \frac{1}{\beta}$$

and in the longitudinal direction

$$\sigma_x \quad \sigma \; \alpha$$

and hence

$$(101) \qquad \frac{\sigma_r}{\sigma_x} \quad \frac{1}{\beta^2} \quad \frac{4}{2} \approx 0\ 4$$

The anisotropy of the external medium can be taken into account by assuming that th fibre is surrounded by a homogeneou medium of different conductiviti s in the fibre direction and perpendicularly to it This approximation is justified when the distance is large as comp red to the di meter of the fibre

We therefore have the following conductivity tensor:

$$(102) \qquad \sigma \quad \begin{Bmatrix} \sigma_r & 0 & 0 \\ 0 & \sigma_r & 0 \\ 0 & 0 & \sigma_x \end{Bmatrix}$$

Simila ly the capacitivity is represented by a tensor:

$$(103) \qquad \varepsilon \quad \begin{Bmatrix} \varepsilon_r & 0 & 0 \\ 0 & \varepsilon_r & 0 \\ 0 & 0 & \varepsilon_x \end{Bmatrix}$$

The electromagnetic field is determined by equations (1) (8) of Section 1 together with (102) and (103) Let us consider the elec tric displacement $\vec{D}$ as consisting of two parts

$$(104) \qquad \vec{D} \quad \vec{D}_1 + \vec{D}_2$$

where

(105) $\vec{D}_1 \quad (D_x \quad D_y, \quad 0)$

and

(106) $\vec{D}_2 = (0 \quad 0 \quad D_z)$

Similarly the charge density ρ is resolved in two parts

(107) $\rho \quad \rho_1 + \rho_2$

defined by:

(108) $\mathrm{div}\,\vec{D}_1 \quad 4\pi\rho_1$

and

(109) $\mathrm{div}\,\vec{D}_2 \quad 4\pi\rho_2$

From (3) (5) (6) (8) (102) and (103) we obtain:

$$\rho \quad \frac{\sigma_r}{\varepsilon_r}\left(\frac{\delta D_x}{\delta x} + \frac{\delta D_y}{\delta y}\right) + \frac{\sigma_z}{\varepsilon_z} \quad \frac{\delta D_z}{\delta z}$$

and hence according to (104) (109)

$$\rho_1 \quad \rho_2 \quad \frac{\sigma_r}{\varepsilon_r}\ \mathrm{div}\,\vec{D}_1 + \frac{\sigma_z}{\varepsilon_z}\ \mathrm{div}\,\vec{D}_2$$

$$\frac{4\pi\sigma_r}{\varepsilon_r} \quad \rho_1 + \frac{4\pi\sigma_z}{\varepsilon_z} \quad \rho_2$$

A solution of this equation is

$$\rho_1 \quad \rho_1(x\ y\ z)\ \exp(\ 4\pi\sigma_r/\varepsilon_r\ t)$$

$$\rho_2 \quad \rho_2(x\ y\ z)\ \exp(\ 4\pi\sigma/\varepsilon_z\ t)$$

and hence

$$\rho \quad \rho_1 \exp(4\pi\sigma_r/\varepsilon_r \, t) + \rho_2 \exp(4\pi\sigma_z/\varepsilon_z \, t)$$

In Section 1 the time constants of this expression were estimated to be $2\ 10^{-9}$ sec; hence ρ can be assumed to be zero as in the isotropic case

Introducing the scalar and vector potentials as defined by (10) and (11) we find from (5) (6) and (102):

$$\mathrm{div}(g \ \{ \ \mathrm{grad}\, \varphi \quad \frac{1}{c} \frac{\partial \vec{A}}{\partial t} \ \}) \quad 0$$

i.e

$$(110) \quad \sigma_r \ \frac{\partial^2 \varphi}{\partial x^2} + \sigma_r \ \frac{\partial^2 \varphi}{\partial y^2} + \sigma_z \ \frac{\partial^2 \varphi}{\partial z^2} \quad \frac{1}{c} \ \mathrm{div}(g \ \vec{A})$$

If we introduce the condition

$$\mathrm{div}(g \ \vec{A}) \quad \frac{\sigma_z \ \varepsilon_z \mu}{c} \quad \varphi$$

(110) becomes

$$(111) \qquad \frac{\sigma_r}{\sigma_z} \left(\frac{\partial^2 \varphi}{\partial x^2} + \frac{\partial^2 \varphi}{\partial y^2}\right) + \frac{\partial^2 \varphi}{\partial z^2} \quad \frac{\varepsilon \ \mu}{c^2} \quad \varphi$$

For an isotropic medium the right hand term of (111) could be neglected this holds also in the anisotropic case and hence:

$$(112) \qquad \frac{\sigma_r}{\sigma_z} \left(\frac{\partial^2 \varphi}{\partial x^2} + \frac{\partial^2 \varphi}{\partial y^2}\right) + \frac{\partial^2 \varphi}{\partial z^2} \quad 0$$

To simplify this equation a new coordinate system is introduced

$$(113) \qquad \begin{cases} x_1 & x\sqrt{\sigma / \sigma_r} \\ y_1 & y\sqrt{\sigma_z / \sigma_r} \\ z_1 & z \end{cases}$$

Thereby (112) is transformed to:

$$\frac{\partial^2 \varphi}{\partial x_1^2} + \frac{\partial^2 \varphi}{\partial y_1^2} + \frac{\partial^2 \varphi}{\partial z_1^2} = 0 \tag{114}$$

Thus the transformation (113) formally changes (112) to the equation of the isotropic case. Denoting the potential corresponding to anisotropic conditions by φ_{an} and that of the isotropic case by φ_{iso} it follows from (114) that:

$$\varphi_{an}(x\ y\ z) = k\ \varphi_{iso}(x_1\ y_1\ z_1)$$

where x_1 y_1 z_1 are given by (113) k is a proportionality factor which is determined by σ_r and σ and the conductivity σ_e of the isotropic conductor. Introducing (113) we get

$$\varphi_{an}(x\ y\ z) = k\ \varphi_{iso}\left(x\sqrt{\frac{\sigma_x}{\sigma_r}}\ \ y\sqrt{\frac{\sigma_x}{\sigma_r}}\ \ z\right) \tag{115}$$

Considering fields which are radially symmetrical around the Z-axis the distance from this axis is related to x and y by:

$$r = \sqrt{x^2 + y^2}$$

Hence

$$\varphi_{an}(r\ z) = k\ \varphi_{iso}\left(r\sqrt{\frac{\sigma_x}{\sigma_r}}\ \ z\right) \tag{116}$$

To determine the proportionality factor k the density of the membrane current $i_m(z)$ is assumed to be independent of whether the external medium is isotropic or not. Therefore

$$\sigma_e \left.\frac{\partial \varphi_{iso}}{\partial r}\right|_{r=a} = \sigma_r \left.\frac{\partial \varphi_{an}}{\partial r}\right|_{r=a}$$

Using (115) we obtain.

$$k \quad \frac{\sigma_e}{\sqrt{\sigma_r \sigma_z}} \quad \frac{\left.\frac{\partial \varphi_{iso}}{\partial r}\right|_{r=a}}{\left.\frac{\partial \varphi_{iso}}{\partial r}\right|_{r=a\sqrt{\sigma_z/\sigma_r}}}$$

and hence (116) becomes

$$(117) \quad \varphi_{an}(r\ z) \quad \frac{\sigma_e}{\sqrt{\sigma_r \sigma_z}} \quad \frac{\left.\frac{\partial \varphi_{iso}}{\partial r}\right|_{r=a}}{\left.\frac{\partial \varphi_{iso}}{\partial r}\right|_{r=a\sqrt{\sigma_z/\sigma_r}}} \quad \varphi_{iso}\left(r\sqrt{\frac{\sigma_z}{\sigma_r}}\ z\right)$$

As to the relative decline of the potential in the radial direction we get from (116)

$$(118) \quad \frac{\varphi_{an}(r\ z)}{\varphi_{an}(\ z)} \quad \frac{\varphi_{iso}\left(r\sqrt{\frac{\sigma_z}{\sigma_r}}\ z\right)}{\varphi_{iso}\left(a\sqrt{\frac{\sigma_z}{\sigma_r}}\ z\right)}$$

According to the estimate (101)

$$\sqrt{\frac{\sigma_z}{\sigma_r}} \quad \frac{x}{2} \quad 1\ 87$$

so that (118) becomes:

$$(119) \quad \frac{\varphi_{an}(r\ z)}{\varphi_{an}(a\ z)} \quad \frac{\varphi_{iso}\left(\frac{xr}{2}\ z\right)}{\varphi_{iso}\left(\frac{xa}{2}\ z\right)}$$

From (118) it follows that the anisotropy of the external conductor causes a radial attenuation of the action potential which is larger than that corresponding to isotropic conditions.

Introducing the decline calculated for isotropic conditions (*Fig* 2) into (119) $\sigma_r/\sigma \quad 4/x^2$ brings about a decline to one tenth within a distance which is about 26 per cent smaller than for an isotropic medium (Table 2) Similarly (118) gives that the distance over which the amplitude decline to one tenth i 40 50 per cent smaller than for an isotropic medium if the anisotropy has the degree indicated by H rmann s (1879) findings ($\sigma_r/\sigma \quad 1/5$) (Table 2)

As to the absolute values of the potential at the surface of the fibre (r a) we get from (117) and (101)

$$\varphi_{an}(a\ z) \quad \frac{\sigma_e}{\sqrt{\sigma_r \sigma_z}} \quad \frac{\left.\frac{\delta \varphi_{iso}}{\delta r}\right|_{r=a}}{\left.\frac{\delta \varphi_{iso}}{\delta r}\right|_{r\ \frac{ax}{2}}} \quad \varphi_{iso}\left(\frac{ax}{2}\quad z\right)$$

and hence

$$(120) \quad \varphi_{an}(a, z) \quad \frac{\sigma_e}{\sqrt{\sigma_r \sigma_z}} \quad \frac{\left.\frac{\delta \varphi_{iso}}{\delta r}\right|_{r\ a}}{\left.\frac{\delta \varphi_{iso}}{\delta r}\right|_{r\ \frac{ax}{2}}} \quad \frac{\varphi_{iso}\left(\frac{ax}{2}\quad z\right)}{\varphi_{iso}(a\ z)} \quad \varphi_{iso}(z\ z)$$

As mentioned above this relation is valid for all value of the conductivity of the isotropic volume conductor (σ_e) To obtain an isotropic case which is a first approximation to the actual conditions we may either assume

$$\sigma_e \quad \sqrt{\sigma_r\ \sigma_z}$$

or

$$\sigma_e \quad \frac{\sigma_r + \sigma_z}{2}$$

so that

$$(121) \qquad \frac{\sigma_e}{\sqrt{\sigma_r \sigma_z}} \quad 1 \quad \text{or} \quad \frac{1}{x} + \frac{x}{4} \quad 1\ 10$$

The ratio between the radial gradients of (120) can be estimated by using (100a) and a table of K_1 For the Fourier components with frequencies of 1000 2000 Hz and with the values of the fibre radius and conduction velocity given in Section 8 we obtain

$$(122) \qquad \frac{\left.\frac{\delta \varphi_{iso}}{\delta r}\right|_{r\ a}}{\left.\frac{\delta \varphi_{iso}}{\delta r}\right|_{r\ \frac{ax}{2}}} \approx 1\ 6$$

From the curves of Fig 2 we get the following estimate:

$$(123) \qquad \frac{\varphi_{iso}(\frac{\pi a}{2} \quad x)}{\varphi_{iso}(a \quad)} \approx 0\ 75 \quad \text{or} \quad 0\ 83$$

Combining (120) (123) we finally obtain:

$$(124) \qquad \varphi_{an}(a\ x) \approx 1\ 05\ 1\ 6\ 0\ 75\varphi_{iso}(a\ x) \quad 1\ 26\varphi_{iso}(a\ x)$$

or

$$(125) \qquad \varphi_{an}(a\ x) \approx 1\ 05\ 1\ 6\ 0\ 83\varphi_{iso}(a\ x) \quad 1\ 38\varphi_{iso}(a\ x)$$

Thus taking the anisotropy into account we obtain for $\sigma_r/\sigma_z \quad 4/\pi^2$ an action potential amplitude which is 25-40 per cent higher just outside the fibre than under isotropic conditions if the conductivity σ_e in the isotropic case is given by (121) Similarly assuming $\sigma_r/\sigma_z \quad 1/5$ (117) shows that the amplitude just outside the fibre is about 50 per cent higher than in case of isotropy

Inserting (121) and (122) in (117) we obtain the following expression for the amplitude-distance relationship ($\sigma_r/\sigma_z \quad 4/\pi^2$):

$$\varphi_{an}(r\ x) \approx 1\ 68\ \varphi_{iso}(\frac{\pi r}{2} \quad x)$$

and for $\sigma_r/\sigma_z \quad 1/5$ the relation is

$$\varphi_{an}(r\ x) \approx 3\ \varphi_{iso}(r\sqrt{5} \quad x)$$

Section 10

The simulated intracellular action potentials

The preceding sections contain mathematical expressions to calculate the intracellular and the extracellular action potentials from the action potential measured just inside the membrane of the fibre

The applicability of the theory is tested by its ability to account for the extracellular action potentials observed experimentally The mathematical model can also be tested by means of a simulated intracellular action potential. Since some integrations can be performed analytically a *mathematical expression for the boundary* values simplifies the calculations

The simulated action potentials were chosen so as to approximate the intracellular action potentials of nerve and muscle fibres and to be mathematically simple without regard to membrane theories for the conduction of action potentials along excitable fibres as e g the Hodgkin Huxley equations

In preliminary calculations expressions of this type were used.

$$G(z) \begin{cases} Az^2 \exp(\lambda z) \quad B & \text{for} \quad z \geq 0 \\ B & \text{for} \quad < 0 \end{cases}$$

where z U t U being the conduction velocity A, B and λ are parameters They were adjusted to give reasonable fit with experimental resting and action potentials in nerve and muscle The factor exp(λ) was chosen since the later part of the phase of repolarization in a muscle fibre declines nearly exponentially Multiplying exp(λ z) by z^2 gave a simulation of both the phase of depolarization and of the initial phase of repolarization. In the calculations to be described z^2 was replaced by z^3 to avoid the discontinuity of the second derivative G (z) at 0

A The muscle action potential

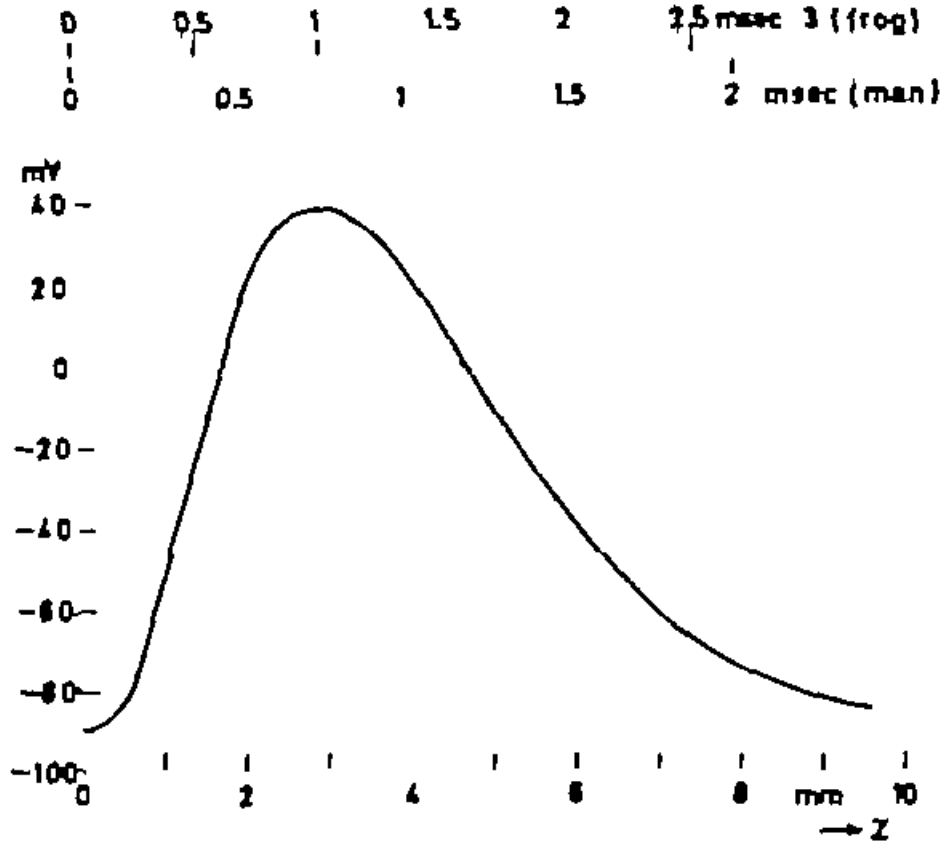

Fig 3 Simulated intracellular action potential of a muscle fibre

$$G(\ ) \begin{cases} 96\ ^{3}\exp(\ x) - 90 & \text{for} \quad x \geq 0 \\ -90 & \text{for} \quad x < 0 \end{cases}$$

x distance along the fibre in mm (abscissa below)
G potential in mV (ordinate)
Upper scale time in msec when the conduction velocity is 3 m/sec (frog) and 4 m/sec (man)

To simulate the intracellular action potential of a muscle fibre the following function was chosen.

$$(126) \qquad G(\ ) \begin{cases} 96\ ^{3}\exp(\ x) - 90 & \text{for} \quad x \geq 0 \\ -90 & \text{for} \quad x < 0 \end{cases}$$

where x is measured in mm and G in mV (Fig 3) From (126) it follows that

(127) $G(x) \quad 96x^2(3-x)\exp(-x) \quad \text{for} \quad x \geq 0$

and hence

$$G(x) \quad 0 \qquad \textit{for} \quad x \quad 0 \quad \text{and} \quad 3 \ \textit{mm}$$

i.e the action potential G(x) has its maximum at x 3 mm. With a conduction velocity of 3 m/sec (frog) or 4 m/sec (man) this corresponds to a duration of 1 or 0 75 msec for the phase of depolarization The maximum deflection is 129 mV

Regarding the second derivative we get from (127)

(128) $G''(x) \quad 96x(6-6x+x^2)\exp(-x) \quad \textit{for} \quad x \geq 0$

and therefore

$$G''(x) \quad 0 \quad \text{for} \quad x \quad 0 \quad \text{and} \quad x \quad 3 \pm \sqrt{3} \ \text{mm}$$

The corresponding maximum and minimum slopes of G are

$$G'_{max} \quad 75 \text{ mV/mm} \quad \text{at} \quad G \quad 35 \text{ mV}$$

and

$$G'_{min} \quad 33 \text{ mV/mm} \quad \text{at} \quad G \quad 0\ 4 \text{ mV}$$

With the conduction velocities of 3 and 4 m/sec this means that

$$G'_{max} \quad 225 \quad \text{or} \quad 300 \text{ V/sec}$$

and

$$G'_{min} \quad 98 \quad \text{or} \quad 131 \text{ V/sec}$$

Further differentiation of (128) gives:

(129) $G'''(x) \quad 96(6-18x+9x^2-x^3)\exp(-x) \quad \text{for} \quad x \geq 0$

From (129) it follows that

$$G''(z) = 0 \quad \text{for} \quad z = 0.42 \;\; 2.29 \;\; \text{and} \;\; 6.29 \text{ mm}$$

The corresponding maxima and minima of G are:

$G_{max\ 1}$ 97 mV/mm^2

G_{min} 66 mV/mm^2

$G_{max\ 2}$ 9 mV/mm^2

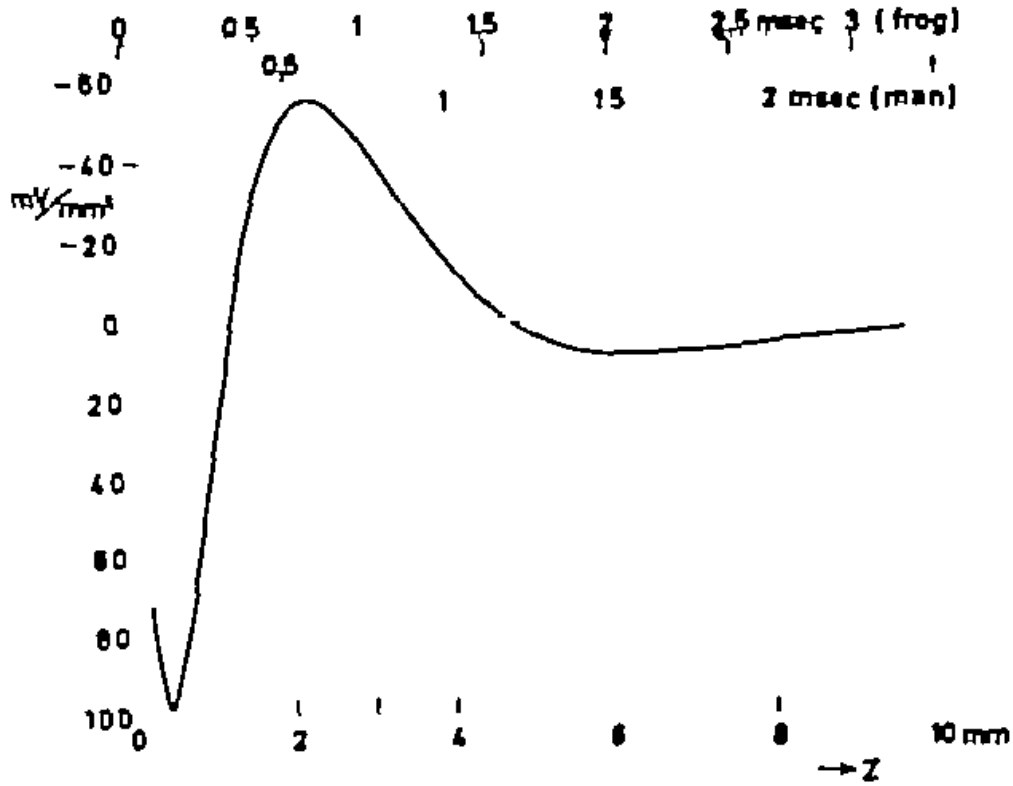

Fig 4. Second derivative of a simulated intracellular action potential of a musol fibre (see Fig 3)
Abscissae below distance along the fibre in mm (z); above: time in msec for a conduction velocity of 3 m/sec (frog 20 C) and 4 m/sec (man 36.5 C)

or in other units

$$G_{max\ 1} \quad 8\ 7\ 10^5 \text{ or } 15\ 8\ 10^5 \text{ V/sec}^2$$
$$G_{min} \quad 5\ 0\ 10^5 \text{ or } 8\ 9\ 10^5 \text{ V/sec}^2$$
$$G_{max\ 2} \quad 0\ 8\ 10^5 \text{ or } 1\ 4\ 10^5 \text{ V/sec}^2$$

Section 3 and 5 have shown that the density of the membrane current and the extracellular action potentials are closely related to the second derivative of the intracellular action potential Fig 4 gives the second derivative G (x) of the simulated intracellular action potential G is triphasic the duration of the initial positive phase being 0 42 or 0 32 msec of the negative phase 1 15 or 0 87 msec depending on the conduction velocity assumed

These data show that G(x) is a satisfactory representation of the intracellular muscle action potential

B The nerve action potential

An approximation to the intracellular action potential of a giant unmyelinated nerve fibre is given by

$$(130) \qquad G(x) = \begin{cases} 0\ 179\ ^3\ (20-x)\ \exp(\ 0\ 3\ x) \quad 60 & \text{for } \geq 0 \\ 60 & \text{for } x \quad 0 \end{cases}$$

where x is measured in mm and G in mV (Fig 5) Th slope of G is given by

$$(131) \qquad G(x) \quad 0\ 179x^2\ (60\ 10x+0\ 3x^2)\ \exp(\ 0\ 3\ x) \text{ for } x \geq 0$$

Hence the maximum and minimum of G occur at 7 85 mm and 25 5 mm The maximum deflection is 100 mV and the positive afterpotential is 7 8 mV Assuming a conducti n velocity of 20 m/sec the phase of depolarization lasts 0 4 msec and the spike 1 msec The maximum rate of rise is 430 V/se and of decline 240 V/sec occurring at 16 mV and at +2 mV respectively The second derivative of G obtained from (131) i

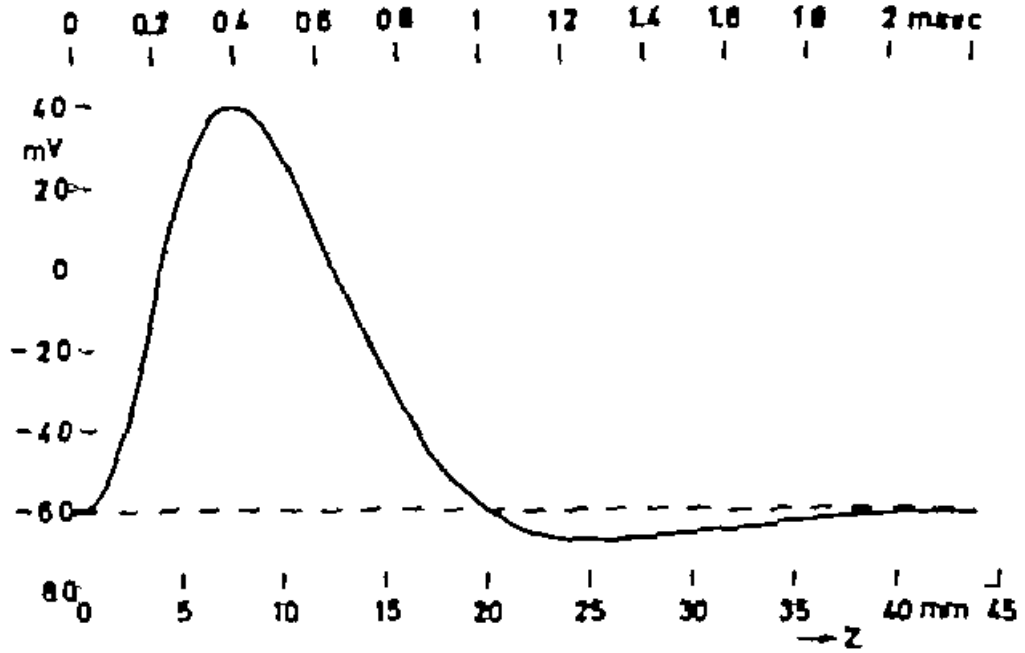

Fig 5 Simulated intracellular action potential of a non medullated quid giant nerve fibre

$$G(x) \begin{cases} 0.179\,x^3(20-x)\exp(-0.3x)-60 & \text{for } x \geq 0 \\ -60 & \text{for } x < 0 \end{cases}$$

x distance along the fibre in mm (abscissa below);
G potential in mV (ordinate)
Upper abscissa time in msec conduction velocity 20 m/sec 18 C

(132) $G'(x) = 0.179\,\{120 - 48x + 4.2x^2 - 0.09x^3\}\exp(-0.3x)$ for $x \geq 0$

and is plotted in Fig 6

Further differentiation leads to

(133) $G''(x) = 0.179\,\{120 - 152x + 27x^2 - 1.62x^3 + 0.027x^4\}\exp(-0.3x)$

and:

$$(134)\quad G^{zz}(z) \;=\; 0.179\,\{\,1.68+93.6z-12.96z^2+0.594z^3-0.0081z^4\}\,\exp(-0.3z)$$

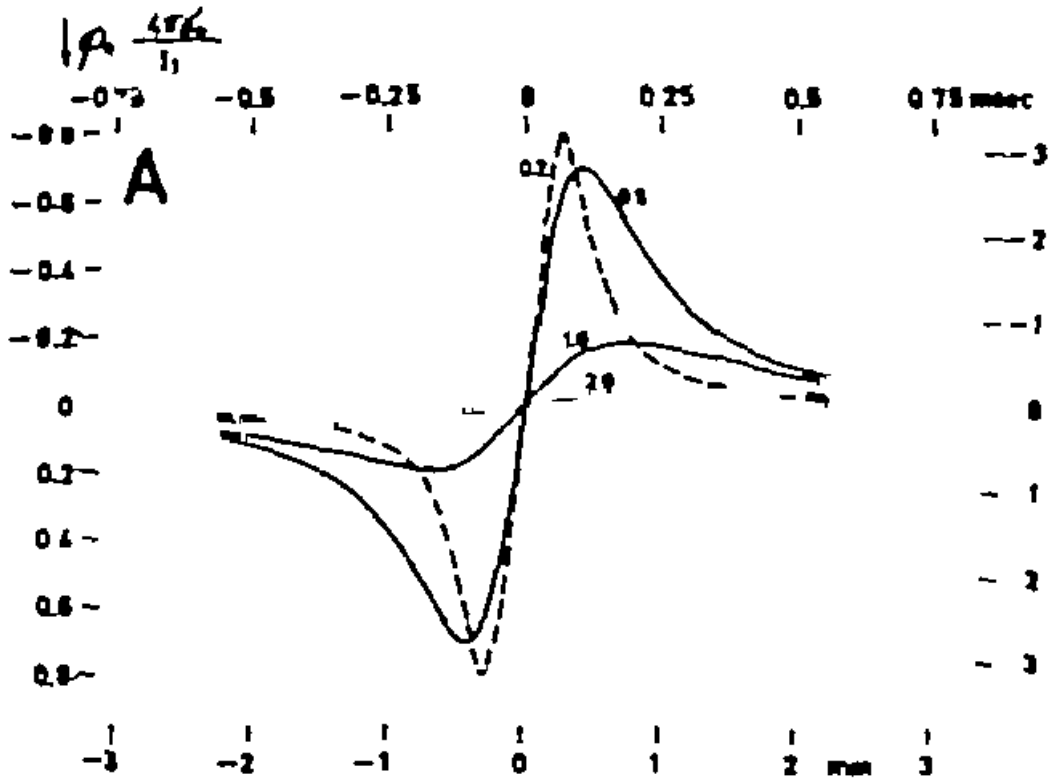
Section 11

The potentials produced by dipole and tripole generators

The simplest model used to interpret extracellular action potentials of muscle is the dipole concept applied to cardiac as well as to skeletal muscle (Wilson McLeod and Barker 1933 Hecht 1957 Craib and Canfield 1927) To account for the triphasic shape of the action potentials of skeletal muscle Craib (1928) considered two dipoles directed oppositely i.e a tripole



Let us consider point sources and sinks of current in an infinite isotropic and homogeneous medium of conductivity σ_e The arguments used in Section 1 to derive Laplace s equ tion for the scalar potential do not hold at the sources and sinks since the *equation of continuity (8) is not fulfilled at these points* At all other points Laplace equation still has to be satisfied. A current source of strength I_1 produces the spherically symmetric potential field.

$$\varphi_e(r) \quad \frac{I_1}{4\pi\sigma_e r}$$

where r is the distance from the source The potential produced by dipole generator consisting of a source I_1 and a sink I_1 a distance 2 apart is

$$\varphi_e(r \quad) \quad \frac{I_1}{4\pi\sigma_e}\left[\frac{1}{\sqrt{(z+a)^2+r^2}} \quad \frac{1}{\sqrt{(z \quad a)^2+r^2}}\right]$$

if th source i situated in (o a) and the sink in (o a) Examples of the action potentials of dipole generator with the poles 0 5 mm apart are given in Fig 7 A. These calculated action potentials are similar to th extracellular action potentials of single frog muscl fibres in Ringer solution (Håkanasson 1957a) except that the radial decline of the calculated ction potentials i somewhat f ster (Fig 7 B) Thus in the experiments the peak to peak amplitude 2 mm from the fibre axis was 4 per cent of that measured at a distance of 0 2 mm; the corresponding calculated amplitude was 1 6 pe cent.

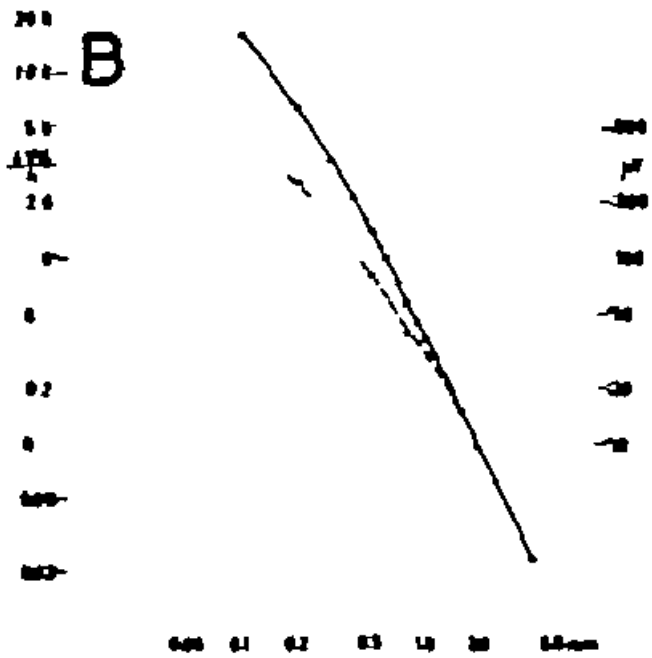


Fig 7

Let us next consider a tripole generator consisting of two sources I_1 and I_3 and a sink I_2 situated on a common axis so that I_1 is at (0 s) I_2 at (0 z) and I_3 at (0 u)

Let us assume that

$$I_1 \quad \alpha \; I_2$$

$$I_3 \quad (1 \quad \alpha)\, I_2$$

The potential produced by the tripole in the infinite conductor then is

$$\varphi_e(r\ z) \quad \frac{I_2}{4\pi\sigma_e}\left[\frac{\alpha}{\sqrt{(z+s)^2+r^2}} \quad \frac{1}{\sqrt{(z\ s)^2+r^2}} + \frac{1\ \alpha}{\sqrt{(z\ u)^2+r^2}}\right]$$

An example of a tripole action potential is given in Fig 8 The positions and strengths of sink and sources were chosen on the basis of the experimental intracellul r action potentials (p 88) The calculated action potential was triphasic the amplitude of the t rminal positive phase being 15 per c nt of the peak to-peak amplitude

PART *

QUANTITATIVE TESTS AND APPLICATION OF THE MATHEMATICAL THEORY

Section 1

The intracellular action potentials

The radial variation of the action potential within a nerve or muscle fibre is usually assumed to be negligible (e g Taylor 1963) That this is justified can be shown by the following considerations and calculation

From Hâkansson s (1957) measurements on single frog muscle fibres the radial gradient of the extracellular potential field is at most 3 mV/mm. With a specifi resistance of 87 Ω cm in the Ringer solution and 230 Ω cm in the sarcoplasm the radial variation inside the fibre amounts to at most 3 $\frac{230}{87}$ 8 mV/mm In a fibre 100 μ in diameter this corresponds to a radial variation in potential of no more than 8 0 05 0 4 mV Although the radial variation is negligibl the second derivative of the potential in the radial direction cannot be disregarded. The second derivative may be s great as 8/0 05 160 mV/mm^2 f the same ord r as th second deri vative in th fibre direction In the muscle fibres considered in my calculati ns it was at most 700 mV/mm^2 (p 92)

A more exact expression f the variation of the action potential within a fibre can be obtained from (30)

$$\varphi_1(\quad) \quad \frac{1}{2}\int_{-\infty}^{\infty} \frac{I_0(rp)}{I'(ap)} \exp(\,ip\,) \left\{ \int_{-\infty}^{\infty} V_1(u)\, \exp(ipu)du \right\} dp$$

wh re φ_1 and V_1 are m asured from th resting leval To analyse this potential the simulated ction potentials (p 58) were used

A. The simulated muscle fibre

Following (126) we put

$$V_1(u) \begin{cases} 96u^3\exp(-u) & \text{for } u \geq 0 \\ 0 & \text{for } u < 0 \end{cases} \tag{135}$$

Inserting (135) in (30) integration gives:

$$\varphi_1(r,x) \frac{288}{\pi} \int_{-\infty}^{\infty} \frac{I_o(rp)}{I_o(ap)} \frac{\exp(-ipx)}{(ip-1)^4}\, dp \tag{136}$$

I_o is a symmetric function and (136) is transformed to

$$\varphi_1(r,x) \frac{288}{\pi} \int_0^{\infty} \frac{I_o(rp)}{I_o(-p)} \left\{ \frac{\exp(-ipx)}{(ip-1)^4} + \frac{\exp(ip)}{(ip+1)^4} \right\} dp$$

from which is found

$$\varphi_1(r,x) \frac{576}{\pi} \int_0^{\infty} \frac{I_o(rp)}{I_o(ap)} \frac{(p^4-6p^2+1)\cos p}{(1+p^2)^2} \frac{(4p^3-4p)\sin px}{} dp \tag{137}$$

Let us introduce a phase angle $\theta(p)$ to reformulate (137) in a more convenient way:

$$\cos\theta(p) \frac{p^4-6p^2+1}{(1+p^2)^2} \tag{138}$$

$$\sin\theta(p) \frac{4(p^3-p)}{(1+p^2)^2} \tag{139}$$

i.e.

$$\theta(p) \tan^{-1} \frac{4(p^3-p)}{p^4-6p^2+1} \tag{140}$$

(137) can now be written

$$(141)\quad \varphi_1(r\ z)\quad \frac{576}{\pi}\quad \int_0^{\infty} \frac{I_o(rp)}{I_o(ap)}\ \frac{\cos(pz+\theta(p))}{(1+p^2)^2}\ dp$$

With $I_o(o)$ 1 the potential on the axis of the fibre is

$$\varphi_1(o\ z)\quad \frac{576}{\pi}\quad \int_0^{\infty} \frac{1}{I_o(ap)}\ \frac{\cos(pz+\theta(p))}{(1+p^2)^2}\ dp$$

Just inside the surface of the fibre the potential is:

$$(142)\quad \varphi_1(a\ z)\quad \frac{576}{\pi}\quad \int_0^{\infty} \frac{\cos(pz+\theta(p))}{(1+p^2)^2}\ dp$$

This results in a total radial variation of the potential of

$$(143)\quad \varphi_1(a\ )-\varphi_1(o\ z)\quad \frac{576}{\pi}\quad \int_0^{\infty} \left\{1\quad \frac{1}{I_o(ap)}\right\} \frac{\cos(pz+\theta)}{(1+p^2)^2}\ dp$$

$\theta(p)$ defined by (138) (140) is a monotonically decreasing function and approach s an asymptotic valu as $p \to \infty$ (Fig 8) Thus $\theta(p)$ has a negative slope which goes towards zero

$$\frac{d\theta}{dp}\quad \frac{4}{1+p^2}$$

θ varies only slightly fo $p > 4$ mm ^{1}

The integral (143) can be evaluated numerically Values of p for which $ap > 0\ 5$ hardly contribute to it Introducing

$$1\quad \frac{1}{I_o(\ p)} \approx \frac{(ap)^2}{4}$$

(Carslaw & Jaeger 1959) in (143) a simple approximate expression is derived

$$(144)\quad \varphi_1(a\ z)\ \varphi_1(o\ z) \approx \frac{144\,a^2}{\pi}\quad \int_0^{\infty} \frac{p^2\cos(p\ +\theta)}{(1+p^2)^2}\ dp$$

From (142) follows that

density of the longitudinal current decreases insignificantly (probably less than 1 per cent) towards the axis of the fibre (Table 4)

Table 4

p (mm $^{-1}$)	0	5	10	15
$1/I_0(0\ 05\ p)$	1	0 9845	0 9403	0 8729

B The simulated nerve fibre

In accordance with (130) we put

$$V_1(u) \begin{cases} 0\ 179u^3(20\ u)\exp(-0\ 3u) & \text{for } u \geq 0 \\ 0 & \text{for } u < 0 \end{cases} \tag{147}$$

Inserting this in the expression for the intracellular action potential (30) integration after u give

$$\varphi_1(r\ z)\ \frac{10\ 74}{\pi} \int_{-\infty}^{\infty} \frac{I_0(rp)}{I_0(ap)}\ \frac{ip\ 0\ 5}{(ip-0\ 3)^5}\ \exp(-ipz)dp$$

The symmetry of I_0 gives

$$\varphi_1(r\ z)\ \frac{10\ 74}{\pi} \int_0^{\infty} \frac{I_0(rp)}{I_0(ap)} \left\{ \frac{ip-0\ 5}{(ip-0\ 3)^5}\ \exp(-ipz) + \frac{ip+0\ 5}{(ip+0\ 3)^5}\ \exp(ipz) \right\} dp \tag{148}$$

which can be written as

$$\varphi_1(r\ z)\ \frac{21\ 48}{\pi} \int_0^{\infty} \frac{I_0(rp)}{I_0(ap)}\ \frac{1}{(0\ 09+p^2)^5} [(p^5\ 0\ 15p^4\ 0\ 0945p^2+0\ 001215)\cos pz + (p^5+0\ 15p^3\ 0\ 01782p)\sin pz]\ dp$$

To simplify this expression the phase angles $\theta_1(p)$ and $\theta_2(p)$ are introduced

$$(149)\qquad \begin{cases} \cos\theta_1(p) & \dfrac{0.5}{\sqrt{0.25+p^2}} \\ \sin\theta_1(p) & \dfrac{p}{\sqrt{0.25+p^2}} \end{cases}$$

i.e.

$$(150)\qquad \theta_1(p) \quad \tan^{-1} 2p$$

Similarly

$$(151)\qquad \begin{cases} \cos\theta_2(p) & \dfrac{0.3}{\sqrt{0.09+p^2}} \\ \sin\theta_2(p) & \dfrac{p}{\sqrt{0.09+p^2}} \end{cases}$$

i.e.

$$(152)\qquad \theta_2(p) \quad \tan^{-1}\frac{p}{0.3}$$

With

$$(153)\qquad \theta(p) \quad 5\theta_2 \quad \theta_1$$

(148) can be written as

$$(154)\quad \varphi_1(r,x) \quad \frac{21.48}{x}\int_0^{\infty}\frac{I_0(rp)}{I_0(ap)}\,\frac{(0.25+p^2)^{1/2}}{(0.09+p^2)^{5/2}}\,\cos(px-\theta(p))\,dp$$

$\theta(p)$ increases monotonically with p but changes only little for $p > 2\ \mathrm{mm}^{-1}$ (Fig. 10). For unmyelinated nerve fibres the radius a can be as great as 0.2–0.35 mm (Spector 1956). However values of $p < 1\ \mathrm{mm}^{-1}$ contribute insignificantly to the integral (154)

density of the longitudinal current decreases insignificantly (probably le s than 1 per cent) towards the axis of the fibre (Table 4)

Table 4

p (mm ^{1})	0	5	10	15
$1/I_0(0\ 05\ p)$	1	0 9845	0 9403	0 8729

B The simulated nerve fibre

In accordance with (130) we put

$$(147) \qquad V_1(u) \begin{cases} 0\ 17\,u^3(20\ u)\exp(\ 0\ 3u) & \text{for } u \geq 0 \\ 0 \quad \text{for} \quad u < 0 \end{cases}$$

Inserting this in the expression for the intracellular action potential (30) integration after u gives

$$\varphi_1(r\ z)\ \frac{10\ 74}{\pi}\int_{-\infty}^{\infty}\frac{I_0(rp)}{I_0(ap)}\ \frac{ip-0\ 5}{(ip-0\ 3)^5}\ \exp(\ ipz)dp$$

Th symmetry of I_0 gives

$$(148) \quad \varphi_1(r\ z)\ \frac{10\ 74}{\pi}\int_{0}^{\infty}\frac{I_0(rp)}{I_0(ap)}\left\{\frac{ip\ 0\ 5}{(ip-0\ 3)^5}\ \exp(\ ip\ )\right.$$

$$\left. +\ \frac{ip+0\ 5}{(ip+0\ 3)^5}\ \exp(ipz)\right\}dp$$

which can be written as

$$\varphi_1(r\ )\ \frac{21\ 48}{\pi}\int_{0}^{\infty}\frac{I_0(rp)}{I_0(ap)}\ \frac{1}{(0\ 09+p^2)^5}$$

$$[(p^6\ 0\ 15p^4\ 0\ 0945p^2+0\ 001215)\cos pz$$

$$(p^5+0\ 18p^3\ 0\ 01782p)\sin pz]\,dp$$

Therefore we can assume $a_p < 0.4$ and the radial variation of the action potential within the nerve fibre is approximated by (146) The radial difference varies between 0.31 mV and +0.20 mV (Table 5)

As in the muscle fibre expression (148) for the intracellular action potentials shows that the longitudinal current density $\sigma_i \frac{\partial \varphi_i}{\partial x}$ varies only little over the cross section of the nerve fibre

Section 2

The density of the membrane current

General expressions for the density of the membrane current are given by (33) (34) (38) and (40) e g

$$(39)\quad i_m(z) \quad \frac{\sigma_i a}{2} \frac{d^2 V_i}{dz^2} + \frac{\sigma_i a}{4\pi} \int_{-\infty}^{\infty} \frac{p^2 I_2(ap)}{I_0(ap)} \exp(ipz) \left\{ \int_{-\infty}^{\infty} V_i(u) \exp(ipu)du \right\} dp$$

A. The "muscle fibre

Using the simulated muscle action potential (126) th procedure described in Section 1 gives

$$(155)\quad i_m(\ ) \quad \frac{\sigma_i a}{2} \frac{d^2 V_i}{dz^2} + \frac{288\sigma_i a}{\pi} \int_0^{\infty} \frac{p^2 I_2(\ p)}{I_0(ap)} \frac{\cos(p\ +\theta(p))}{(1+p^2)^2} dp$$

According to (145)

$$(156)\qquad \frac{d^2 V_i}{dz^2} \quad \frac{576}{\pi} \int_0^{\infty} \frac{p^2 \cos(p\ +\theta)}{(1+p^2)^2} dp$$

and (155) an be rewritten s

$$(157)\quad i_m(z) \quad \frac{288\sigma_i a}{\pi} \int_0^{\infty} \left\{ 1 \quad \frac{I_2(ap)}{I_0(ap)} \right\} \frac{p^2 \cos(p\ +\ )}{(1+p^2)^2} dp$$

Hence the influence of the second term in (155) is determined by $\frac{I_2(ap)}{I_0(ap)}$

(157) shows that p-value above 10 mm ^{1} contribute only litl to the membrane current and that the econd term in (155) only a few per cent of the first term (Table 6) A better estimate is obtained by means of the following pproximations which are valid for small values of ap

Table 6

p (mm^{-1})	$\frac{I_2(0\ 05\ p)}{I_o(0\ 05\ p)}$
0	0
4	0 005
6	0 011
8	0 020
10	0 030
16	0 072
20	0 107
24	0 145

(158) $$I_o(ap) \approx 1 + \frac{a^2}{4} p^2$$

(159) $$I_2(ap) \approx \frac{a^2}{8} p^2$$

Therefore

(160) $$\frac{2\pi\sigma_1 a}{\kappa} \int_0^\infty \frac{p^2 I_2(ap)}{I_o(ap)} \frac{\cos(px+\theta)}{(1+p^2)^2} dp$$

$$\approx \frac{3\pi\sigma_1 a^3}{\kappa} \int_0^\infty \frac{p^4 \cos(px+\theta)}{(1+p^2)^2} dp$$

According to (156)

$$\frac{d^4 V_1}{dx^4} \frac{576}{\kappa} \int_0^\infty \frac{p^4 \cos(px+\theta)}{(1+p^2)^2} dp$$

Hence (160) can be expre sed as

$$\frac{2\pi\sigma_1 a}{\kappa} \int_0^\infty \frac{p^2 I_2(ap)}{I_o(ap)} \frac{\cos(p\ +\theta)}{(1+p^2)^2} dp \approx \frac{\sigma_1 a^3}{16} \frac{d^4 V_1}{dx^4}$$

Table 7

The ratio α between the second and the first term of (155)

z(mm)	α
0 4	2 3 10 ^{3}
1 2	4 0 10 ^{3}
2 2	0 5 10 ^{3}
4 8	0 1 10 ^{3}
6 4	0 1 10 ^{3}
8 2	0 1 10 ^{3}

The ratio α between the second and the first t rm of (155) is therefore

$$\alpha \approx \frac{a^2}{8} \frac{\frac{d^4V_i}{dx^4}}{\frac{d^2V_i}{dx^2}} \tag{161}$$

Using (135) and differentiating we get

$$\approx \frac{a^2}{8} \quad 3 \quad \frac{12z^2 + 36z \quad 24}{3 \quad 6z^2 + 6z}$$

With 0 05 mm $|\alpha|$ is less than 4 10 ^{3} (Table 7) i e the econd term in (155) is n gligible so that

$$i_m(z) \approx \frac{\sigma_i a}{2} \frac{d^2V_i}{dx^2} \tag{162}$$

(162) is the membrane current derived from th core conductor model (cf (47))

Introducing the temporal derivative in stead of the spatial and the conduction velocity U of the action potential (162) becomes

$$(163) \qquad i_m(t) \approx \frac{\sigma_i a}{2U^2} \frac{d^2V_i}{dt^2}$$

B The nerve fibre

Similar considerations can be applied to the artificial nerve action potential (130) Inserting (130) in (39) gives:

$$(164) \quad i_m(z) \quad \frac{\sigma_i a}{2} \frac{d^2V_i}{dz^2} + \frac{10\ 74\sigma_i a}{\pi} \int_0^{\infty} \frac{I_2(ap)}{I_o(ap)} \frac{p^2\ (0\ 25+p^2)^{1/2}}{(0\ 09+p^2)^{5/2}} \cos(pz-\theta)\,dp$$

Using (154) this can be transformed to

$$(165) \quad i_m(\ ) \quad \frac{10\ 74\sigma_i a}{\pi} \int_0^{\infty} \left\{1 \quad \frac{I_2(ap)}{I_o(ap)}\right\} \frac{p^2\ (0\ 25+p^2)^{1/2}}{(0\ 09+p^2)^{5/2}} \cos(pz\ \theta)\,dp$$

Thus also in the nerve fibre the second term of (164) is determined by $I_2(ap)/I_o(ap)$ The integrand of (165) declines so rapidly that p-value above 3 mm ^{1} contribute insignificantly and the main contribution is due to p-values which are smaller than 1 mm ^{1}

This implies that for non-myelinated giant axons the second term of (164) amounts to only a few per cent of the first term (Table 8)

Table 8

$p(mm^{-1})$	$\frac{I_2(0\ 35\ p)}{I_o(0\ 35\ p)}$	$\frac{I_2(0\ 2p)}{I_o(0\ 2p)}$

1	0 016	0 005
2	0 057	0 020
3	0 116	0 043
4	0 185	0 072
6	0 320	0 145

Section 3

The surface action potential

The approximate expression (81) for the action potential recorded on the surface of a thin layer of conducting fluid around a fibre contained as the first term the extracellular potential calculated from the linear core-conductor model (45) (81) can with (82) and (83) be written:

$$(166)\quad \varphi_e(b\ z) \approx \frac{r_e}{r_i}\ V_i(z) + \frac{r_e}{2\pi r_i} \int_{-\infty}^{\infty} \frac{I_2(ap)}{I_o(ap)} \exp(\ ipz) \left\{ \int_{-\infty}^{\infty} V_i(u)\ \exp(ipu)du \right\} dp$$

Inserting (80) in (166) allows an estimate of the second term of (166)

$$(167)\quad \varphi_e(b\ \ ) \approx \frac{r_e}{2\pi r_i} \int_{-\infty}^{\infty} \left[1 \quad \frac{I_2(ap)}{I_o(ap)} \right] \exp(\ ipz) \left\{ \int_{-\infty}^{\infty} V_i(u)\ \exp(ipu)du \right\} dp$$

A. The muscle fibre

Introducing the simulated intracellular muscle action potential (126) in (167) we obtain (cf Section 1):

$$(168)\quad \varphi_e(b\ \ ) \approx \frac{575\, r_e}{\pi r_i} \int_0^{\infty} \left\{ 1 \quad \frac{I_2(ap)}{I_o(ap)} \right\} \frac{\cos(px + \theta(p))}{(1+p^2)^4}\, dp$$

where $\theta(p)$ is given by (140) $I_2(ap)/I_o(ap)$ increases slowly with p and i only 0 011 if p 6 mm^{-1} and a 0 05 mm (Table 6) The integrand of (168) declines so rapidly with increasing p that p-value exceeding e g 6 mm^{-1} can be disregarded. Therefore the second term of (166) which corresponds to the I_2/I_o term of (168) is less than 1 per cent of the first term of (166) Hence:

$$(169) \qquad \varphi_e(b\ x) \approx \frac{r_o}{r_i}\ V_i(x)$$

$V_i(\ )$ being measured from the resting level.

β The nerve fibre

Use of the simulated intracellular nerve action potential (130) leads to the same result as obtained with the simulated muscle action potential Thus (167) gives:

$$(170) \quad \varphi_e(b\ x) \approx \frac{21\ 48\, r_o}{\pi r_i} \int_0^\infty \left\{1 - \frac{I_2(\pi p)}{I_0(\pi p)}\right\} \frac{(0\ 25+p^2)^{1/2}}{(0\ 09+p^2)^{5/2}} \cos(p\pi\ \theta(p))\, dp$$

where $\theta(p)$ is given by (153) Inspection of the integrand shows that p-values above 2 mm^{-1} only contribute little to the integral and the second term of (168) is at most a few per cent of the first (Table 8) Hence (169) expresses the surface action potential to good approximation.

Section 4

The extracellular action potentials in an unlimited conductor

A. The simulated muscle fibre

Inserting the intracellular muscle action potential (126) in the expression (57) we get.

$$(171)\quad \varphi_e(r\ z) \quad \frac{288\sigma_i}{\pi\sigma_e} \int_{-\infty}^{\infty} \frac{I_1(a|p|)K_0(r|p|)}{I_0(ap)\ K_1(a|p|)} \frac{\exp(\ ipz)}{(ip\quad 1)^4}\ dp$$

As in the case of the intracellular potential (cf p 70) (171) is transformed to:

$$(172)\quad \varphi_e(r\ z) \quad \frac{576\sigma_i}{\pi\sigma_e} \int_0^{\infty} \frac{I_1(ap)K_0(rp)}{I_0(ap)K_1(ap)} \frac{\cos(pz + \theta(p))}{(1+p^2)^2}\ dp$$

where $\theta(p)$ is defined by (138) (140) I_1 can be expressed in terms of I_0 and I_2 (Carslaw & Jaeger 1959)

$$(173)\quad \varphi_e(r\ \ ) \quad \frac{288\sigma_i a}{\pi\sigma_e} \int_0^{\infty} \left\{1 \quad \frac{I_2(ap)}{I_0(ap)}\right\} \frac{K_0(rp)}{K_1(ap)} \frac{p}{(1+p^2)^2}$$

$$\cos(pz + \theta)dp$$

With a 0 05 mm the integrand of (173) declines rapidly and the contribution from p-value above 8 mm $^{-1}$ (i.e ap > 0 4) to the potential is negligible as assumed in deriving the line integral expression (62) for the extracellular action potentials in terms of the density of the membrane current $i_m(z)$ distributed as sources and sinks along th axis of the fibre:

$$(63)\qquad \varphi_e(r\ z) \approx \frac{a}{2\sigma_e} \int_{-\infty}^{\infty} \frac{i_m(s)}{\sqrt{r^2 + (z\ s)^2}}\ ds$$

The assumption that p-values above 8 mm $^{-1}$ can be neglected lead also to the expression (66) in which the virtual sources and sinks of the potential were located at the surf ce of the fibre.

$$(169) \qquad \varphi_e(b\ z) \approx \frac{r_e}{r_i}\ V_i(z)$$

$V_i(z)$ being measured from the resting level.

B. The nerve fibre

Use of the simulated intracellular nerve action potential (130) leads to the same result as obtained with the simulated muscle action potential. Thus (167) gives

$$(170) \qquad \varphi_e(b\ z) \approx \frac{21\ 48\ r_e}{\pi r_i} \int_0^\infty \left\{1 - \frac{I_2(ap)}{I_0(ap)}\right\} \frac{(0\ 25+p^2)^{1/2}}{(0\ 09+p^2)^{5/2}} \cos(pz\ \theta(p))\,dp$$

where $\theta(p)$ is given by (153). Inspection of the integrand shows that p-values above 2 mm^{-1} only contribute little to the integral and the second term of (166) is at most a few per cent of the first (Table 8). Hence (169) expresses the surface action potential to good approximation.

Table 8

5 2	5 07	0 049
6 0	5 51	0 017

) A( ) defined by (179)

To compare $_{1m\ 1}(z)$ and $\frac{\sigma_i a}{2}\ \frac{d^2V_i}{dz^2}$ the following integral wa cal culated for the simulated intracellular muscle action potential (126) nd its second derivative (126):

$$(178) \qquad A(z) \quad \frac{a^2}{2} \int_{-\infty}^{\infty} \frac{\frac{d^2V_i}{ds^2}}{\{(\ \ s)^2+a^2\}^{3/2}}\ ds$$

assuming $\underline{a}$ 0 05 mm. A(z) deviated only slightly from $\frac{d^2V_1}{dz^2}$ (Table 9) Thus the initial positive peak and the negative peak of A(z) were 2 5 and 0 9 per cent lower than those of $\frac{d^2V_1}{dz^2}$ and the initial positive phase of A(z) was only a small fraction of a millimetre wider than that of $\frac{d^2V_1}{dz^2}$

Hence it is justified to apply Lorente de Nó-type approximations in the calculations of extracellular action potentials of muscle fibres.

B The simulated nerve fibre potential

Introducing (130) in (57) we get

$$(180)\quad \varphi_e(r\ z) \quad \frac{21\ 48\sigma_i}{\pi\sigma_e} \int_{-\infty}^{\infty} \frac{I_1(a|p|)K_0(r|p|)}{I_0(ap)\ K_1(a|p|)} \exp(\ ipz) \frac{ip\quad 0\ 5}{(ip\quad 0\ 3)^5}\ dp$$

In analogy to (135) this can be transformed to

$$(181)\quad \varphi_e(r\ z) \quad \frac{42\ 96\sigma_i}{\pi\sigma_e} \int_0^{\infty} \frac{I_1(ap)K_0(rp)}{I_0(ap)K_1(ap)} \frac{(0\ 25 + p^2)^{1/2}}{(0\ 09 + p^2)^{5/2}} \cos(pz\quad \theta)\,dp$$

Introducing I_2 in place of I_1 we get

$$(182)\quad \varphi_e(r\ z) \quad \frac{21\ 48\sigma_i a}{\pi\sigma_e} \int_0^{\infty} \left\{1\quad \frac{I_2(ap)}{I_0(ap)}\right\} \frac{K_0(rp)}{K_1(ap)} \frac{p(0\ 25 + p^2)^{1/2}}{(0\ 09 + p^2)^{5/2}} \cos(pz\quad \theta)\,dp$$

The integrand of (182) declines rapidly and p-values > 2 mm (i.e. $ap > 0.7$ and $ap > 0\ 4$ for a 0 35 mm and 0 2 mm) give an

insignificant contribution. Hence the line and surface integrals (174) and (175) are valid approximations in the case of nerve fibres with a 0 2 mm as well as for the muscle fibre They are probably also applicable to thicker nerve fibres since ap K_1(ap) 0 735 at ap 0 7 i.e not markedly different from 1 (cf p 31)

C Extracellular action potentials calculated from measured intracellular potentials

To study the properties of the extracellular action potential as given by the approximate solution (174) I have used measured intracellular action potentials in frog (Buchthal and Engbæk unpublished) rat (Mu choll 1957 Fig 5b) and human muscle fibres (Lædin unpublished) (Fig 11) The rat muscle fibre potential was recorded far from the end plate of a fibre in an isolated diaphragm kept in Tyrode-solution at 21 C The resting potential was 90 mV the overshoot during the action potential 33 mV The conduction velocity not availabl for thi particular fibre was assumed to be 2 m/sec This was the average propagation velocity along the fibres of the diaphragm which varied little from fibre to fibre (Muscholl 1957) Th action potentials in the frog were derived from single fibres of isolated sartorius muscles kept in Ringer's solution at 25 C and 18 C The resting potentials were 75 and 73 mV; the overshoot during the action potential was 23 mV and 38 mV respectively and th conduction velocity was 3 3 m/sec and 1 8 m/sec Although an overshoot of 23 mV might indicate that th fibre has not been in the best physiological state (see p 98) calculations were made also on this fibre since the conduction velocity was normal and the rate of rise was only slightly reduced (Buchthal and Engbæk 1963) The action potential from man was recorded in excised intercostal muscl of a 45 year old man. The tissue was kept in Tyrode s solution containing 5 4 mM potassium (37 C) A 20 MΩ micro el ctrode was used fo the recording The peak deflection was 97 mV and the maximum rate of rise 420 V/sec. The resting potential most probably was 75–80 mV (Lædin 1958) The second derivative of the action potential was measured by means of two

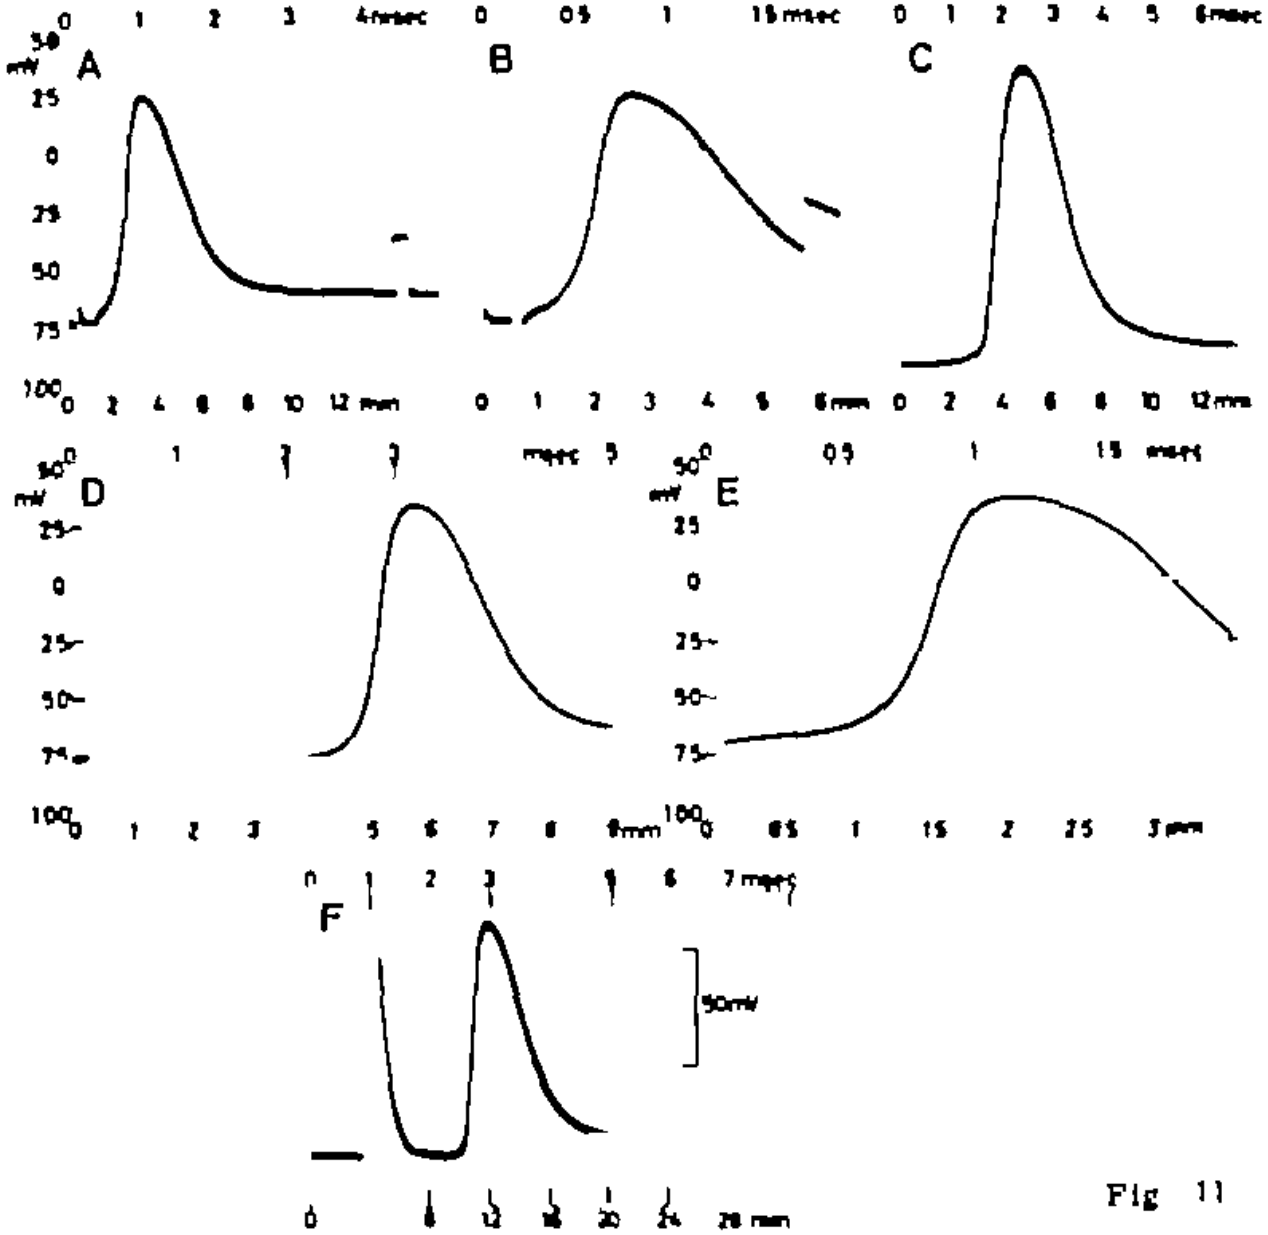

Fig 11

RC units with a time constant of 20 μsec Th conduction velocity was not determined A value of 4 m/sec was assumed in the calculations (Buchthal Guld and Rosenfalck 1955a)

The second derivative of the intracellular muscle action potentials was determin d graphically on photographic enlargements (10×) (Fig 12) The temporal and spatial derivatives are related by (18) Th se distributions of sources and sinks show that the dipole and the tripole model (p 65 Figs 7 and 8) represent approximation to the Lorente d Nó type of model.

The radii of the fibres were not known However Muscholl (1957) found th t the amplitude and the time course of the intracellular action potential were independent of the fibre thickne s and we have chosen a representative value for the radius of 0 05 mm for the mu cle fibres of the frog of 0 02 mm for the fibre of the rat muscle and of 0 028 mm for the human muscle fibre

Fig 11 Intracellular ction potential from fibres of frog at and human muscl

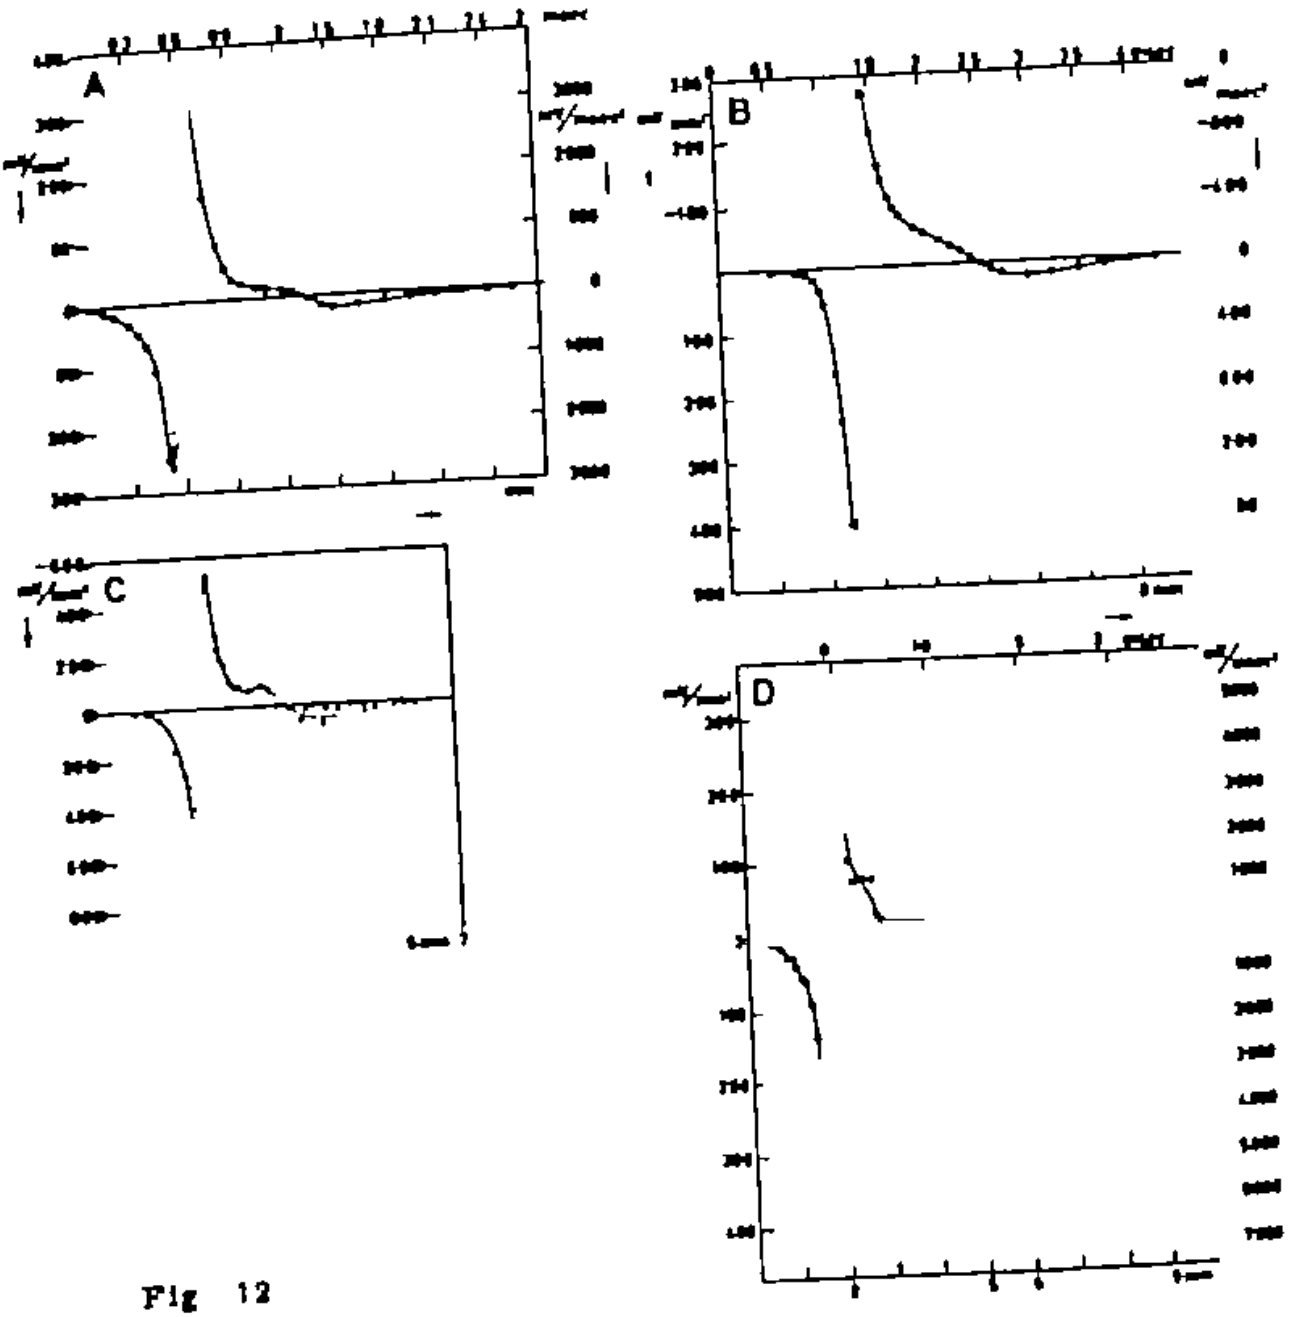

Fig 12

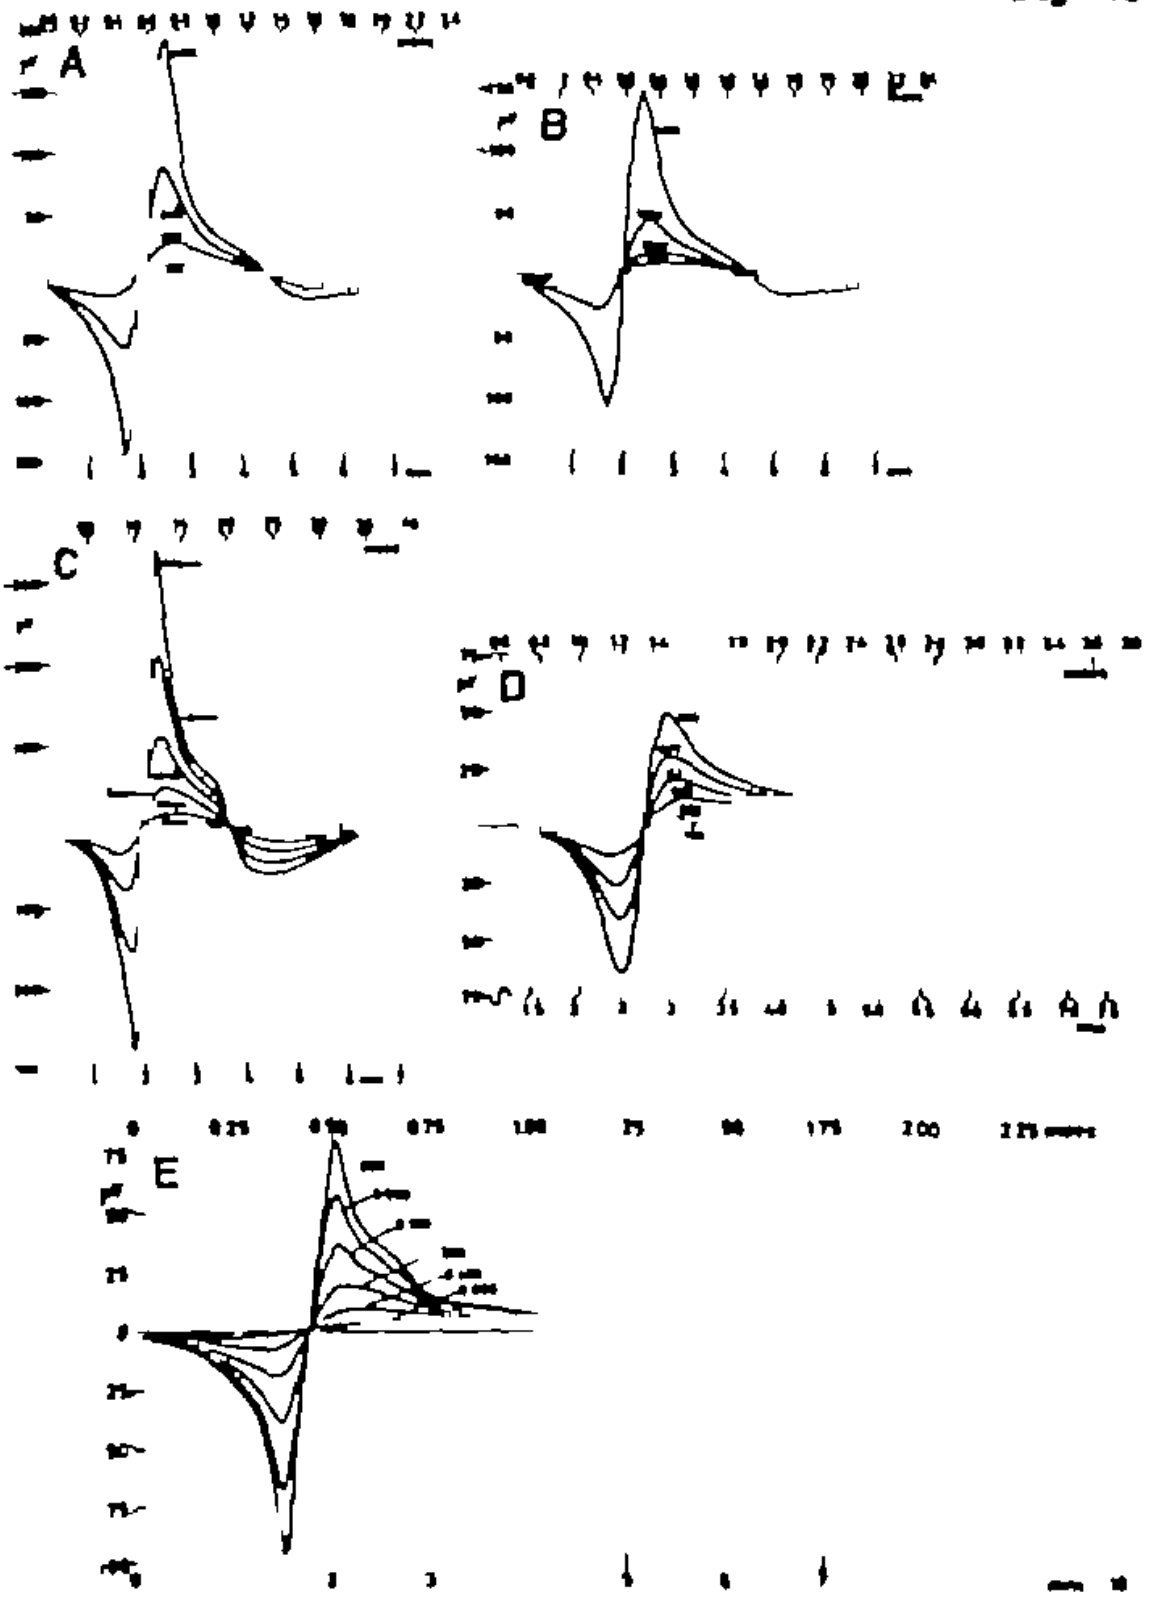
As to the ratio σ_i/σ_e between the conductivities of the axoplasm and the external medium Fatt (1964) found the same conductivity of the axoplasm in fibres of the rat diaphragm and in frog muscle From the values given by Fatt (1964) for rat muscle and by Katz (1948) for frog muscle I assumed that

$$\frac{1}{\sigma_i} \quad 330\ \Omega\ \text{cm}$$

The conductivity of the extracellular fluid was assumed to be identical with that of Ringer's or Ringer Locke solution (Katz 1948 Fatt 1964)

$$\frac{1}{\sigma_e} \quad \begin{cases} 77\ \Omega\ \text{cm (frog 25 C)} \\ 66\ \Omega\ \text{cm (rat 21 C)} \end{cases}$$



Th refore we assume

$$\frac{\sigma_i}{\sigma_e} \quad \frac{1}{3}$$

The integration of (174) was performed numerically at a number of distance r from the axis of the fibre and for different values of z using a step length of 0 167 mm and 0 05 mm for the fibres of frog muscle and 0 1 mm for the fibre of rat and of human muscle

Fig 13

When necessary correction was made for the error introduced by replacing the continuous distribution of (174) with a discrete series of sources and sinks (Appendix 1)

The calculated action potentials (Fig 13) are triphasic in shape the two first phases are similar in size and near the fibre the amplitude of the low terminal phase amounts to only 5-10 per cent of the peak to-peak amplitude The action potential declines rapidly as a function of the distance from the axis of the muscle fibre and the relative decline of the terminal phase is smaller than that of the main phases (Fig 14 cf Fig 2 and Table 2) At a distance (r 0 5 mm) at which the peak to-peak amplitude has declined to about 10 per cent of its maximum value the terminal phase has declined to 20-25 per cent of its value just outside the fibre

Another feature of the radial change of the action potential field is the displacement of the peaks with increasing distance resulting in a doubling of the separation between the two main peaks within 0 3 0 5 mm for the frog muscle fibres and 0 3 mm for the rat muscle fibre (Fig 14D) The increase was demonstrated in

Fig 13 Calculated action potentials at different distances from a muscle fibre Obtained from the intracellular action potentials of Fig 11 on the basis of a Lorente de Nó type approximation for the description of the extracellular field (174)

experiments with single frog muscle fibres in Ringer s solution (Håkansson 1957a) In human muscle the duration of the positive-negative deflection of motor unit spike potentials increased by 75 pe cent over 0 38 mm (Buchthal Guld and Rosenfalck 1957a)

The absolute values of the calculated potentials depend on the radii and conductivity ratio assumed $\varphi_e(r s)$ being proportional to the squar of the radius and to the conductivity ratio (cf 174) Comparing the maximum peak to peak values of Fig 13 (333 μV and 610 μV for the frog fibres 114 μV for the rat fibre and 171 μV for the human muscle fibre) with the findings of Håkans son (1956 1957a) (800-2900 μV average 1800 μV) and Krnjević and Miledi (1958) the calculated values are rather low in case of the rat fibre *If we assume a somewhat larger fibre radius* e g 0 065 mm for the frog 0 030 mm for the rat and 0 05 mm for man the maximum amplitudes are 490 μV and 860 μV (frog) 215 μV (rat) and 395 μV (man) Higher amplitudes are obtained if a correction is introduced to compensate for the 15 25 per cent reduced amplitude of the intracellular action potentials of the frog As to the rat muscle fibre Krnjević and Miledi (1958) did not use isolated fibres but recorded from the surface of a diaphragm.

The density of the membrane current i_m was calculated from (162) Inserting the second derivates of the intracellular action potentials (Fig 12) the conductivity σ_i and the radius a we find that in the rat muscle fibre i_m has maximum values of +0 2 and 0 1 mamp/cm^2 in man +0 25 and 0 2 mamp/cm^2 and in the frog +0 35 and 0 3 mamp/cm^2 in one fibre and +0 8 and 0 6 mamp/cm^2 in anothe The values are compatible with the maximum value of the radial current density 100μ from an isolated frog muscle fibre as estimated by Håkansson (1957a 0 3 mamp/cm^2)

I. The relation between the extracellular action potentials and the thickness of the fibre

To evaluate the influence of the radiu of the fibre on the calculated extracellular action potential knowledge is required of the dependence

of the spatial second derivative of the intracellular action potential $\left(\frac{d^2V_i}{dx^2}\right)$ on the radius

Muscholl (1957) found the time course of the intracellular action potential to be independent of fibre diameter in strips of the rat diaphragm. Also the conduction velocity U was independent of fibre thickness. Therefore (18) shows that $\frac{d^2V_i}{dx^2}$ is independent of the thickness too. Hence the conductivity σ_i being the same in thick as in thin fibres (174) shows that the action potential from a fibre has an amplitude which is proportional to the square of the radius of the fibre. Therefore the amplitude distance relationship of Fig. 14 B can be used to calculate the relationship between fibre radius and the amplitude of the action potential recorded just outside the fibre (Fig. 15).

The amplitude A increases according to:

$$A \quad k\, a^{1.7}$$

where a is the radius of the fibre. No data is available on which this relation can be tested.

In frog muscle the conduction velocity of a single fibre immersed in a Ringer bath increased proportionally to the fibre diameter (Hâkansson 1956). Hâkansson found that the duration of the extracellular action potential increased slightly with the fibre diameter but no mention was made as to a corresponding change of the intracellular action potential (Hâkansson 1957a). Assuming the time course of the intracellular action potential to be independent of the fibre thickness the influence of the radius on the extracellular potential is obtained when (174) is expressed in temporal instead of in spatial terms. Introducing t and u defined as:

$$x \quad U \cdot t$$

$$U \, u$$

where U denotes the conduction velocity.

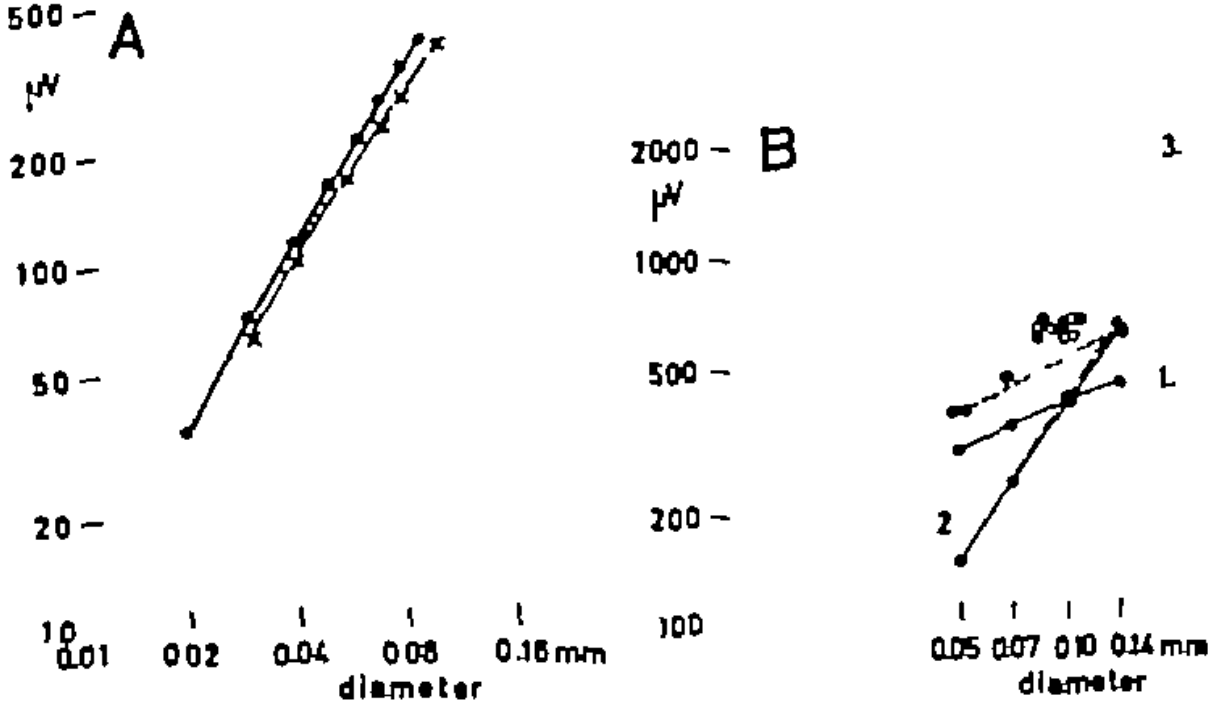

Fig 15 Relation between the peak to-peak amplitude of the calculated action potential and the diameter of the muscle fibre

A. calculated amplitude just outside a rat (●—●) and a human (x—x) muscle fibre assuming the time course and conduction velocity of the intracellular action potential to be independent of fibre thickness

B amplitude at a distance of 38 μ from the surface of a frog muscle fibre

1 calculated assuming (i) the conduction velocity to be proportional to the thickness of the fibre and (ii) the time course of the intracellular action potential (Fig 11 D E) to be independent of the thickness of the fibre

2 calculated assuming (i) the conduction velocity to be proportional to the thickness of the fibre and (ii) the density of the membrane current (Fig 13 D) to be independent of the thickne s of the fibre

Full lines radius of the fibre 50 μ

Broken lines radius: 65 μ

3 measured by Hâkansson (1956 Fig. 9) from isolated frog muscle fibres in Ringer s solution.

$$(184)\quad \varphi_e(r\ t) \quad \frac{a^2\sigma_i}{U^2\sigma_e} \int_{-\infty}^{\infty} \frac{\frac{d^2V_i}{du^2}}{\sqrt{(t-u)^2+(r/U)^2}}\, du$$

Inserting

$$(185)\qquad U \quad k\ a \quad \text{(Håkansson 1956)}$$

in (184) the action potential just outside the muscle fibre is

$$(186)\quad \varphi_e(a\ t) \quad \frac{\sigma_i}{k^2\sigma_e} \quad \int_{-\infty}^{\infty} \frac{\frac{d^2V_i}{du^2}}{\sqrt{(t-u)^2+\frac{1}{k^2}}}\, du$$

Thus the surface action potential should be independent of the thickness of the fibre Håkansson (1956) measured the action potential amplitude 38μ from the surface to avoid damaging the fibre Introducing (185) in (184) it is seen that

$$(187)\qquad \varphi\ (r\ t) \quad f(\frac{r}{a}\quad t)$$

i the potential is a function of the ratio between the radial distance r and the radius of the fibre a Therefore the relation between fibre thickness and action potential amplitude 38μ from the surface can be derived from the amplitude distance relationship (Fig 14 A) The calculated amplitude 38μ outside the fibre increase only slightly with fibre diameter (Fig 15 B) This is in disagreement with the findings of Håkansson (1956)

There are however indications that the electrical properties of the surface membrane depend on the thickness of the fibre (Katz 1948 Håkansson 1956 1957b Fatt 1964 Falk and Fatt 1964) Therefore the rising phase of the intracellular action potential might be faster in thick than in thin fibre This would be the case if we assume the density of the membrane current to be independent of or to increase with the diameter of the fibre; Inserting (185) in the expression (163) for the density of the membrane current

$$i_m(t) \approx \frac{\sigma_i}{2k^2a} \quad \frac{d^2V_i}{dt^2}$$

Hence assuming i_m to be independent of the fibre radius a $\frac{d^2V_i}{dt^2}$ is proportional to a:

(188) $$\frac{d^2V_i}{dt^2} \quad a\ g(t)$$

Introducing (188) in (186) shows that the amplitude of the action potential just outside the fibre is proportional to the thickness of the fibre From (184) (185) and (188) we get

(189) $$\varphi_e(r\ t) \quad a\ h(\frac{r}{a} \quad t)$$

From the amplitude distance relationship (Fig 14) and (189) the amplitude of the action potential lead off 38μ from the surface can be calculated for fibres of different size Fig 15 B shows how the amplitud increases with fibre diameter when i_m is assumed to be independent of the fibre diameter The increase would be larger if the membrane current density increased with the diameter of the fibre

Håkansson s (1956) data follows a relation somewhere between the two possibilities calculated thin fibre obeyed (187) and thick fibres (189) or gave an even steeper relation.

II. Comparison between experimental and calculated radial decline of the extracellular action potentials

a. The frog muscle fibre

The action potential were studied by Håkan son (1956 1957a) around thick and thin fibres immersed in Ringer s solution. Ac cording to my calculations the action pot ntial depends on distance r and fibre radius a according to

$$\varphi_e(r\ t) \quad a^{\alpha}\ h(\frac{r}{a} \quad t)$$

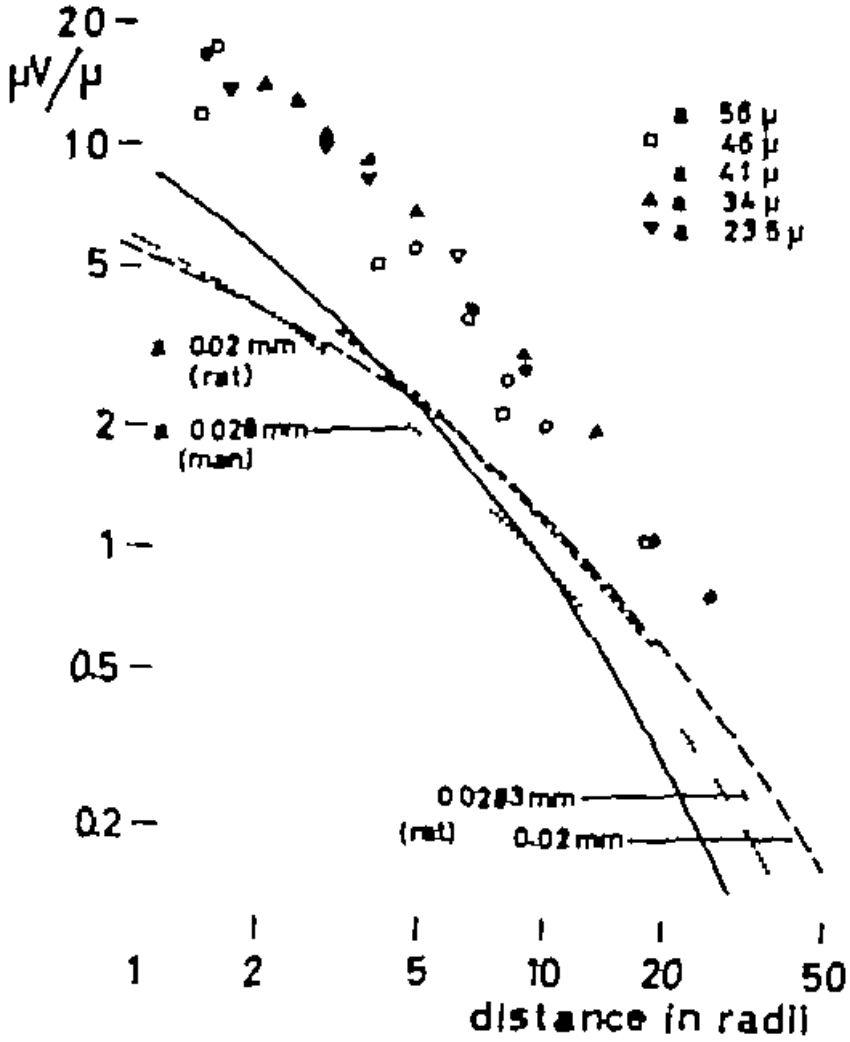

Fig 16 Calculated (full and broken lines) and experimentally determined radial decline (5 different symbol Häkansson (1956 195 a)) in peak to-peak amplitude of th ction potential of a muscle fibre
Full line frog muscle fibre (r dius 0 05 mm)
Broken lines two rat muscle fibres of different radius
Dotted lin human muscle fibre (radius 0 028 mm)
Ordinate peak to peak amplitude divided by th radius of the fibre (μV/μ) (cf (189))
Abscissa distance from the axis of the fibre in units of th radius.

α being bout 1 (cf (189)) To test this conclusion Håkansson s data and the calculated results (Fig 14 A) were plotted as a function of the distance from the axis of the fibre in units of the fibre radius and the amplitude of the action potential was divided by the radius (Fig 16) The data from 4 of the 5 fibres differed very little one fibre had a slightly reduced amplitude The course of the calculated relationship parallels that of the experimental points but th cal culated amplitudes are about half the experimental Up to a distance of 10 radii from the axis the calculated amplitude declined inversely with the distance at larger distances (10 50 radii) the decline was with the inverse square of the distance

Plotting the data calculated on the action potentials of human and rat muscle in the same way (Fig 16) we observe a slightly slower radial decline the amplitude declining to one tenth of its maximum value within 15-20 radii

b Human muscle fibres

In human muscle the radial spread of the spike component of motor unit potentials of fibrillation potentials and of chemically elicited action potentials has been studied (Buchthal Guld and Rosenfalck 1957a Rosenfalck and Buchthal 1962 Buchthal and Rosenfalck 1966 Ekstedt 1964) Multile d electrodes were used for recording to ensure defined distances between the different recording sites The distance between the row of leads and the active fibre(s) was un known. In our study of the spike of the motor unit potential (Buchthal Guld and Rosenfalck 1957a) this distance was deduced by assuming linear amplitude distance relationship on logarithmic cales s in the case of isolated frog muscle fibres (Håkansson 1957a) This a sumption w s objected to by Krnjević and Miledi (1958) who found th t it did not gre with the theoretical relation ship obtained by Lorente de Nó (1947a)

In fact the calculated amplitude distance relationships of Fig 17 A indicate that the assumption of a linear relationship between the l garithm of the spike amplitude and th logarithm of the recording distance might lead to an ov restimate of the recording

distance and hence of the size of spike generator In the following the number of fibres contributing to a spike potential in human muscle is evaluated from the calculated action potentials obtained from intracellular action potentials of human and rat muscle

No data is available regarding the radial decline of the action potential of an isolated fibre of rat muscle immersed in a conducting fluid However the calculated relationship given in Fig 14 B agree with the findings of Krnjević and Miledi (1958) on the surface of the rat diaphragm the amplitude of the action potential of the single muscle fibre decreased to 10 μV or less within about 0 5 mm (Fig 17B) The positive sharp-wave of denervated human muscle (Jasper and Ballom 1948) exhibit a similar amplitude variation (Fig 17 B) suggesting that they represent the activity of a single fibre (Buchthal and Rosenfalck 1966) Let us consider a single muscle fibre with a radius of 0 028 mm which represents an average value in man (Buchthal Guld and Rosenfalck 1955) Taking into account the 10 times higher specific external resistance and the anisotropy which exist in situ (p 50) we obtain from Fig 14 B and C the amplitude distance relationship of the action potential of the fibre and the variation in amplitude along line perpendicular to the fibre direction (Fig 17)

The calculated variation in amplitude along a line perpendicular to the fibre axis decreases and becomes slower when the distance to the line is increased (Fig 17 C) the amplitude decreases to one tenth within 0 35 mm on a line touching the surface of the fibre within 0 6 mm on a line 0 1 mm from the fibre axis and within 0 9 mm on a line 0 2 mm from the axis Thus the motor unit spike potential of small amplitude (235 2400 μV Buchthal Guld and Rosenfalck 1957) and small fibrillation potentials (125-870 μV Buchthal and Rosenfalck 1966) could theoretically represent the activity of a single muscle fibre at a distance of 0 1 0 4 mm from the electrode (Fig 17 C)

The maximum peak to peak amplitudes calculated for the human muscle fibre with a radius of 0 028 mm were 2200 μV and 3200 μV in situ for σ_r/σ_z 10/3 and σ_r/σ_z 0 4 and 0 2 respectively

B: Peak to-peak amplitude of the calculated action potential at the surface of the bundle as a function of the number of fibres in the bundle

tions the calculated amplitude of the action potential of a single normal muscle fibre might attain value of 10-13 mV

To further elucidate this problem calculations were performed to give the variation in action potential amplitude past a small bundle of muscle fibres firing in complete synchrony in situ Single fibre contributions (Fig 17) were superimposed taking into account the different distances to the various fibres of the bundle The maximum amplitude as obtained on the surface of the bundle increases less than proportionally to the number of fibres 25 fibres gave 7 7 times higher amplitude than one fibre (Fig 18) Hence the relative decline in peak to peak amplitude along a line touching the fibre bundle is the smaller the more fibres are active synchronously the amplitude decreasing to one tenth within 0 35 mm for a single fibre within 0 6 mm for 9 fibres and within 0 8 mm for 25 fibres Taking into account the doubling of the calculated maximum amplitude of the action potential due to the wall effect of the multilead electrode (Ekstedt 1964) (Fig 19) we find from the theoretical analysis (Fig 18) that high voltage fibrillation potentials (1 4-6 5 mV) and motor unit spikes (2 5-10 4 mV) which contain a smooth positive-negative deflection of short duration (100-200 μsec) are likely to be derived from the activity of a single muscle fibre lying in contact with the needle electrode The alternative that these spikes represent the synchronous firing of a small group of muscle fibres (a subunit) was arrived at previously from histological evidence and from recording with multilead electrodes (Buchthal Guld and Rosenfalck 1957a Buchthal and Rosenfalck 1966)

The question then arises whether the present estimate of the possible contribution of a single muscle fibre to the motor unit spike potential is compatible with the histological evidence for the existence of subunits within the motor unit containing 10 fibres on the average (Buchthal Guld and Rosenfalck 1957a) This question can only be answered if knowledge is available on the temporal dispersion and the amplitude of the action potential from the fibres contributing significantly to the motor unit potential. With 10 muscle fibres per subunit with 780 fibres per motor unit (in biceps brachii Christensen 1959) and with a diameter of the motor unit territory

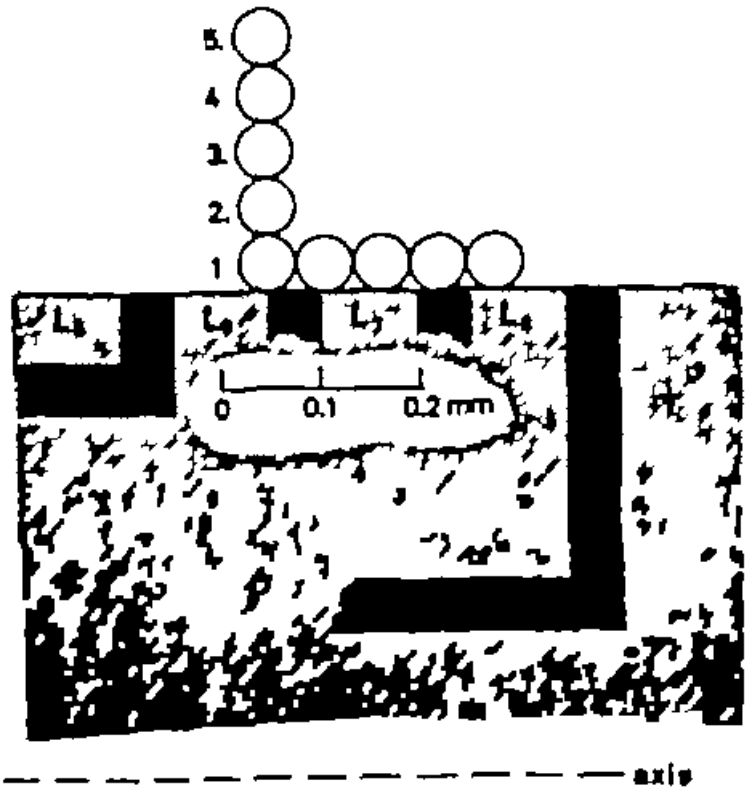

Fig 19 Size of human muscle fibre relative to the multilead electrode (Buchthal Guld and Rosenfalck 1957a) Fibres with a radius of 0 028 mm are shown in cross section positioned near le ds L_5 L_8 The broken line indicate the axis of the cannula of the multil ad el ctrode

of 5 mm (Buchthal Guld and Rosenfalck 1957b) the average distance between the diff rent subunits is $5/\sqrt{75}$ 0 6 mm. A similar stim te (0 7 mm) w btained from the multiel ctrode analysi of the spik components f the mot unit potential (Buchthal Guld and Rosenfalck 1957) The temporal dispersion of clearly di stinguishable spike was 0 5 2 3 msec (see also Ekstedt (1964))

Let us conside a small electrode (30-50 μ diameter) placed in contact with subunit (10 fibres) firing voluntarily On account of the rapid radial declin of the peak to-peak amplitud of the action potential of singl fibre (Fig 17A) other subunits do not contri

bute significantly to the main components of the motor unit potential The distance to the axis of the fibres of the subunit varies between 0 028 mm and 0 140 mm a range over which the calculated peak to-peak amplitude declines by a factor of three The temporal dispersion of the action potentials of the different fibre of the subunit is determined by the dispersion of the motor endplates and the variation in conduction velocity unless the action potentials interact and are propagated synchronously Histological findings in infants (Christensen 1959) suggest that the dispersion of the motor end plates of a subunit is maximally 5 mm in the adult This would cause a temporal dispersion of 0 4-2 4 msec (25 40 mm from the endplates) since the conduction velocity as measured over electrical ly activated muscle fibres had an average value of 4 0 m/sec and varied by 0 2 0 5 m/sec within the same muscle (Buchthal Guld and Rosenfalck 1955a) Hence double spikes triple spikes and other composite motor unit potentials of high voltage (1 mV or more) recorded on an electrode 30 µ in diameter (Ekstedt 1964) might represent the summation of temporally dispersed action po tentials of fibres from a single subunit In fact Ekstedt obtained distance between th spike sources which could be as small a 60 µ judging from the variations in action potential amplitude along the multielectrode

PART 3

DISCUSSION

Section 1

Introduction

The first detailed mathematical analysis of the spread of ction potentials was that of Lorente de Nó (1947a) followed by studies of Krakau (1957 1959) Mauro (1960) Plonsey (1964 1965) and Clark and Plonsey (1966)

The aim of my study was to relate the extracellular action potential originating from singl muscle fibre in a volume conduc tor to the intracellularly recorded action potential Simple consi derations and Lorente de Nó (1947a) de cription of the spre d of nerve action potentials in volume conductors showed that the second derivative of the intracellular action potential appeared in this re lationship (Ro enfalck 1957)

Extracellular ction potentials of single mu cle fibres were calculated from intracellular ction potentials of frog and rat muscle though the degree of pproxim tion btained was not known. Clark and Plonsey (1966) used th rel tions between modifi d Bessel func tion and their symptoti behaviour to evaluate the core-conductor model. Similarly I have derived the Lorent de Nó model th core conductor model and the di o tripol model as diff rent degrees of approximation to the rigorou math matical model.

In the mathem tical tre tment of potential fi lds of active cy lindrical fibre it is assumed th t these fields satisfy Lapl ce s equation (e g Helmholtz 1853 Craib 1928 Benoit 1937) This is the case because phase hifts are negligible in the external medium and within the fibre and hence the fields are qu si stati (Clark and Plonsey 1966) I derived the applicability of Laplace s equation from the Maxwell field quations fo conducting media assuming the

conductors to be isotropic and homogeneous and using the electrical parameters of nerve and muscle fibres

In whole nerve and muscle the action currents of a fibre flow mainly through the extracellular space the passive fibres having membrane impedance which makes them act almost like insulators (Buchthal Guld and Rosenfalck 1955b ee also p 125) This accounts for the low conductivity of nerve and muscle tissue as compared with that of Ringer s solution (Geddes and Baker 1967) Furthermore it explains the different conductivity of the tissue in the fibre direction and transversely Hence also in situ Laplace s equation is applicable if the boundary conditions are introduced that all fibre act as insulators towards the action currents of the others Thus taking into account that the high dielectric constant of muscle at audiofrequencies is due t the membrane capacitance of the fibres (Schwan and Cole 1960) the conditions for the applicability of a quasi stationary field appear more favourable than in the recent analysis of Plonsey and Heppner (1967)

To evaluate the significance of the anisotropy for the spread of action currents in muscle I consid red a fibre surrounded by a con ductor which was anisotropic but homogeneous The field equation corresponding to an anisotropic but homogeneous external medium can be transformed to a Laplace equation by a simple change of variables

Therefore the present m thematical analysis was essentially a study of solutions of Lapl ce s equation satisfying a boundary condition at the surface of the excitable fibre The radial gradient of the intracellul potentials g ve the density of the current passing the surface of the fibre and h nce the radial surface gradient of th extracellular potential According to potential theory (Kellogg 1929) this gradient determined the external potentials uniquely

Section 2

The potential field within an active fibre the membrane current and the core conductor model

Some of the quantitative tests of the theory were based on simulated intracellular action potentials chosen so as to approximate experimentally recorded potentials in a mathematically simple way The calculated radial variation in potential within a muscle fibre was less than 0 1 mV and in a giant nerve fibre it did not exceed 0 4 mV With this small radial variation the density of the longitudinal current within the fibre also varies little over the cross section These results justify depicting the interior of the fibre by an axial ohmic resistance as in the core conductor model

The applicability of this model was supported by the calculations of the density of the membrane current the membrane current of the rigorous mathematical model deviates at most a few per cent from that given by the core conductor model i e the membrane current can be considered proportional to the second derivative of the intracellular action potential. A similar relation stating that the membrane current is proportional to the second derivative of the transmembrane potential has been used in calculations of action potentials based on the Hodgkin-Huxley equations (see e g Noble 1966)

The limitations of the core conductor model appear when the extracellular action potential are considered. The model is linear and does not give information about the radial decline of the action potential field Furthermore the extracellular potential predicted by this model is monophasic like the intracellular potential and is proportional to it.

Since nerve and muscle action potentials lead off from a volume conductor are triphasic or diphasic (Craib 1928 Lorente de Nó 1947a Håkansson 1957 Murakami Watanabe and Tomita 1961) the applicability of the core conductor model to extracellular condition is restricted to the case of a fibre surrounded by a thin layer of the conductor

These conclusions were also arrived at by Clark and Plonsey (1966) in their mathematical evaluation of the core conductor model In an unlimited volume conductor an external longitudinal resistance per unit length of fibre cannot be defined

Section 3

The extracellular action potentials in an unlimited conductor

A The shape of the action potential

Action potentials of nerve and muscle fibres lead off in a volume conductor differ from the intracellular action potentials (i) their amplitude is at most one tenth of the intracellular potential and (ii) their shape is triphasic or diphasic the two first phases coinciding with the phase of depolarization of the intracellular action potential (Håkansson 1957 Murakami Watanabe and Tomita 1961) These differences can be accounted for in terms of the Lorente de Nó type of line integral model using intracellular action potentials recorded from human rat and frog muscle fibres (Fig 20)

> The shape of the extracellular action potential in an unlimited conducting medium can be predicted by simple arguments based on the spread of the action current (see e g Offner 1954) ahe d of the depolarized region of th fibre current flows out of the fibre i.e the potential de reases radially and is therefore positive since t is zero far from the fibre In the depol rized region conditions are oppo ite current flows into the fibre i.e the potential decreases towards the fibre and is negative in this region This explains the two main phases f th extracellular ction potential Finally currents which l ave the fibre in th region under repolari ati n give ri e to a terminal posi tiv deflection.

Considering the compound cti n potentials of bull frog n rve Lorente de Nó (1947a) derived th triphasic sh pe of the pot tial lead off in a volum conduct r from the monophasic surface action potentials recorded with the nerve in ir or oil Hi calculations showed that in the xt rnal medium the compo d nerv acts as a giant fibre which conducts continuously To a count for the di or triphasic shape of extracellular action potential Woodbury (1961) described the potential in t rm of a solid angle formulation (Plonsey 1965) assuming step variations in th membrane potential. According to this model th potential i proportional t the solid angle subtended by that cross ection of the fibre delimiting the ctive region o it s proportional to the diff rence between two

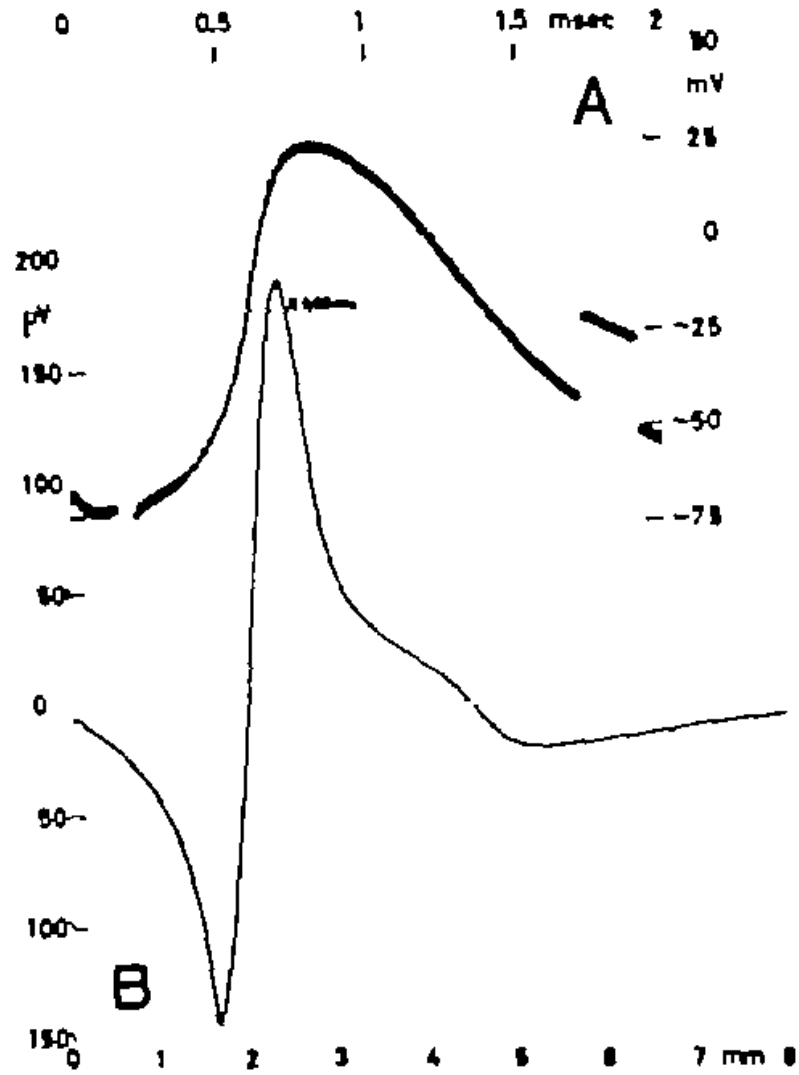

Fig 20 The temporal (and spatial) relationship between the intracellular action potential of a frog muscle fibre (A) and the calculated extracellular action potential obtained with an approximation like Lorente de Nó s (B)

solid angles of this type Mauro (1960) also used the solid angle model but the generator consisted of two plane sheaths depolarized in a narrow band By qualitative graphical solution he found that the external potential became monophasic rather than triphasic as the separation between the two membranes of the generator in creased and became large as compared with the width of th de polarized region Model experiments supported this conclusion Mauro s description of the triph sic external potential is illustrated by model experiments in which the longitudinal potential change is larger in the external than in the int rnal medium This is un fortunate since in fact the opposite is the case Moreover in the model experiments the amplitudes of the positive deflection are small as compared with the negative one even when the width of the depolari ed zone is 15 times the thickness of the generator In fact the initial positive d flection of the extr cellular action potentials of nerve and muscle fibres has about the same amplitude s the negative deflection (Håkansson 1956 1957a Mi rakami Watanabe and Tomita 1961) The simplest models that have been used to account for the shape of extracellul r nerve and muscl action potentials are the dipole and the tripole model (Craib 1928 Wilson MacLeod and Barker 1933) Neglecting th formal character of these models the question has been argued as to wheth r the axis of the dipole w s oriented parall l with the fibres or perpendicular to them (Gilson and Bishop 1937 Bishop 1937) The question is not pertinent when the dipole are considered to represent fictive generators of the ction potential

The extracellul action potential f single frog muscl fibre in Ringer' solution w re diphasic (Håkansson 1957a) My calculations gave triphasic potential (Fig 13). However th terminal positive defl ction wa small and protracted. Th discrepancy could be due to the fact that the intracellular action potentials used in the calculation were derived from singl muscl fibres in situ and not from isolated fibres. Th extr cellular action potentials of fibres on the surface of the toad sartoriu were triphasic as long as the microelectrode had not impaled the fibre (Murakami et al 1961) Murakami et al explain diphasic extracellular action potentials found

after impalement as due to local inactivation of the exitable mem trane This explanation does not apply to the findings of Håkansson (1957) An alternative cause of the lack of a terminal positive deflection is the short length of the fibres The triphasic action potential calculated from the intracellular potential extend over 7 mm of fibre length the two main phases covering 3 5 4 5 mm (Fig 12) Devi tions from the calculated shape can therefore be expected when recording closer than 7 mm from the end of the fibre In fact the triphasic action potential changed to a diphasic one near the tendon end of frog muscle fibres and near the closed end of the motor nerve terminals (Katz and Miledi 1965)

As to the shape of extracellular action potentials of mammalian muscle fibres Buchthal and Rosenfalck (1966) found 36 of 128 fibrillation potentials of denervated human muscle to be triphasic the voltage of the third phase being 10 per cent of the peak-to-peak voltage This agrees with my calculations (Fig 13)

In the theoretical analysis the action potentials were considered to be distant from the site of initiation. Since the depolarization propagates to both sides the terminal positive deflection recorded extracellularly must be more pronounced near the site of initiation than distant from it the late currents leaving the fibre being restricted to a small length and hence having a higher density The fibrillation potentials recorded by Buchthal and Rosenfalck (1966) in or near the endplate zone often had an enhanced positive terminal phase

B The relation between peak to-peak voltage and fibre thickness

The marked difference between th peak deflection of intracellular muscle action potentials and the peak to peak voltage of th extracellular action potentials of a fibre imm rsed in an unlimited volume conductor w s accounted for by calculations on the Lorente de Nó type of expression for the action potentials

The difference between intracellularly and extracellularly recorded amplitudes can also be derived by simple expressions From Ohm s law we expect

(190) $$\frac{A_e}{A_i} \quad \frac{r_e}{r_i}$$

where A_e and A_i are the amplitudes of the extracellular and intracellular action potential and r_e and r_i the extracellular and intracellular impedance Let n denote the number of radii within which most of the extracellular action current flows (190) can then be written

$$\frac{A_e}{A_i} \quad \frac{\sigma_i}{\sigma_e} \quad \frac{1}{n^2 \quad 1}$$

According to Katz (1948) $\sigma_i/\sigma_e \approx 1/3$ From experiments like those of Håkansson (1957a) we learn that action currents mainly flow within about 10 radii from the fibre axis i e n ≈ 10 This leads to

$$\frac{A}{A_i} \approx \frac{1}{300}$$

With A_i 120 mV we get

$$A_e \approx 400 \ \mu V$$

which is of the order found experimentally Even if half the current were to flow within 3 radii from the axis th amplitude of the extracellular action potential would maximally be only 2 5 mV as is seen by inserting $r_e/r_i \quad \frac{\sigma_i}{\sigma_e} \quad \frac{1}{2(3^2 \quad 1)}$ in (190)

The calculated relation between the thickness (2a) of the fibre and the amplitude (A) of the action potential recorded just outside the fibre is given by

$$A \quad k \, a^{1 \ 7}$$

provided the time course and conduction velocity of the intracellular action potential as well as th conductivity σ_i are independent of the fibre size (cf Muscholl 1957) N data is as yet available on mammalian muscle fibre on which this relation can be tested.

For frog muscle fibres the theoretical analysis lead to

$$\underline{A} \text{ independent of } \underline{a}$$

provided the intracellular action potential is independent of the thickness of the fibre Since this result is in disagreement with the findings of Håkansson (1956) an alternativ assumption was made i.e that th density of the membrane current is independent of fibre siz This lead to:

$$A \quad h\, a$$

Håkansson s findings gave a smaller increase in amplitude with fibre radius in th thin fibres and a l rger variation in the thick ones (Fig 15 B) His findings are in favour of an increased density of the membrane current with increasing fibre diameter An experimental study of the relationship between the fibre diameter and the density of the membrane current would be of interest in view of the decrease in specific resistance of the resting membrane with increasing thickness of the fibre (Katz 1948 Falk and Fatt 1964)

The maximum amplitude of the calculated action potentials was 610 μV fo the frog muscle fibre (Fig 11 D E 13 C) when a radius of 80 μ was assumed With a radiu of 70 μ the maximum value in the fibres studied by Håkansson (1956) the amplitude would be 1000 μV In fact Håkansson (1957a) report d maximum amplitudes of 800 2900 μV A deviation from a circula shape of the fibre cross section might contribute to these high amplitudes (Håkansson 1956) It would be of interest to extend the theoretical analysis to fibres of ellipti al cross section to evaluate this effect.

C The radial decline of the action potential

I Frog muscl fibres

Lorent de Nó s (1947a) theoretical analysis of the spread of action potential in a volume conductor was used by Buchthal Guld and Ro enfalck (1957a) to estimate how the di meter of the generator

of the action potential and the length along the generator over which the action currents extend affect the radial spread of the action potential. Thereby it was possible to explain the larger spread of the ction potential of the bullfrog nerve than that of a frog muscle fibre by the large diameter of the nerve and the broad region along the nerve over which the action currents extend Krakau (1957) suggested the use of the Fourier transform of the extracellular action potential to test the model developed by Lorente de Nó He showed that the transform should decline radially as $K_0(\frac{r\omega}{U})$ i e the same vari tion as obtained with the m re general model (p 47) Krakau (1959) demonstrated that the data from one of Håkansson s experiments followed the expectations closely for frequencies between 425 and 2975 Hz In the present study extracellular action potentials w re calcul ted using the theory derived by Lorente de Nó (1947a) except that the intracellular action potential wa used and not the surface action potential recorded with the fibre in air or oil. The calculated radial decline in th amplitude of the action potential agreed with Håkansson s finding (Fig 16)

Even dipole model can fairly well account f r the shape and radial decline of the action potential of a frog muscle fibre This is to be expected from the pronounced positive and negative peak of the distribution f the fictive sources and sinks obtained with the Lorente de Nó type of model (Fig 12)

II. Human muscl

Not until th completion of the first edition of my manuscript I got re cordings of intracellular ction potential of human muscle fibres with a resolution in time suffici nt to allow the second derivative to be obtained as t must be if the extracellular action potentials are to be calculated Therefore I performed th calculations on an intracellul action potential f a rat diaphragm recorded by Muscholl (1957) The results from rat and human muscle differed little from calculation on frog mu cle The radial spread of the action currents around isolated mammalian mu cle fibres has not been studied experime tally The spread of the action currents

around a fibre in an isolated rat diaphragm (Krnjević and Miledi 1958) is satisfactorily described by the calculations (Fig 17 B)

a. The generator of high voltage spike potentials

The spread of action currents around the fibres in human muscle has been studied by means of multilead electrodes (Buchthal Guld and Rosenfalck 1957a Rosenfalck and Buchthal 1962 Buchthal and Rosenfalck 1966 Ekstedt 1964 Stålberg 1966) My calculations of the variation in action potential amplitude along lines perpendicular to a single active fibre or a group of synchronously firing muscle fibres showed that the high voltag spikes of motor unit potentials and of fibrillation potentials could arise from the activity of a single muscle fibre In these calculations the high specific resistance and the anisotropy of the muscle tissue were tak n into account. A different estimate of the size of the generator of high voltage spikes was obtained by Buchthal Guld and Rosenfalck (1957a) who studied motor unit potentials electrophysiologically and correlated their finding with histological specimens Buchthal and Rosenfalck (1966) found the same radial decline in voltage for large fibrillation po tentials as for motor unit spike potentials therefore the high-voltage spikes of denervated muscle were assumed to originate similarly from the synchronous activity of a group of up to 10 30 muscle fibre a subunit

Ekstedt (1964) interpreted high voltage motor unit spikes and chemically induced spike potentials as arising from single mu cle fibres He rejected the subunit concept a being derived from observations on human muscle only under special pathological con ditions He did not find indications of a pi rcing of a subunit with the Janus electrode which allowed recording from opposite ides of the needle Finally he postulated th t the voltage decrement curves recorded by Buchthal Guld and Rosenfalck (1957a) were distorted by cros talk in th multilead electrode resulting in an apparent in crease of the spread of the action potentials Krnjević and Miledi (1958) did not find it compatible with the alculations of Lorente de Nó (1947a) to assum the linearity u ed by Buchthal et al in the analysis of the amplitude distance curves (cf p 104) This assump-

tion leads to an overestimate of the number of fibres involved and Krnjević and Miledi find it more likely that no more than one or two fibres contribute to the spike These problems were discussed by Buchthal and Rosenfalck (1966) Cross talk was larger in the multilead electrode used by Ekstedt (1964) than in that of Buchthal and co-workers and cannot account for the difference between the voltage decrement curves The difference between the decrement curves of Ekstedt and those of Buchthal and co-workers must be related to the selection of the spikes to be studied in that Ekstedt required that they had to satisfy some single fibre criteria Furthermore Ekstedt studied the voltage decrement over 0 3 mm in steps of 0 06 mm whereas Buchthal et al. covered 0 6 0 75 mm in steps of 0 15 and 0 3 mm

Further evidence supporting the single fibre interpretation was found in studies of the effect of d tubocurarine on motor unit spike potentials satisfying the single fibre criteria of Ekstedt. A fractionation of such potentials was never seen (Ekstedt and Stålberg 1967)

In the calculations on groups of synchronously conducting fibres I assumed that the action currents of the individual fibre do not pass through adjacent fibres to any significant degree Thi is true as long as the adjacent fibre are in the resting state (Buchthal Guld and Rosenfalck 1955b)

> During the early phase of repolarization the specific resistance of the muscle membrane is about 1 per cent of the resistance of the resting membrane (Fatt and Katz 1951) The decrease in resistance begins at the time when th initial positive phase of the extracellular action potential has reached its peak the membrane current being mainly capacitive up to this point (Murakami et al 1961)
>
> How much th membrane resistance decrease during the positive-negative deflection of the extracellular action potential is not known but probably it does not fall much below that measured in the early phase of repolarization (Cole and Curtis 1939 Hodgkin and Huxley 1952) Even when the membrane resistance i only 1 per ent of the resting value the transverse resistance of the fibre is larger than that of the adjacent inter space Let us consider 1 cm length of a quadratic "fibre 50 μ thick and let u assume the xtracellular space locally to amount to only 6 pe cent of the muscle volume i.e half the overall valu (cf. Buchthal Guld and Rosenfalck 1955b)

The interspace then has a width which is 3 per cent of the fibre thickness that is 1 5 μ The transverse ohmic resistance of the fibre is $\frac{2\ 50\ \Omega\ cm^2}{0\ 0050\ 1\ cm^2}$ 12000 Ω neglecting the resi stan e of the sarcoplasm. The resistance of the interspace is

$$\frac{87\ \Omega\ cm\ \ 0\ 0050\ cm}{0\ 00015\ 1\ cm^2} \qquad 2900\ \Omega$$

The membrane capacitance changes insignificantly during acti vity (Cole and Curti 1939) Hence the reactance of the c tive fibre at 5000 Hz is

$$\frac{1}{2}\ 2\ 6\ 10^{6}\ 0\ 0050\ 1\ 2\pi\ 5000 \qquad \Omega \qquad 5000\ \Omega \quad 1\ e$$

even at this high frequency larger that the resistance of th int rspace The time constant of fibre plus interspace is

$$2900\ \frac{1}{2}\ 2\ 6\ 10^{6}\ 0\ 0050\ 1\ s\ c \qquad 19\ \mu\ sec$$

This is short as compared with the duration of the po itive negative deflection of the extracellular action potential

Therefore also when the adjacent muscle fibres are active the action currents of a fibre pass mainly through the extracellular space Under these conditions it does not seem likely that the ac tion potentials of adjacent muscle fibres in situ interact to a degree that affects their propagation and results in a complete synchroniza tion a has been assumed previously (Buchthal Guld and Ro enfalck 1955a 1957a) An interaction between the action potentials of two large (30 μ) non medullated nerve fibres (Carcinus maenas) in paraffin oil was demonstrated by Kats and Schmitt (1940) This condition favours the interaction a does the reduction of the con ductivity of the saline in which the prepar tion was initially soaked. Complete synchrony wa obtained if th fibre had the same con duction velocity when stimul ted separately If the velocitie differed but no more than 10 per cent an out-of phase synchrony was ob- served In view of these findings and of the uncertaintie involved in the calculations above it would be of interest to study experiment ally whether or not there is an int r ction in muscle The experi ments of Tamai Abe and Goto (1961) on the interaction between

neighbouring fibres in fibrillating skeletal muscle of the frog were made with a time base which was too slow to allow a measurement of the temporal dispersion of the potentials

The temporal dispersion of the action potentials of the fibres of a subunit that could be expected in the absence of interaction was estimated to be at most 2 4 msec (p 112) This is also the maximum interval between the high amplitude double spikes and "triple spikes recorded by Ekstedt (1964) Let us theoretically consider subunits in which the interaction does not remove the temporal dispersion. As long as the t mpo al dispersion is small g 0 4 msec the compound potential of the subunit can only be distinguished from that of a single fibre by the occurrence of abrupt changes in slope on the positive-negative d flection (Fig 21 A) With increasing temporal dispersion the subunit potential recorded just outside the subunit g ts irregular (Fig 21 B and C) though not necessarily polyphasic. The shape and amplitude of the subunit potential depend on the recording electrode as well With concentric needle electrodes (area of inner core 0 1 0 4 mm^2) isolated spike components in th motor unit potential were considerably more difficult to obtain than with the 30 μ leads of a multielectrode (Ekstedt 1964) The spike amplitudes were about 5 times smaller and the duration of the positive n gative deflection w s twice that found with the 30 μ leads These ffects are to be expected from the radial chang of the action potential of th single fibre (Fig 1 A and p 105) though the spike amplitudes obtained with concen tric el ctrode appear rath r small and might be due to the different distortion of the action potentials by the large recording surface of the concentric l ctrode as compared with that caused by the multi lead l ctrode An experimental comparison f these distortions would be of interest. Ekstedt (1964) refers to unpublished obse vations by Ekstedt and Stålberg on the wall eff ct produced by the insulato in which the 30 μ leads are embedded He illustrates th influence of the electrode area by connecting seven leads of th multi lectrode distributed over 0 37 mm but gives only a single example A 20 per cent de rease in spike amplitude was observed.

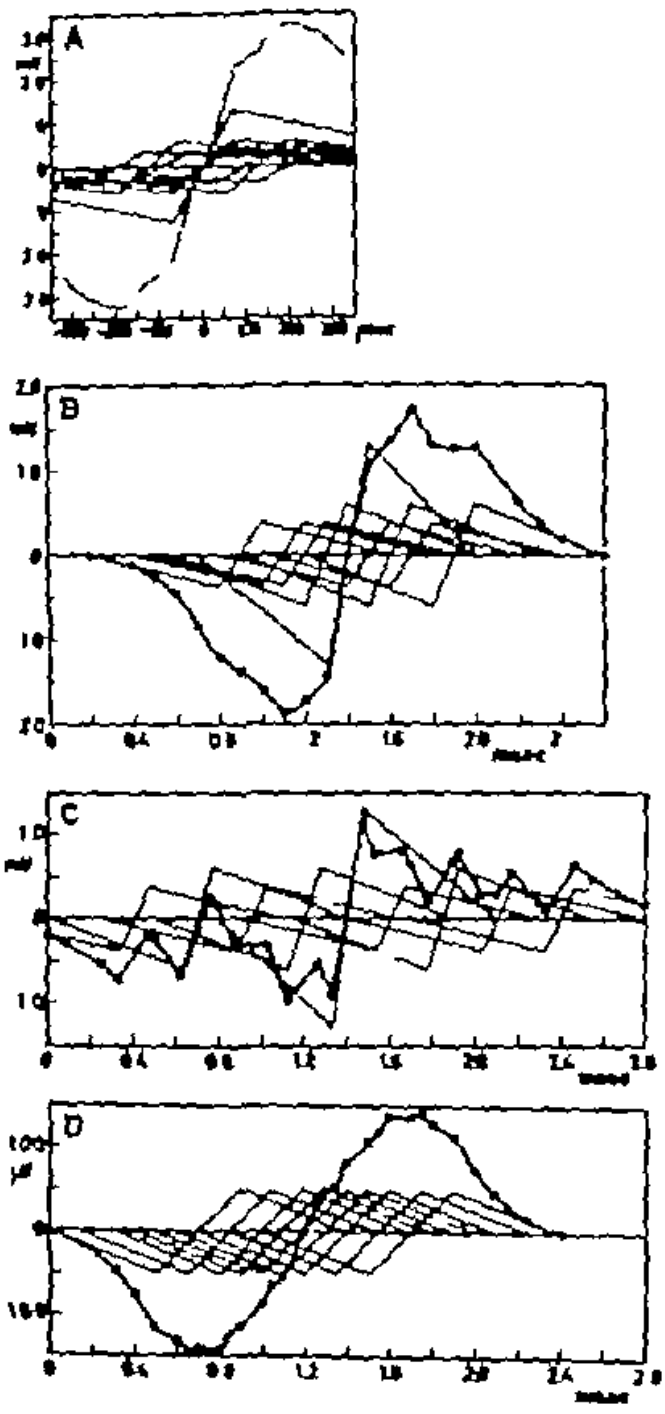

Fig 21

Subunit potentials constructed by summation of 9 temporally dispersed single fibre potentials
A. temporal dispersion 0 4 msec Rise time of single fibre potential 140 μ sec to simulate recording with a small electrode near the fibres
B temporal dispersion 1 msec Rise time of single fibre potential 200 μ sec to simulate recording with a concentric electrode near the fibres
C temporal dispersion 2 msec Rise time of single fibre potential 140 μ sec to simulate recording with a small electrode near the fibres
D temporal dispersion 1 msec. Rise time of single fibre potential 400 μ sec to simulate recording with a concentric electrode 0 8 mm from the fibres

At a distance of e g 0 6 mm from the subunit the increased duration of the positive negative deflections of the action potentials of the single fibres (Fig 14 D) effects a subunit pot ntial in which irregularitie are hardly detectable even when the temporal disper sion within the subunit is 1 msec (Fig 21 D) Under these circum stances the peak to-peak amplitude is about three times and the duration of the positive negative deflection about twice that of the action potential of a single fibre

In summary: the present result that a single muscle fibre can give rise to the high voltage motor unit spike potential containing fast and smooth positive negative deflection is not incompatible with the subunit concept. Even if the fibres do not interact the compound potential of the subunit is not necessarily polyphasic but humps and other irregularities occur

b Application

The knowledge regarding the radial change in shape and amplitude of the action potential of a single muscle fibre as obtained experi mentally and by th calculations can be used to derive information about the location of the fibres of a motor unit from the shape and amplitude of the motor unit potential. Thus Buchthal Guld and Rosenfalck (1957b) used an el ctrode containing 12 l ad (0 1 mm 1 5 mm 0 5 mm apart) to delineate the territory of the muscle cross section within which the fibre of a motor unit were located It appears from Fig 17 A and 14 D that the presence in th motor unit potential of a positive negative deflection with an amplitude above 50 μV and lasting less than 300-400 μsec indicates that an active fibre (or a subunit) is within a distance of less than 1 mm from the recording lead. Such criteria were used in the study of the limb mu cle f man where the diameter of the motor unit territory averaged 5-10 mm (Buchthal Erminio and Rosenfalck 1959). The accuracy of the delineation might be increased by using smaller leads and requiring a higher amplitude and a shorter duration of the positive negative deflection but the number of re cording sites would then have to be increased correspondingly to cover the same stretch in th muscle

Section 4

The muscle fibre in air

The action potential of a fibre surrounded by a thin layer of conducting fluid was derived in terms of the intracellular action potential. The theoretical expression was within few per cent identical with that obtained from the core conductor model both for muscle fibres and for nerve fibres

$$\varphi_e(b) \approx \frac{r_e}{r_i} V_i(z) \tag{191}$$

This model leads to surface action potentials which are higher in amplitude than the intracellular action potential if the external longitudinal resistance per unit length (r_e) exceeds the internal (r_i). This does not imply that the surface potential may increase indefinitely. It cannot exceed the electromotive force of the "battery" of the membrane of the fibre. In isolated frog muscle fibres in moist air the amplitude of the surface action potentials was the same as that measured intracellularly with the fibre in Ringer's solution (Håkansson 1957a). Theoretically this is to be expected if the external resistance with the fibre in air is large as compared with the internal resistance, that is if $(r_e/r_i) \gg 1$. According to (82)-(83) this condition is fulfilled if the thickness (b-a) of the conducting layer satisfies the relation:

$$b-a \ll \frac{\sigma_i a}{2\sigma_e}$$

i.e. if $b-a \ll 8.3\,\mu$ assuming $\sigma_i/\sigma_e = 1/3$ and $a = 50\,\mu$. From the conduction velocities in air and in Ringer's solution Håkansson (1957a) actually calculated a thickness of $2.3\,\mu$. The surface action potential in air had about half the rise time (from 20 to 100 per cent of peak) of the intracellular potential recorded from fibres in Ringer's solution (Håkansson 1957a). This was unexpected in view of the slower propagation along the fibre in moist air

Theory (p 38) predicts about the same rise time of the surface action potential as of the intracellular potential No experimental data are available about the rise time of the intracellular action potential with the fibre in moist air

Section 5

Conclusion future work

The mathematical analysis of potential fields presented in this study deals with continuously conducting circular cylindrical fibres of infinite length. Without doubt this is a very simplified type of po tential field. Still it proved to be useful. Though the evaluation related to excised muscles of man rat and frog gave similar re sults calculations based on an intracellular action potential of human muscle in situ ought to be made to support my interpretation of the extracellular spike potentials In connection with the numerical evaluations related to isolated muscle fibres reference was made to the fact that the fibres are elliptical rather than circular in cross section. Hence it seems of interest to extend the mathe matical analysis to elliptical fibres Furthermore one could take into account the finite length of the fibre and the fact that action potentials are propagating towards both ends

Next it would be of interest to perform a mathematical ana lysis of the action potentials of a single myelinated nerve fibre in a volume conductor

The potential field of the active soma of a nerve cell has been treated in detail by Rall (1962) assuming the soma to be spherical and to have one or a number of cylindrical dendrites attached to it (p 13) Rall (1962) assumed the soma to be a sink of current and the membrane of the dendrites to remain passive throughout Still more complicated is the field of a pool of neurones Rall (1962) pointed out that in superposing the potentials of several neighbouring neurones one had to consider the cell spacing and the extent of dendritic branching A qualitative analysis of such fields was made by Lorente de Nó (1947b) Closed fields arise in case of spherical symmetry s when the somas are located in the central zone of the pool while thin dendritic branches and tips are preponderant in the marginal zones If the pool does not show spherical symmetry ac tion currents spread outside it to produce an open field In view of the physiol gical importance attached to the effect of the action

currents of a cell on the excitability of neighbouring cells a mathe matical analysis of the potential field of a pool of active neurones seems desirable

The problems referred to in this Section cannot be solved ana lytically They are too complicated mathematically Numerical methods have to be used like those indicated by Rall (1962) and by the present study The impedance of the passive membrane and the properties of active membranes as described e g by the Hodgkin Huxley equations have to be taken into account to calculate the di stribution of the virtual sources and sinks of the extracellular ac tion potentials

APPENDIX 1

Comparison between the potential generated by a point source and a linearly extended source

Let us consider an electrostatic potential generated by a linear source along the z axis the charge density being

$$\rho(z) \quad \begin{cases} \frac{q_0}{2c}(1 + \alpha z) & \text{for } c \leq z \leq c \\ 0 & \text{for } |z| > c \end{cases}$$

Thus q_0 represents the total charge of the source The potential $\varphi(r\ z)$ produced by this distribution is

$$\varphi(r\ z) \quad \int_c^c \frac{q_0(1+\alpha s)}{2c\sqrt{(z\ s)^2 + r^2}}\, ds$$

Solving this integral we get

$$\varphi(r\ z) \quad \frac{q_0}{2c}\Big[(1+\alpha\ )\log \frac{z + c + \sqrt{(z+c)^2 + r^2}}{z\ \ c + \sqrt{(z\ c)^2 + r^2}}$$

$$\alpha\left(\sqrt{(\ +c)^2 + r^2} \quad \sqrt{(\ \ s)^2 + r^2}\right)\Big]$$

The potential corresponding to a source with constant density ρ is obtained by putting $\alpha \quad 0$

$$\overline{\varphi}(r\ z) \quad \frac{q_0}{2c}\log \frac{+c + \sqrt{(z+c)^2 + r^2}}{c + \sqrt{(\ \ c)^2 + r^2}}$$

We therefore have

Table A 1

Percentage difference between the potential of a point source (φ_p) and of a linear source of constant density ($\bar{\varphi}$)
(Length of the source 2c)

r	x 0	x ±c	x ±2c	x ±4c
0 4c	52	20	8	2
0 6c	30	11	7	2
0 8c	19	5	6	2
1 0c	13	2	5	2
1 2c	10	0	3	2
1 5c	7	1	3	2
2 0c	4	2	1	1

Table A 2

Percentage difference between the potential of a point source (φ_p) and of a linear source with zero density in one end (φ)
(Length of the source 2c)

r	x 4c	x 2c	x 0	x 2c	x 4c
0 4c	7	11	52	21	9
0 6c	7	11	30	19	9
0 8c	7	10	19	18	8
1 0c	7	10	13	16	9
1 5c	7	9	7	11	9
2 0c	6	8	4	8	7

$$\varphi(r\ z) \quad (1+\alpha z)\ \bar{\varphi}(r\ z) \quad \frac{\alpha q_0}{2c}\left(\sqrt{(z+c)^2+r^2} \quad \sqrt{(z\ c)^2+r^2}\right)$$

The potential generated by the total charge q_0 when concentrated at $z \quad 0$ is:

$$\varphi_p(r\ z) \quad \frac{q_0}{\sqrt{r^2+z^2}}$$

Tables A1 and A2 show that the error is le s than 10 per cent when the line source is replaced by a point source This applies to radial distances greater than half to three quarters of the length of the source and at axial distances larger than one to two times the length of the source

In these evaluations the charge density ρ of th line source was assumed either to be constant (Table A1) or to increase linearly from zero along the source (Table A2) If the charge density changes polarity along the source the total charge may become zero In such case the point source approximation is inappli cable Therefore if a linear charge distribution of variable density has to be approximated by a series of equidistant point charges the intervals must be chosen so that polarity is constant within each of them.

APPENDIX 2

The potential produced by a circular ring of charges of constant density

Let us consider a total charge Q distributed uniformly along a circle of radius a i.e the density of charge is $Q/2\pi a$ per unit length. The electrostatic potential generated by these charges is with the notation indicated in Fig 22 given by

$$\varphi(r\ z) \quad \frac{Q}{\pi} \int_0^{\pi} \frac{d\theta}{\sqrt{z^2+a^2+r^2 \quad 2ar\cos\theta}}$$

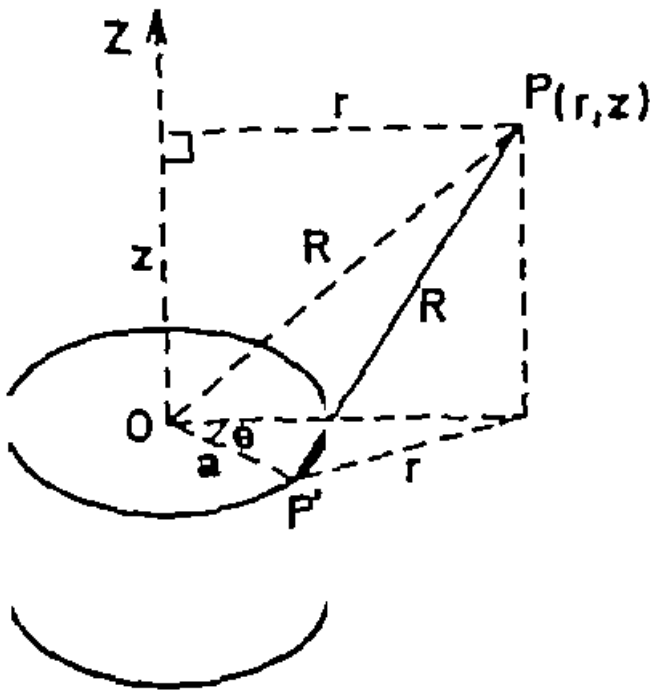

Fig. 22. Parameters used in the calculation of the potential produced by a circular ring of charges of constant density

ference is still smaller Thus in a plane one radius from that of the charges the difference is less than 2 per cent at axial distances $r > 1\ 3a$

Thus when Lorente de Nó (1947a) replaced a cylindrical distribution of charges by a linear one on the axis the error was negligible even close to the cylinder

SUMMARY

This monograph presents a mathematical analysis of intracellular and extracellular potential fields of active muscle fibres and of giant unmyelinated nerve fibres. The aim of the study was

(i) to derive the relation between the extracellular action potentials and the intracellular potential

(ii) to account for the shape duration amplitude and radial decline of the extracellular action potentials and

(iii) to study the relation between the present mathematical theory and other models the core-conductor model (Hermann 1879) introduced to account for the electrotonic spread of current along nerve and muscle fibres and the theory developed by Lorente de Nó (1947a) to explain the distribution of the action currents of nerve in volume conductors The theory of Lorente de Nó (1947a) was used previously by Buchthal Guld and Rosenfalck (1957a) and by Krakau (1957 1959) to interpret the radial decline of the extracellular action potentials of frog muscle fibres

On th basis of the Maxwell field equations it was shown that the potential fields of fibres along which conduction of action potentials takes place at a constant speed satisfy Laplace s equation if the intracellular and extracellular volume conductors are homogeneous and isotropic. In solving Laplace s equation the fibre was assumed to be infinitely long and to have a circular cross section so that the fields were symmetrical around the axis of the fibre Fourier transforms were used to obtain the formal solution The field within the fibre was derived the action potential measured just inside the surface giving the boundary condition. Th density of the membrane current was deduced from the radial gradient of the intracellular potential field at the surface of the fibre and could be written as a sum of two terms one of them being identical with the density of the membrane current as obtained from the core

conductor model With the current density thus derived as boundary condition the extracellular action potentials were deduced. The com plicated expression for the potential field contained an integral in volving modified Bessel functions of the second kind Considering the asymptotic behaviour of these functions at small arguments approximations to the potentials were obtained suitable for a numerical evaluation and easier to interpret than the true solution. One approximation was a line integral similar to that arrived at by Lorente de Nó (1947a) in his analysis of the spread of nerve action currents The other approximation was a surface integral

To compare the present findings with those of Lorente de Nó (1947a) the special case was considered when the fibre was sur rounded by a thin layer of the conductor The surface action potential could be considered a sum of two terms one of which was iden tical with the extracellular potential expected from the linear core-conductor model Furthermore the density of the membrane current was identical with that derived from this model In the analysis of the theory of Lorente de Nó (1947a) an expression was derived which compared the true membrane current with that arrived at by his theory As to the radial decline of the extracellular action potentials of the rigorous three dimensional model the high frequency components (4000 6000 Hz) decayed 8-10 times faster than the low frequency components (250-300 Hz)

Muscle is an anisotropic volume conductor of low conductivity inactive fibres acting almost as insulators The reduced conductivity by itself gives rise to an about 10 times higher amplitude of the extracellular action potential in situ than in Ringer's solution. The anisotropy caused a radial constriction of the potential field by 25 45 per cent and a further increase in the amplitude of the action potential recorded just outside the fibre by 35 60 per cent depend ing on the degree of anisotropy

The quantitative tests and the application of the mathematical theory were based on measured intracellular action potentials as well as on potentials simulating them.

The radial variation of the intracellular action potentials was negligible in muscle fibres as well as in unmyelinated giant nerve

fibres i.e the longitudinal current density varied insignificantly over the cross section of the fibre The membrane current was to good approximation proportional to the second derivative of the intracellular action potential i.e identical with that derived from the linear core conductor model. Furthermore the surface action potential of a fibre surrounded by a thin layer of conductor deviated insignificantly from that predicted by the core conductor model.

In the case of an extended external conductor the validity of the Lorente de Nó type of approximations to the extracellular field was confirmed by the finding that the membrane current calculated from them differed only insignificantly from the true value Calculations based on measured intracellular muscle action potentials lead to extracellular action potentials triphasic in shape the two main phases being of similar amplitude and the terminal positive deflection being 5-10 per cent of the peak to-peak value The peak to-peak amplitude declined to one tenth within about 0 5 mm from the fibre axis It was deduced that the amplitude of the action potential recorded just outside a rat muscle fibre increases almost as the square of the radius of the fibre and for a frog muscle fibre a proportionality between amplitude and radius was derived The difference between rat and frog muscle was due to the different relationship assumed between fibre diameter and conduction velocity The amplitudes calculated for th frog muscle fibres were too small by a factor of about two possibly due to the low resting and action potential of the fibres on which the calculations were based. The calculations relating to rat and human muscle accounted for the amplitude variation past a single fibre of the diaphragm observed by Krnjević and Miledi (1958) as well as for the volume conduction of spontaneous positive sharp-waves of human muscle studied by Buchthal and Rosenfalck (1966)

Finally the calculations showed that high voltage fibrillation potentials (1 4 6 5 mV Rosenfalck and Buchthal 1962) and motor unit spikes (2 5 10 8 mV Buchthal Guld and Rosenfalck 1957a) of human muscle can be derived from the activity of a single muscle fibre as suggested by Krnjević and Miledi (1958) and by Ekstedt (1964) This result is not incompatible with the existence of sub-

units within a motor unit It differs from the view previously held (Buchthal Guld and Rosenfalck 1957a Buchthal and Rosenfalck 1966) in that the present study indicates that interaction between the action potentials of adjacent muscle fibres is not likely to affect their conduction to a degree that complete synchrony results This problem needs experimental testing

The models used previously to describe the spread of nerve and muscle action potentials (the Lorente de Nó model the core conductor model and the di or tripole model) could be accounted for as different degrees of approximation to the rigorous mathematical model. This was shown by using the asymptotic behaviour and the relations between modified Bessel functions referred to by Clark and Plonsey (1966) They studied the applicability of the core-conductor model and their conclusions are supported by my findings. The core-conductor model could be applied extracellularly only when the fibre was surrounded by a thin conducting layer

The extracellular action potentials calculated from the approximation similar to that developed by Lorente de Nó (1947a) were triphasic That the action potentials recorded from isolated frog muscle fibres were diphasic (Håkansson 1956 1957) does not invalidate the calculations because the action potential changed from a triphasic to a diphasic configuration as the recording electrode approached the tendon end of the fibre (Katz and Miledi 1965)

In evaluating the relation between the amplitude of the action potential and the fibre thickness I assumed that the density of the membrane current was independent of the thickness Better agreement with the experimental findings would obtain if the density of the membrane current increases with the thickness of the fibre

RESUMÉ

Denne monografi indeholder en matematisk analyse af intra og extracellulære aktionspotentialfelter for umyeliniserede nervefibre og for muskelfibre Formålet med arbejdet var:

(1) at udlede sammenhængen mellem de extracellulære aktionspotentialer og det intracellulære potential

(2) at gøre rede for de extracellulære aktionspotentialers form vo righed amplitude og radiale dekrement samt

(3) at sammenligne den foreliggende matematiske model med (a) kerneleder modellen (Hermann 1879) der benyttes til forklaringen af elektrotonus hos nerve og muskelfibre og med (b) den mate matiske model Lorente de Nó (1947a) udviklede for at redegøre for spredningen af nerveaktionsstrømmene i en volumenleder Buchthal Guld og Rosenfalck (1957a) og Krakau (1957 1959) har tidligere benyttet Lorente de Nó s model til at gøre rede for den radiale aftagen af aktionspotentialerne fra isolerede frømuskelfibre

Først vises det på basis af Maxwell s ligninger at det intra såvel som det extracellulære aktionspotentialfelt skal tilfredsstille Laplace's ligning, idet det antages at aktionspotentialerne for planter sig med konstant hastighed hen langs fiberen og at volumenlederne er homogene og isotrope

Ved løsningen af denne ligning antage fiberen at være uendelig lang og at have et cirkulært tværsnit hvorfor felterne er rotationssymmetriske om fiberaksen. Ved den formelle løsning benyttes en Fourier transformation. Feltet inde i fiberen udledes idet man be nytter potentialet målt lige indenfor overfladen som grænsebetingelse Membranstrømtætheden bestemmes derefter udfra det intracellulære l ns gradient ved fiberens overflade og det vises at den kan skrives som en sum af to led hvoraf det ene er identisk med den membranstrømtæthed der fås udfra kerneleder modellen. Med den således bestemte membranstrømtæthed som grænsebetingelse udledes

derefter det extracellulære aktionspotentialfelt Den komplicerede løsning indeholder et integral hvori der indgår modificerede Besselfunktioner af 2 art. Ved brug af disse funktioners asymptotiske opførsel ved små argumenter viser det sig muligt at udlede approximationer til feltet der er egnet til numerisk behandling og lettere at fortolke end den sande løsning Den ene approximation var et linieintegral af samme type som det Lorente de Nó (1947a) ledtes til i sin analyse af spredningen af nerveaktionsstrømme og den anden approximation var et overfladeintegral

For at kunne sammenligne de foreliggende resultater med Lorente de Nó s (1947a) betragtes det specielle tilfælde hvor den ydre leder omkring den excitable fiber kun er et ganske tyndt lag. Det vises at overfladeaktionspotentialet kan betragtes som en sum af to led hvoraf det ene er identisk med det den lineære kerneledermodel vil give Desuden er membranstrømtætheden den samme som følger af denne model I en analyse af Lorente de Nó s allerede omtalte matematiske model foretages en sammenligning mellem den sande membranstrømtæthed og den der følger af hans model

Med hensyn til den radiale aftagen af det extracellulære aktionspotentialfelt således som den beregnes udfra den tredimensionale model vises det at de højfrekvente komponenter (4000 5000 Hz) aftager 8-10 gange hurtigere end de lavfrekvente (250 300 Hz)

Muskelvæv er en anisotrop volumenleder med lav ledningsevne da inaktive fibre virker næsten som isolatorer Den reducerede ledningsevne giver i sig selv anledning til at det extracellulære aktionspotential har en ca 10 gange større amplitude in situ end i Ringeropløsning Anisotropien bevirker en radial kompression af aktionspotentialfeltet på 25-45 procent og en yderligere forøgelse af amplituden på aktionspotentialet målt lige udenfor fiberen på 35 80 procent alt efter graden af anisotropi

Ved den numeriske afprøvning af den matematiske model benyttes dels virkeligt målte intracellulære aktionspotentialer dels simulerede potentialer Det vises at den radiale variation af det intracellulære felt er forsvindende i både muskel og nervefibre og at derfor den longitudinale strømtæthed varierer ubetydeligt over

fiberens tværsnit. Det vises endvidere at membranstrømtætheden med god tilnærmelse er proportional med den anden afledede af det intracellulære aktionspotential dvs identisk med den der følger af den lineære kernoledermodel Hvad angår det tilfælde da fiberen kun er omgivet af et ganske tyndt ledende væskelag viser beregningerne at overfladeaktionspotentialet kun adskiller sig uvæsentligt fra hvad der følger af kernoledermodellen.

Ved beregningerne vedrørende en ubegrænset ydre volumenleder bekræftes det tilladelige i at anvende den tilnærmelse til det extracellulære aktionspotentialfelt der er af samme type som Lorente de Nó s idet det f ex demonstreres at den membranstrømtæthed der følger af denne approximation, kun afviger ubetydeligt fra den sande værdi. De beregninger der derefter foretages udfra de faktisk målte intracellulære aktionspotentialer giver extracellulære potentialer som er trifasiske idet de to første faser har amplituder af samme størrelsesorden mens amplituden for den afslutte nde positive fase kun beløber sig til 5 10 procent af totalamplituden, Totalamplituden aftager til mindre end en tiendedel indenfor ca, 0 5 mm fra fiberaksen.

Beregningerne viser d suden at amplituden af det aktionspotential der måles lige udenfor en muskelfiber fra en rotte skulle vokse omtrent som kvadratet på fiberens radius mens man for en frømuskelfiber lede til simpel proportionalitet mellem amplitude og radius Denne forskel m llem rotte og frø skylde de forskel lige sammenhænge mell m propageringshastighed og fibertykkelse som er anvendt ved beregningerne De beregnede amplituder er for frømuskelfiberen ca halvdelen af det eksperimentelt fundne hvad der sandsynligvis hænger sammen med det lave hvile og aktionspotential hos de fibre hvorpå beregningerne er baseret. Hvad rotte muskelfiberen angår kan beregning rne gøre rede for den amplitudevariation Krnjevic og Miledi (1958) iagttog hen over overfladen af diafragma når de passerede den enkelt aktive fiber Beregningerne på det intracellulære aktionspotential fra human muskel kan redegøre for volumenledningen af de spontane positive potentialer sådan som den r iagttaget af Buchthal g Rosenfalck (1966) i denervered muskler ho mennesket. Det følger endvidere t

fibrillationspotentialer med stor amplitude (1 4 8 5 mV Rosenfalck og Buchthal 1962) og høje spidspotentialer i de vilkårlige potentialer hos mennesket (2 5 10 8 mV Buchthal Guld og Rosenfalck 1957a) kan repræsentere en enkelt fibers aktivitet som forestået af Krnjević og Miledi (1958) og af Ekstedt (1964) Dette resultat er ikke uforeneligt med existensen af underenheder (sub-units) i den motoriske enhed selvom det afviger fra den tidligere opfattelse (Buchthal Guld og Rosenfalck 1957a Buchthal og Rosenfalck 1966) Den foreliggende analyse viser at det er lidet sandsynligt, at vekselvirkningen mellem nabofibres aktionspotentialer påvirker deres propagering i en sådan grad at de synkroniseres fuldstændigt.

Hovedresultatet af det foreliggende arbejde er at det er muligt at udlede de forskellige modeller der hidtil er anvendt ved beskrivelsen af nerve og muskelaktionspotentialfelter Lorente de Nó's model kerneledermodellen og di og tripolmodellen som forskellige grader af tilnærmelse til den strenge 3 dimensionale matematiske model Dette vises ved at gøre brug af de modificerede Bessel funktioners asymptotiske opførsel og relationerne der gælder mellem dem og som Clark og Plonsey (1966) har benyttet i deres analyse af kerneledermodellens anvendelighed. Deres konklusioner støttes af mine resultater Kernelederen kan kun anvendes extracellulært når fiberen er omgivet af et ganske tyndt ledende væskelag.

De extracellulære aktionspotentialer der beregnes udfra den approximation der er af samme type som den Lorente de Nó (1947a) udviklede er trifasiske Den tilsyneladende modstrid med de difasiske aktionspotentialer som Håkansson (1956 1957) registrerede fra isolerede frømuskelfibre gør ikke beregningerne unanvendelige Katz og Miledi (1965) har nemlig vist at aktionspotentialets form ændres fra at være trifasisk til at blive difasisk når registreringselektroden nærmes fiberens sarcemme

Ved udledningen af sammenhængen mellem aktionspotentialamplitude og fibertykkelse blev det antaget at membranstrømtætheden er uafhængig af tykkelsen Bedre overensstemmelse med de eksperimentelle fund vil man få hvis membranstrømtætheden voksede med fibertykkelsen.

ACKNOWLEDGEMENTS

The subject of this monograph arose from studies on the motor unit potentials of normal human muscle initiated and conducted by Professor dr med. F Buchthal in the Institute of Neurophysiology of the University of Copenhag n These studies aimed at accounting for the duration shape and amplitude of the motor unit potenti ls in terms of the summation of the spatially and temporally dispersed action potentials of the individual fibres of the unit. Therefore knowledge of the volume conduction of the action potential of a single muscle fibre was required. My mathematical analysis of thi problem intended to derive an approximation to the action potential in terms of an expression containing the second derivative of the intracellular action potential but otherwise similar to that deduced by Lorente de Nó to account for the spread of the compound action potential of a nerve Several attempts at obtaining an approximation of this type had to be discarded since they lead to integrals which I was unable to interpret.

My work has been much stimulated by the members of the Institute Profe sor Buchthal has with never failing energy introduced me to the biological problems and to scientific methods has encouraged inspired and teased me whatever was most appropria Our joint collaboration with the m ticulously wo king and ever ing Chr Guld E E provided detailed experimental information the el ctrophysiology of the m tor units Prof sor dr med. O Sten-Knudsen and I have often di cu sed common mathemati problems He pointed out th weaknesses in the first edition of the manuscript. Prof sso Buchthal sought the expert advice Profe sor dr techn. H Lottrup Knudsen when we encount problem of evaluating the influence of the anisotropy of the tissu on the spread of the a tion currents He provid the solution of th problem which I hav presented in a version. Prof sor Lottrup Knudsen and the late Professor

R Petersen made valuable suggestions after reading the first edition of the manuscript Dr med Lise Engbæk supplied me with the intracellular action potentials of frog muscle Dr E Muscholl Main permitted me to use one of his recordings from rat muscle and Dr H P Ludin Bern provided the action potential from human muscle At a time when my mathematical problems looked too discouraging I decided to try to evaluate by numerical methods alone the degree of approximation that was obtained by means of my modified Lorente de Nó model This involved the application of a digital computer and I wa given valuable dvice on numerical methods as well as on computer problems by Mr B Svejgaard Nielsen M Sc. Head of the Section on Information Processing at the H C. Ørsted Institute However in the end a simpler solution was found as described in this monograph For critical reading of my manuscript and for correcting my English I am in debt to M. A Lennox Buchthal M D Mr F Riis skilfully made the illu strations and Mrs E M Fischer typed with rapidity and excellence the several editions of the manuscript. I thank most heartily for all the help hereby given to me in completing this thesis

My work has been supported by grants from Købmand i Odense Johann og Hanne Weimann født Seedorffs legat The Danish State Research Found tion put a punched paper tape typewriter and a programmable desk calculator at my disposal.

I dedicate this book to my wife Anneliese Rosenfalck E E and to Professor Dr H Pau Düsseldorf Without their support it had never appeared

Bagsværd December 1968

INTRODUCTION

The arterial blood pressure in mammals varies as the product of cardiac output and peripheral resistance. Among the components influencing these factors the neural control through the autonomic nervous system is perhaps the most important. The main determinants of cardiac output are heart rate and stroke volume. The former is governed by sympathetic and vagal impulses which act on the basal rhythmicity of the heart muscle cells, stroke volume is mainly adjusted by alterations in sympathetic activity (review by Sarnoff and Mitchell 1962). Total vascular resistance is determined by a balance between the effects of nervous vasoconstrictor discharge and the basal tone of the vessels, with contributions from locally produced vasoactive substances (review by Folkow, Heymans and Neil 1965). The morphological and physiological basis for this autonomic control of circulation has been extensively studied in recent years. The development of specific and sensitive biochemical assay systems for the determination of monoamines in tissues and body fluids, as well as the introduction of the fluorescence method for visualizing these amines in histological preparations, has greatly added to the clarification of functional and structural aspects of the sympathetic nervous system throughout the body. This subject has been covered in several reviews e.g. Euler (1959, 1966), Hillarp (1959, 1960), Carlsson (1966), Norberg (1967). The use of refined physiological techniques has expanded our knowledge of central nervous cardiovascular control considerably; the information has been summarized by e.g. Uvnäs (1960), Folkow *et al* (1965).

As an introduction to this summary, a brief review will be presented of some relevant anatomical and functional points in the regulation of blood pressure. Special attention will be drawn to the importance of the sympathetic nervous system.

The peripheral division of the sympathetic system will be considered first. It has long been known that the transmission of nerve impulses to the effector cells from postganglionic sympathetic nerves is mediated by a humoral mechanism, and the work of Euler (1946, 1948) established that the transmitter is noradrenaline (NA). However, certain sympathetic fibres are cholinergic, notably those subserving a vasodilator function (see Uvnäs 1960). By means of the fluorescense method it has been found that the NA in sympathetic nerves is located in intensely fluorescent enlargements on the postganglionic nerve terminals, the varicosities. The varicose terminals are enclosed in an autonomic ground plexus (Hillarp 1946, 1960) in close contact with the effector cells. In the heart, the rhythm-regulating structures, the conduction system and the muscle cells are abundantly supplied by NA-containing

vasoconstrictor tone and hence arterial blood pressure by excitation and inhibition, respectively of the spinal neurons. Alterations in cardiac activity are conveyed through sympathetic accelerator and parasympathetic inhibitory pathways. The contractile force of heart muscle may be specifically influenced (Rushmer 1962).

Higher levels of central vasomotor control are found in e.g. the mesencephalon, the hypothalamus and the cerebral cortex. The type of regulation exerted by these centres often is of a more complex nature than at lower levels. Reflex patterns comprising differentiated vasoconstrictor influences, sometimes with concomitant vasodilatation in other vascular beds, have been described. The hypothalamus is often ranked with the vasomotor centre in the medulla oblongata as the most important level of superior autonomic circulatory control. Excitatory and inhibitory responses of vessels and heart have been obtained on stimulation of various hypothalamic areas and its integrative function is evident from the fact that most of the corticofugal pathways involved in blood pressure control pass through or are relayed in this region. In addition the majority of the efferent fibres from the hypothalamus seem to have synapses in the medullary vasomotor centre. However some neurons project directly on the spinal sympathetic centre. Among cortical regions of importance for cardiovascular regulation are the motor and premotor areas, the anterior part of the temporal lobes and certain sections of the limbic system. Thus, Löfving (1961) observed that stimulation in the cingulate gyrus may elicit pronounced alterations in sympathetic tone. Of special interest is the possibility of a differential vasoconstrictor control by a selective excitation of pathways to either muscle, renal or intestinal vessels.

The precise morphological basis of cardiovascular regulatory activity at suprabulbar levels is only partly understood. Studies with the histochemical fluorescence method have demonstrated extensive NA-containing terminal networks in the relevant regions of the brain stem, the mesencephalon and the hypothalamus. 5-HT terminals have been found in the brain stem and biochemical determinations have shown high concentrations of this amine in e.g. the hypothalamus. In some instances it has been possible to trace complete neuron systems which may correspond to pathways with similar localisation previously demonstrated with e.g. neurophysiological techniques. Short NA and 5-HT-containing neurons with both the cell bodies and the nerve terminals located in the lower brain stem, sometimes innervating autonomic nuclei, may be involved in cardiovascular reflex activity at these levels. Ascending catecholamine and 5-HT neurons have been shown to run from these regions to e.g. the hypothalamus, the limbic system and the neocortex. Further studies will no doubt provide more informations regarding the precise functional significance of such monoamine pathways.

Aim of the present investigation

Drugs which influence the formation, storage and release of monoamines are often found to exert profound effects on autonomic neuronal mechanisms. This may

reflect an interference with monoaminergic neuron systems of the kind previously mentioned. Many currently used antihypertensive agents seem to have such effects and, as evident from the survey presented above, their action may be located at several different levels of central cardiovascular control. An important aim in studying the mechanisms of action of such drugs should therefore be to localize the effect of the drug within the regulating systems. In addition, it may be of considerable relevance to establish the precise locus of the effect on adrenergic neurons thus may have important therapeutical implications, e.g. in cases of possible interactions with other drugs.

The DOPA analogues L-α methyl-DOPA (α-methyldopa, α MD) and L-α methyl *m*-tyrosine (α MmT) interfere with the metabolism of the biogenic monoamines in several respects. They may thus be assumed to influence the function in neurons utilizing these amines as neurotransmitters. The abundant literature on α MD and α-MmT has been summarized in several recent review articles (Muscholl 1966, Holtz and Palm 1966, Stone and Porter 1966, 1967, Sourkes and Rodriguez 1967, Kopin 1968). However, in spite of several years of concentrated research, the mechanisms underlying the hypotensive action of α-MD are not clearly understood.

It is commonly agreed that the effect of α MD is mediated through an interference with the sympathetic system. However, the exact site of action has not been established. Opinions differ as to the function of the peripheral sympathetic nerves after treatment with α MD (see reviews mentioned above and Paper 3). On the other hand, several obvious effects of the drug on the central nervous system have been reported.

The interrelation of the alterations in monoamine metabolism and the functional effects of α MD is also subject to debate. It has been suggested that the amines formed on metabolism of the drug may take over the function of DA and NA in the brain (Carlsson and Lindqvist 1962), as well as that of NA in peripheral sympathetic nerves (Day and Rand 1964). The activity on the adrenergic receptors of the amines formed from α MD appears to be less than that of NA and it has been proposed that the α-methylated derivatives act as substitutes or "false" transmitters in the sympathetic nerves, thereby explaining the hypotensive effect of α-MD (Day and Rand 1963, 1964). This hypothesis seems to have become widely accepted (see reviews by Crout 1966, Muscholl 1966, Stone and Porter 1966, Sourkes and Rodriguez 1967, Kopin 1968).

The studies summarized here were undertaken to examine the relationship of the hypotensive action of α-MD and the effects of the drug on monoamine metabolism. Basic to the hypothesis of false transmitters is that the lowering of blood pressure depends on the formation of amines from α MD. It was found that decarboxylation of the drug in the central nervous system is a prerequisite for the antihypertensive effect (Paper 1), thus pointing to the involvment of a central mechanism in the action of α-MD on blood pressure. When the NA levels in peripheral tissues were examined in parallel with blood pressure after a single dose of α-MD (Paper 2), there was no

clear-cut correlation in time between these parameters. The assumed false transmitters do not lower blood pressure by themselves (Brunner *et al* 1966, 1967 Paper 2) and the function in peripheral sympathetic nerves is only slightly impaired at the time of maximal fall in blood pressure (Paper 3) These results seemed to point to the importance of an effect of α MD on central mechanisms. In Paper 4 direct evidence was obtained showing that α-MD is capable of lowering blood pressure by acting via the central nervous system

METHODOLOGICAL CONSIDERATIONS

The methods used have been described in detail in the individual papers and only a summary will be presented here.

Experiments on anaesthetized animals

In Paper 3 preganglionic stimulation of the cervical sympathetic trunk was performed in rats anaesthetized with urethane (1.2 g/kg body weight s.c.). A Grass stimulator model S4 was employed and stimulation parameters were 5 V 1 msec rectangular pulses with frequencies from 0.4–25.6 imp./sec in geometrical succession using bipolar platinum electrodes. The response of the inferior eyelid was recorded with a Grass force displacement transducer model FT03. A graduated coil spring was inserted in the system connecting the eyelid to the transducer allowing for a convenient adjustment of the initial tension to 0.50 g. Since this device permitted a certain amount of movement of the eyelid, the contractions were regarded as semi-isometrical. Blood pressure was taken from the left carotid artery to a Statham model P23Dc pressure transducer. The contractions of the eyelid and the blood pressure were recorded on a Grass Model 5 Polygraph via suitable preamplifiers.

In Paper 4 changes in blood pressure were recorded from a femoral artery with similar techniques after infusion of drugs into the left vertebral artery of cats under chloralose anaesthesia (60–70 mg/kg i.p.). Since cannulation of the vertebral artery involved thoracotomy artificial respiration was applied throughout these experiments by means of a positive pressure respiration pump. An attempt was made to evaluate if the artificial respiration was adequate by stopping the pump temporarily at intervals throughout the experiments and observing the spontaneous respiratory movements of the animals.

Blood pressure recording in conscious rats

Previous studies on α methyldopa indicated that the hypotensive effect of this drug was difficult to demonstrate in anaesthetized animals. Most of the techniques available in the literature for recording of blood pressure in conscious animals were adapted for use in small animals e.g. rats. In addition, several previous investigations on the effects of α MD on monoamine metabolism had been performed in rats, allowing a direct comparison with the present findings.

The methods for measuring blood pressure in conscious rats fall in two main categories. True arterial blood pressure may be recorded through a catheter implanted

in a suitable artery Indirect estimations are possible by recording the pressure required to occlude the circulation to a peripheral tissue in which the blood flow can be qualitatively monitored, e.g. by plethysmography or auscultation in a paw or the tail. The more direct method of measurement was chosen to avoid erroneous results after administration of vasoactive drugs. Popovic and Popovic (1960) have described a convenient preparation which involves cannulation of the thoracic aorta via the left carotid artery This method, with some modifications, was used in the present study and a brief description will be given of some technical details.

In Sprague-Dawley rats weighing 180–250 g anaesthesia was induced by pentobarbital (Nembutal® Abbott) 30–40 mg/kg i p and the left carotid artery was carefully isolated and ligated A polyethylene catheter (as a rule Portex Tubing PP 25 outer diameter 0 80 mm) shaped as described by Popovic and Popovic (1960) was introduced into the artery and pushed distally until the tip reached the aorta. The catheter was then withdrawn a few mm and secured by double ligatures. The free end was passed subcutaneously between the eye and the ear on the left side of the animal and exteriorized midway between the ears on the back of the neck. A piece of an injection needle of suitable gauge ending with a short piece of heat-sealed polyethylene tubing was attached. The animals were kept in individual cages and their catheters were flushed at least 1–2 times daily with about 0.5 ml of a solution of heparin (25 IU/ml in 0 9 / saline) Body weight, which as a rule showed a transient decrease during the first 1–2 days after the operation, was checked frequently and animals not displaying a normal gain in weight were discarded. As a rule no recordings were performed for the first two postoperative days, although no systematic variation could be detected in repeated measurements beginning immediately after recovery from anaesthesia. For recording of blood pressure, the catheter protruding from the rat was clamped by means of a hemostat with both tips protected by polyethylene tubing (to avoid damage to the catheter), the heat-sealed piece removed and the needle adapter joined to a length of tubing which permitted free movements of the rat in its cage. The connection to the transducer (Statham P23Dc recording on a Grass Model 5 or Model 7 Polygraph) was made through a 3-way stopcock to enable periodical flushing with saline-heparin solution as required The entire system was filled with this solution. Owing to the small diameter of the catheter and the length of the system only average pressures could be recorded Basal values of blood pressure were obtained by continuous recording for 10–40 minutes 3–4 times daily for at least 2 days, usually at a paper speed of 0.25 mm/sec. During the first few minutes the blood pressure of the rats tended to be somewhat higher than at later intervals. The initial five minutes of each recording were therefore always disregarded and the average of the following 5–10 minutes was taken as the level of blood pressure Blood pressure varied little at various times of the day or during subsequent days Daily recordings of blood pressure were made in nine rats analysis of variance with two criteria of classification did not show any significant variation between days (Table 1) The basal values were therefore

Table 1 Mean arterial blood pressure of 9 normal rats during four subsequent days. Analysis of variance using two criteria of classification shows that there is a significant variation between rats ($p < 0.01$) but not between days ($p > 0.10$).

Rat No.	Day 1	Day 2	Day 3	Day 4
1	105	105	120	120
2	105	110	110	115
3	100	95	95	115
4	125	110	115	115
5	135	120	120	135
6	115	120	120	110
7	115	115	120	115
8	100	110	110	105
9	125	115	105	110

estimated as an average of all basal recordings in individual rats and drug effects were expressed as changes from this mean in mm Hg. Care was always taken to follow the blood pressure to complete recovery after drug treatment and, usually recordings from 6 or more days after the last drug administration were included in the basal values. The mean value of all basal recordings in 57 normotensive rats was 112 mm Hg with a standard deviation of 13 8. This value is comparable to the values reported by Stanton and White (1965) and Stanton and Cooper (1966, 1967) (average basal pressure was 108 mm Hg, s.d. 10 7 in 100 rats recordings were made from a catheter in the abdominal aorta). Other investigators, using the same technique have found somewhat higher basal pressures (Weekes and Jones 1960, McIlreath De Graw and Kadar 1965) However in these studies, both experimental conditions and animal strains were different.

The influence of an i p injection of 2.0 ml 0 9% saline is shown in Fig. 1 The changes in blood pressure are small and statistically insignificant (t-test)

In spite of daily flushing with heparin solution as indicated above the arterial catheters were eventually occluded by thrombus formation around the tip. The average time during which reliable blood pressure recordings could be taken was about 15 days with a range of 10–40 days.

Induction of arterial hypertension in rats

Several possibilities for induction of experimental hypertension in rats have been described (for reviews, see Green 1963 Plummer 1967). Studies of drug effects on blood pressure have mostly been performed with renal hypertensive animals the technique described by Sokabe and Grollman (1963) which involved a partial infarction of one kidney and a contralateral nephrectomy was used. The operations were performed on young Sprague Dawley rats of either sex (body weight 80–100 g) under pentobarbital anaesthesia (Nembutal® Abbott, 30–40 mg/kg). Through a

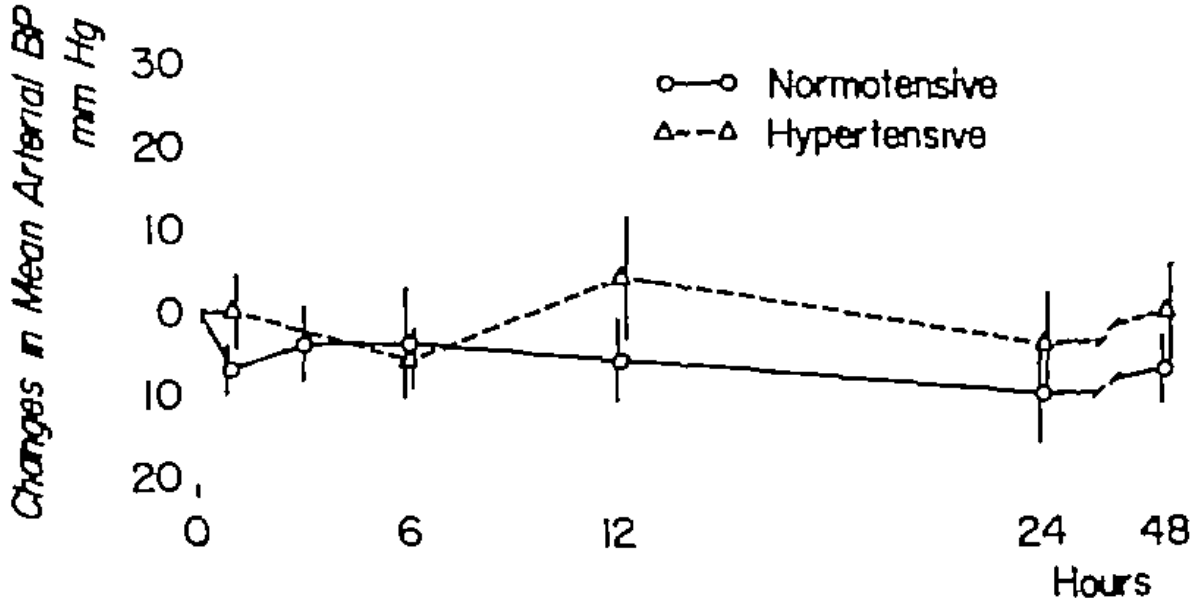

Fig. 1 Effect of an i.p. injection of 2.0 ml 0.9% saline to normal (circles) and hypertensive (triangles) rats. Basal pressures were 111 mm Hg (s.e.m.=5.0, n=4) and 170 mm Hg (s.e.m.=5.4 n=9), respectively

longitudinal incision the right kidney was exstirpated and an anterior branch of the left renal artery was ligated in order to produce an infarction of the ventral half of the kidney The operative mortality was about 20 per cent. About 80 per cent of the surviving animals slowly developed an arterial hypertension reaching stable high blood pressure levels 4–6 weeks after the operation The hypertensive rats increased their body weight slower than normal animals and also showed gross pathological signs of hypertensive disease, e g. left ventricular hypertrophy

Recording of blood pressure in these animals was performed as described above for normotensive rats and hypertension was defined as the average basal blood pressure exceeding 140 mm Hg. This corresponds to a mean basal blood pressure of the normotensive rats plus two times the standard deviation of this value Using this criterion, 65 out of 78 rats cannulated after operation for induction of hyper tension were hypertensive with an average basal blood pressure of 167 mm Hg (standard deviation 19 2) A few of these animals had a basal blood pressure in excess of 200 mm Hg. The results of an i.p injection of saline is shown in Fig. 1 the changes were not significant.

Biochemical determination of monoamines in tissues

Tissue levels of the following amines were determined after homogenization and extraction in ice-cold perchloric acid. The organs from two animals were always pooled The individual methods have been described in the references listed below

noradrenaline (Bertler Carlsson and Rosengren 1958)

dopamine (Carlsson and Waldeck 1958 modified according to Carlsson and Lindqvist 1962)

5-hydroxytryptamine (Bertler 1961 modified according to Andén and Magnusson 1967)

α-methyldopamine (Carlsson and Lindqvist 1962).

Drugs used

atropine sulphate
carbachol chloride
chloralose
eserine salicylate
DL-α-hydrazino-α-methyl β-(3 4-dihydroxyphenyl) propionic acid (MK 485)
4-(m-chlorophenylcarbamoyloxy)-2 butynyltrimetylammonium chloride (McN A 343)
L-α-methyl-3 4-dihydroxyphenylalanine (α methyldopa)
D-α-methyl-3 4-dihydroxyphenylalanine (D-α methyldopa)
DL-α methyl-*m* tyrosine
(±)-α-methyldopamine hydrobromide
(−)-noradrenaline-d-bitartrate
pentobarbital sodium (Nembutal®)
DL-seryl 2,3 4-trihydroxybenzyl-hydrazine hydrochloride (Ro 4-4602)
tyramine hydrochloride
urethane.

The doses given refer to the salts

Statistical methods

Tests of significance were conducted using Student s t test and analysis of variance with one or two independent criteria of classification (Davies 1949).

RESULTS AND DISCUSSION

Introductory remarks

α-MD was synthesised with the aim of obtaining a DOPA decarboxylase inhibitor and it was believed that such a compound might be therapeutically useful in the treatment of hypertension (Sourkes 1954). DOPA decarboxylase inhibition by α MD *in vivo* was demonstrated by Dengler and Reichel (1957) and Westermann Balzer and Knell (1958) The closely related, possibly identical enzyme (Rosengren 1960) catalyzing the decarboxylation of 5-HT was also inhibited by α-MD (Westermann *et al* 1958 Smith 1959 1960) These properties of α MD are also shared by α MmT which is however considerably less active than α MD (Porter Totaro and Leiby 1961 Hansson and Clark 1962, Carlsson 1964) The pharmacology of decarboxylase inhibitors has been extensively reviewed by Clark (1959) Sourkes (1966) and Sourkes and Rodriguez (1967)

α-MD may also inhibit monoamine synthesis at the stage where tryptophan or tyrosine are hydroxylated (Sharman and Smith 1962, Roos and Werdinius 1963 Ross and Haljasmaa 1963 Pletscher Burkhard and Gey 1964 Pletscher and Gey 1964 Nagatsu Levitt and Udenfriend 1964 Udenfriend 1966) It should be pointed out that α MD is a relatively weak inhibitor of tyrosine hydroxylase and α-MmT is only slightly active in this respect.

Treatment of animals with α MD or α MmT results in a decrease in the levels of DA and 5-HT in various tissues, as first reported by Murphy and Sourkes (1959) and Smith (1959 1960) Soon after this it was found that tissue levels of NA were also lowered by these drugs (Oates *et al* 1960 Sourkes *et al* 1961 Hess *et al* 1961 Kuntzman *et al* 1961) These findings are substantiated in numerous later studies (for references, see reviews mentioned above) Only the laevo isomers are capable of inducing amine depletion and the lowering of NA is more long lasting than that of DA and 5-HT α MmT seems to be more active than α-MD The mechanism underlying the depletion of catecholamines by these drugs has been subject to considerable argument (see review by Muscholl 1966) The lack of specificity of the enzymatic mechanisms in the synthesis of DA and NA allows for a metabolism of the α-methylated amino acids to form their corresponding amines. It is now generally agreed that α MD and α MmT lower catecholamine levels chiefly by a mole for mole displacement of these amines from their intraneuronal storage sites by the amine metabolites of the α methylated acids (Carlsson and Lindqvist 1962, Maitre and Staehelin 1963 Muscholl and Maitre 1963 Andén 1964 Shore, Busfield

and Alpers 1964 review by Muscholl 1966) Inhibition of synthesis may contribute to the effect, particularly in the case of 5-HT lowering after α-MD (Sharman and Smith 1962, Roos and Werdinius 1963 Carlsson 1964 Pletscher *et al* 1964).

After treatment with α MD the depleted amines are replaced by metabolites of α MD i.e. α methyldopamine (α-MDA) or α-methylnoradrenaline (α-MNA) Both compounds have been identified in the brains and peripheral tissues of animals given α MD (Carlsson and Lindqvist 1962, Muscholl and Maitre 1963 Porter Totaro and Burcin 1965 Torchiana *et al* 1965) In addition, the presence of small amounts of α-methyl-adrenaline in the adrenal medulla was reported by Muscholl (1965) In the case of α MmT the depleting agents are α methyl-*m*-tyramine and metaraminol both of which have been found in brain and peripheral organs of experimental animals treated with α MmT (Carlsson and Lindqvist 1962, Andén 1964).

Evidence is accumulating that α methylated amines are stored in the same manner as normal transmitters. Their displacement of NA appears to be stoichiometric (for references, see above) and it is evident from histochemical studies that α-MNA (*Hillarp and Malmfors 1964 Malmfors 1965*) as well as *metaraminol* (*Jonsson* and Ritzén 1966) are taken up and accumulate in adrenergic nerves after administration of the corresponding amino acids. α-MNA appears to have an intracellular distribution closely resembling that of NA following pretreatment with reserpine neither of these amines are taken up by the granules but appear to be located extra granularly Furthermore injected radioactive α-MNA and metaraminol are taken up by the adrenergic nerve fibres and retained by a particulate fraction of sympathetically innervated tissues (Lundborg and Stitzel 1967*a* 1967*b*), indicating a granular storage of these amines. In addition, reserpine blocks the granular uptake of ^{3}H-α MNA. The time course of this blockade, measured by means of ^{3}H NA uptake, recovers simultaneously with the adrenergic function (Lundborg and Stitzel 1967*b* 1968) The uptake and storage of α-MNA and metaraminol by the adrenergic nerves may thus be regarded as a partial fulfillment of the criteria for their identification as false transmitters Another requirement necessary for this is that a presumed transmitter substance should be released by nerve stimulation. Muscholl and Maitre (1963) were able to demonstrate that α-MNA formed from α-MD was released during stimulation of the sympathetic nerves in isolated rabbit hearts. Crout *et al* (1964) have made similar observations with regard to metaraminol which had replaced NA in the hearts of cats

These findings suggest that the amine metabolites of α-MD and α MmT function as pseudo-transmitters, as was originally suggested by Carlsson and Lindqvist (1962) with respect to the central nervous system. Later Day and Rand (1964) hypothesized a similar mode of action of α MD in the peripheral nervous system Day and Rand found α MNA to have less vasoconstrictor activity than NA and suggested that the substitution of α MNA for NA would diminish the effectiveness of sympathetic impulses to the blood vessels, thus leading to a reduction in blood

pressure. Basic to this concept is that the new transmitter has less receptor activity than the natural substance This problem has been the subject of several investigations The two drugs were found largely equipotent in raising the blood pressure of the pithed rat (Ahlquist 1948, Muscholl and Maitre 1963 Maitre and Staehelin 1963) or the anaesthetized dog (Sydow 1959) and in increasing the heart rate in the anaesthetized cat (Gaddum Peart and Vogt 1949). Ahlquist (1948) also examined the direct receptor activity of these amines in the heart and the blood vessels in animals of various species and found α MNA less effective than NA A similar relation has been found for the blood pressure increases after intravenous infusion of the two amines to conscious humans, NA being 3–4 times more potent than α-MNA (Mueller and Horwitz 1962) Day and Rand (1964) found α MNA 2–3 times less potent than NA in increasing the arterial blood pressure in several laboratory animal species under anaesthesia. In the conscious rat, α MNA had a pressor activity of about a third of that for NA (Brunner *et al* 1967) Holtz and Palm (1967) studied these relations extensively and reported that the vasoconstrictor effect of α-MNA relative to that of NA in the anaesthetized cat was dose-dependent In small doses, the two amines were equipotent while in higher dose ranges α MNA was a weaker vasoconstrictor The chronotropic action of the two amines in anaesthetized dogs was identical over a wide dose range (Sugarman *et al* 1968) The widely different conditions of these experiments, as well as possible differences in species and target organ sensitivity make it difficult to estimate the potency of α MNA as a substitute for NA at the vasoconstrictor nerve endings. However it seems quite obvious that α MNA is only little less effective than NA and, judging from the above-mentioned studies, a factor of 2–4 would seem a reasonable estimate

Homeostatic mechanisms often tend to oppose drug induced changes in the function of various systems in the intact organism. This is especially obvious in the control of blood pressure a drop in pressure at baroreceptor level may elicit reflex vasoconstriction and cardioacceleration, counteracting the change. In view of this a purely peripheral site of action of α-MD is not likely Physiological impulse flow in sympathetic nerves is normally only a fraction of that observed at maximal activity (Celander 1954) and it appears reasonable that the nerves are capable of increasing their frequency 2–4 times to compensate for the lower receptor activity of the new transmitter released after treatment with α MD Obviously this compensatory mechanism does not operate The present studies were initiated by considerations of this kind and it was felt necessary to examine critically the arguments in favour of a possible mechanism of "false" transmission in peripheral sympathetic nerves.

The theory that the α MNA formed from α-MD acts as a pseudotransmitter which produces a functional impairment in sympathetic nerves and hence a decrease in blood pressure seems to be widely accepted at the present time. Several recent review articles have emphasized the importance of this concept for explaining the antihypertensive effect of α MD (Crout 1966 Muscholl 1966 Stone and Porter

1966, 1967 Sourkes and Rodriguez 1967 Kopin 1968) On the other hand Holtz (1963 1965) has pointed out certain observations which are difficult to reconcile with this hypothesis (cf also Holtz and Palm 1966)

Interaction of decarboxylase inhibitors with the effects of α-methyldopa on blood pressure and monoamines

A main prerequisite for the false transmitter theory is that prevention of the formation from α-MD of a false transmitter should abolish the hypotensive action Since only a few studies of this kind have been performed and, in addition, have yielded contradictory results, this assumption was re investigated in Paper I The experiments were set up in two series, studying the effect of two different decarboxylase inhibitors on the action of α MD on blood pressure and tissue monoamines in rats. One group of animals was given hydrazino-methyldopa (MK 485) which has previously been shown to inhibit preferentially peripheral decarboxylase (Porter *et al* 1962) Another group received seryl-2,3 4-trihydroxybenzyl-hydrazine (Ro 4-4602). This inhibitor when given in large doses, inhibits both peripheral and central decarboxylase (Pletscher and Gey 1963 Burkhard *et al* 1962, 1964). The inhibitors were given alone or in combination with α MD and in repeated doses to ensure a sufficient degree of enzyme inhibition In addition α MD was studied separately A significant reduction of mean arterial blood pressure was observed 1–12 hours after α MD (100–200 mg/kg i p.) maximal effect occurred after 3–6 hours. In rats pretreated with the decarboxylase inhibitor Ro 4-4602, the fall in blood pressure which occurred 1–6 hours after α-MD administration was completely prevented. This is in contrast to the results obtained from rats which received MK 485 in combination with α MD 100 mg/kg i.p. in spite of the lower dose of α-MD used, no protective action of the decarboxylase inhibitor was observed in these experiments. In both groups there was a delayed hypotensive effect when the two drugs were given in combination This was also evident after the decarboxylase inhibitors alone Tissue monoamine levels were decreased by α-MD after both doses. It is of interest to note that femoral muscle NA content, i.e. the transmitter content of the vasomotor nerves of this tissue, was not altered and that the lowering of heart NA amounted to only 30–40 per cent of the controls at the time of maximal effect on blood pressure. The interaction of the two decarboxylase inhibitors with the effects of α MD on tissue monoamines was difficult to assess due to changes in these amines brought about by the inhibitors alone. These relations are discussed in detail in Paper I However it was established that both inhibitors completely prevented the formation of α MDA in the heart after α MD while that in the brain was significantly reduced by Ro 4-4602 only

This observation should be viewed in conjunction with the results obtained in the blood pressure experiments. In animals pretreated with Ro 4-4602 the hypotensive action of α-MD was inhibited but this effect was unchanged after pretreatment with

MK 485 These findings show that the decarboxylation products of α-MD play an important role in mediating the blood pressure effect of the latter drug. Further it may be concluded that decarboxylation of α MD in the central nervous system is necessary for its hypotensive action. However the question whether α MDA or α-MNA or both are responsible for the effect must be left open, as must also the possibility of these amines acting by false transmitter mechanisms in central neurons. It may also be pointed out that the findings do not exclude the contribution of a peripheral component such an action must be of little importance by itself (see below). This was shown also by the fact that the NA levels in the heart and the femoral muscle were slightly or not at all reduced at the time of maximal fall in blood pressure after α MD

Relationship of blood pressure and monoamine levels after α-methyldopa

If the depletion of the NA stores in sympathetically innervated organs is due to a substitution of this amine for α MNA which then acts as a less active false transmitter one would expect a rather close time correlation between the effect of α MD on NA level and on blood pressure The validity of this assumption was tested in Paper 2. Blood pressure and tissue monoamine levels were examined in parallel following the administration of a single large dose of α-MD to rats. After an i p injection of 400 mg/kg the blood pressure of normal as well as renal hypertensive rats was significantly reduced for 1–12 hours with maximal effect after 3–6 hours. Normal values were reached 24 hours after the administration of α MD The rats were sedated and showed a tendency to develop hypothermia during a period of time corresponding to the fall in blood pressure.

The same dose of α MD caused a transient fall in brain DA and 5-HT levels. This decrease was about 75 per cent of the control value and the time course of this depletion was rather similar to that of the blood pressure effect. Brain NA was also lowered but with a slower onset and a longer duration than DA and 5-HT minimum values were observed after 6–12 hours and the levels were still depressed after 72 hours. Heart NA was not maximally depleted until after 24–48 hours and did not return to normal until after 72 hours These biochemical determinations were made using normotensive rats. Supplementary studies were also performed in rats with renal hypertension using the same methods (see under Methodological considerations). The results are presented in Table 2. Analysis of variance showed that the values from hypertensive rats were not significantly ($P>0.05$) different from those obtained at corresponding intervals in normal rats. However femoral muscle NA was decreased significantly more ($P<0.005$) in hypertensive rats than in normal animals 24 hours after α MD

A comparison of the effects of α-MD on blood pressure and tissue monoamine levels shows that the former action was apparent at a time when there was only a small depletion of brain NA and an insignificant lowering of heart NA (cf also the

Table 2. Levels of noradrenaline (NA) in brain, heart and femoral muscle dopamine (DA) in brain and 5-hydroxytryptamine (5-HT) in brain normally and after an i.p. injection of α-methyldopa (α MD) or α-methyl-*m*-tyrosine (α MmT) to normotensive and hypertensive rats. The values are means in μg/g and number of experiments is shown in brackets. Variance and standard deviation was calculated with analysis of variance.

findings in Paper 1) The blood pressure had returned to normal values long before the NA stores were refilled. The same was true of the sedation and the hypothermia after α MD As stated in the introduction to this section, previous studies have established that the NA depletion after a single dose of α MD lasts for several days (cf also Paper 2). A number of earlier investigators have also noted that the hypo-

tensive effect of a single dose of the drug is of considerably shorter duration than the depletion of NA Directly comparable with the findings in Paper 2 are those studies which have been performed with similar techniques in conscious rats. Thus, Torchiana *et al* (1965) observed that maximal hypotensive effect occurred 2–6 hours after a moderately large dose of α MD to renal hypertensive rats return to control values was observed after 16 hours. Stanton and White (1965) and Stanton and Cooper (1966 1967) found that these events occurred 3 hours and 24 hours, respectively after α MD administration to normal as well as to hypertensive rats After repeated doses of α MD (hypertensive rats), the indirectly recorded blood pressure returned to control levels within 16 hours (Kroneberg 1963*a*) Similar results were obtained in conscious dogs (Goldberg, Da Costa and Oznki 1960 Kroneberg 1963*b*) Thus, there seems to be an obvious discrepancy between certain functional effects of α MD such as the lowering of blood pressure and the depression of monoamine levels in peripheral tissues. It should be pointed out, however that nerve function seems to be correlated to only a small fraction of the amine store (see Introduction) and it may be that this part of the store is influenced by α MD with a time course similar to that of the hypotensive effect. This functionally important depletion is then too small to be detected as a change in tissue NA levels when determined by the methods used in Paper 2.

Comparison of the effects of α-methyldopa and α-methyl-*m*-tyrosine on blood pressure and monoamine levels

Another implication of the false transmitter concept is that there should exist a parallellism between the receptor activity of the assumed transmitter and the magnitude of the hypotensive response This assumption was also tested in Paper 2 by comparing the effects of α-MD and α MmT on blood pressure The pressor activity of metaraminol in the conscious rat has been estimated to be about 10 times less than that of α MNA and about 20 times less than that of NA (Brunner *et al* 1966, 1967) Consequently α MmT should be proportionally more active than α MD in decreasing blood pressure. However after an i p injection of α MmT 400 mg/kg, normal as well as hypertensive rats responded with a moderate increase in blood pressure after 1–6 hours and no hypotension was observed even up to 72 hours after the injection This should be compared with the effect of α MD 200 mg/kg, as the α MmT used was a racemic mixture of the dextro and laevo isomers and only the latter are substrates for the decarboxylase *in vivo* (Sjoerdsma 1961 Porter *et al* 1961 Gillespie *et al* 1962, Sjoerdsma, Vendsalu and Engelman 1963) In similar experiments this dose of α MD lowered blood pressure significantly 3 12 hours after the injection in normal rats and 1–12 hours in hypertensive rats Both drugs produced roughly the same depletion of NA, as shown in Table 2 α MmT even appeared to be more active than α-MD in this respect, as also found by e g. Porter *et al* (1961) Udenfriend and Zaltzman-Nirenberg (1962) Andén (1964) Previous

studies on the cardiovascular effects of α MmT have not given conclusive results. Stone *et al* (1961) reported that α-MmT lacked an effect on blood pressure in renal hypertensive rats. Similarly Horwitz and Sjoerdsma (1964) found α MmT less effective than α-MD on acute administration to hypertensive patients however Holtmeier *et al* (1966) failed to reproduce these results and recent studies seem to indicate that α MmT may lower blood pressure on chronic administration to renal hypertensive rats (Brunner *et al* 1966 1967). Differences in species, dosage schedules or experimental conditions may partly account for these variable results. It might be noted, however that no pharmacological evidence of an impairment of sympathetic transmission has been obtained in animal experiments with α MmT despite a severe reduction in peripheral NA stores (Stone *et al* 1961 Andén and Magnusson 1964)

Effects of α methyl-DA on blood pressure and monoamines

It has long been known that sympathetic nerves are able to take up and store other amines than NA (for references, see Andén 1964 Andén *et al* 1964*c*). Utilizing this property of the nerves as well as the fact that catecholamines generally show a poor penetration through the blood-brain barrier it was considered possible to mimic the action of α-MD in peripheral sympathetic nerves by administration of the amine metabolites of α MD In Paper 2, the effect of α MDA was studied in normotensive rats which had been pretreated with α MDA (5 × 5 mg/kg s.c. during two subsequent days). No significant alteration in blood pressure was observed upon examination 16–18 or 40–42 hours after the last injection of α MDA. The treatment was found to produce a depletion of heart NA of at least the same magnitude as that observed after α-MD 400 mg/kg. Brain NA was not changed. A supplementary investigation was performed using rats with renal hypertension. α MDA was given for 3 days as indicated above and the blood pressure was followed during the first 12 hours after the last injection, i.e. the time corresponding to the hypotensive action of α MD (Table 3). No significant lowering of blood pressure occurred after α MDA during this period. Twelve hours after the termination of a similar treatment, four other

Table 3. Changes in mean arterial blood pressure of four hypertensive rats treated with (±)-α-methyldopamine (α-MDA) 5 × 5 mg/kg s.c. for 3 days. The changes are expressed in mm Hg from the individual basal values average initial pressure was 185 mm Hg (s.e.m.—4.1).

Hours after administration of last dose of α-MDA	3	6	9	12
Change in blood pressure mm Hg	+5	−6	−1	−5

	0 022	0.051	0.040	0.008
	(10)	(8)	(8)	(6)
After α MDA	0.43	0.75	0.19	0.09
	0.012	0.034	0.014	0.012
	(4)	(4)	(4)	(4)

hypertensive rats showed a reduction of the heart NA to 17 per cent and of the femoral muscle NA to 84 per cent of the control animals. No change was observed in brain NA or DA. The absolute values are given in Table 4

Thus, it appears that depletion of NA by α MDA in peripheral tissues to a level even lower than that after α MD at maximal hypotensive effect is not accompanied by a reduction in blood pressure. α MNA is also devoid of antihypertensive properties (Brunner *et al* 1966, 1967)

Adrenergic nerve function at maximal hypotensive effect of α-methyldopa

If α MNA takes over the function of NA in the sympathetic nerve endings, the nerve function would be expected to decrease in proportion to the lower activity of the substitute transmitter Numerous studies have been performed to determine the influence of α MD on peripheral adrenergic function. Unfortunately investigations of this kind have yielded variable and sometimes conflicting results. This is possibly due to widely different experimental conditions, using several different animal species and after varying types of pretreatment schedules. A review of the findings from the literature has been given in Paper 3 This study was initiated to investigate if a sympathetic blockade of relevance to the antihypertensive effect of α MD should be easily demonstrable at the time of maximal fall in blood pressure after the drug Since this was found to occur 3–6 hours after a single i.p. injection of 400 mg/kg (Paper 2), a number of pharmacological tests of adrenergic nerve function were applied in anaesthetized rats after the same dose of α MD The responses of the lower eyelid to graded preganglionic stimulation of the cervical sympathetic trunk showed a tendency to be lower in treated rats but they were not significantly different from control animals. The blood pressure increases to graded doses of the

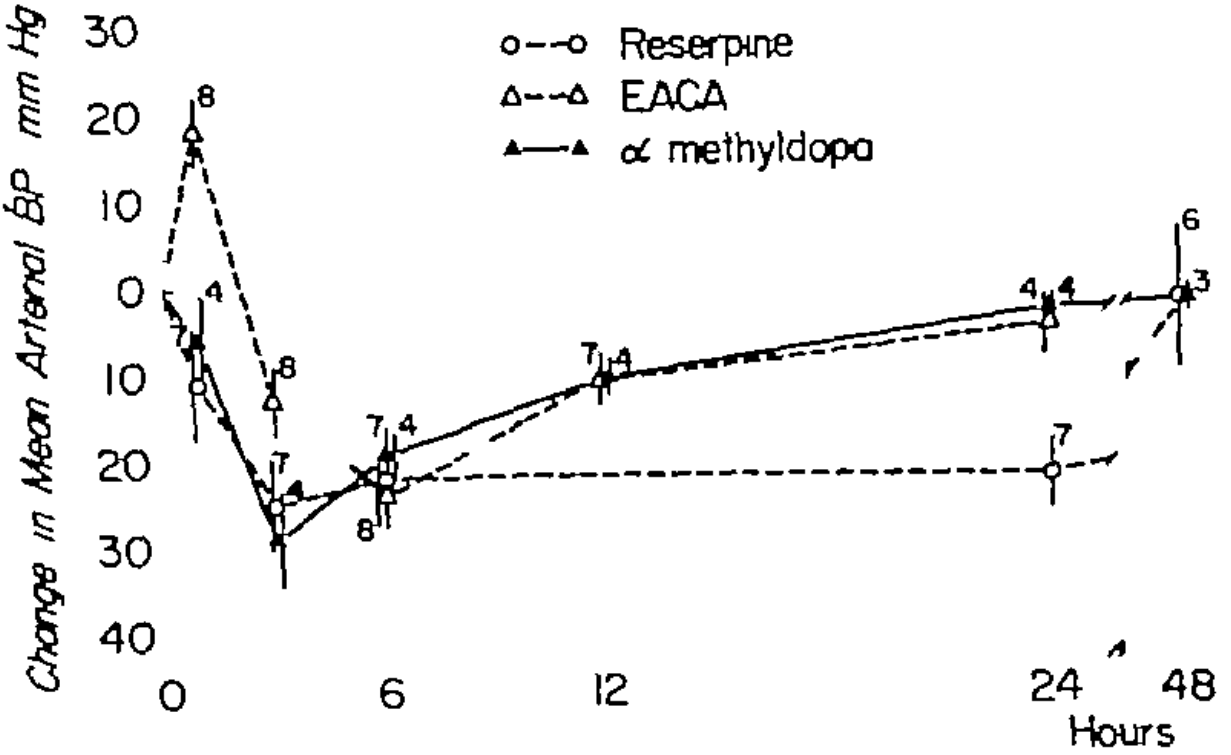

Fig. 1. Changes in mean arterial blood pressure of normotensive rats after i.p. injections of reserpine (Serpasil®) 10 mg/kg (circles), epsilon amino caproic acid (EACA) 2 g/kg (open triangles) and α-methyldopa 200 mg/kg (filled triangles). Blood pressure was recorded in conscious animals as described in Methodological considerations and basal pressures were 122 mm Hg (s.e.m.=4.2 n=7), 119 mm Hg (s.e.m.=3.5, n=6) and 121 mm Hg (s.e.m.=3.8, n=4), respectively. The data for EACA were taken from Andén, Henning and Obianwu (1968) and those for α-methyldopa from Paper 2.

sympathetic ganglion stimulant drug McN A 343 were slightly reduced by α MD but were likewise not significantly different from those obtained in untreated rats. The same was also true of the small contractions of the lower eyelid elicited by McN A 343. The response of the blood pressure to ganglionic stimulation by carbachol 0.15 mg/kg after atropine was significantly reduced. The blood pressure and eyelid responses to NA and tyramine were unaffected by α MD.

In summary these findings indicated that the responses of the peripheral adrenergic nerves may be slightly reduced at the time of maximal effect on blood pressure after α MD. This is also evident from the previous work summarized in Paper 3. Most investigators find an approximately normal sympathetic transmission when this was studied several hours after treatment with α MD. If on the other hand, the interval was relatively short, a moderate impairment of sympathetic function was sometimes observed. This effect then coincided with the period during which the blood pressure was lowered. It should be stressed, however, that such a blockade when it occurs is always considerably less prominent than that observed after adrenergic neuron blocking drugs or reserpine. Epsilon amino caproic acid (EACA) has recently been shown to produce an almost complete blockade of peripheral

sympathetic nerves equivalent to that observed after e.g. guanethidine leading to a reduction of the arterial blood pressure (Fig. 2 Andén Henning and Oblanwu 1968) In the present experiments, α MD lowered blood pressure to a similar extent yet α MD showed only a slight impairment of the peripheral sympathetic function. Similar relations are found for reserpine In spite of an almost complete adrenergic blockade in the rat (Andén *et al* 1964*b*) reserpine gives almost the same hypotensive response as α-MD on administration in the same doses to conscious rats (Fig. 2). These comparisons seem to indicate that the impairment of peripheral sympathetic function of α MD is not by itself of sufficient magnitude to account for the anti hypertensive effect of α-MD

Evidence for a centrally mediated hypotensive effect of α-methyldopa

The present results (Papers 1–3) do not support the false transmitter concept in its simplest outline. It was shown (Paper 1) that the hypotensive effect of α MD persisted when the decarboxylation of the drug was prevented peripherally but not centrally However if decarboxylation of α MD was blocked both peripherally and centrally the hypotensive effect was prevented There was no clearcut time relation between the NA depletion in peripheral tissues and the decrease in blood pressure after a single dose of α MD the latter effect being more rapid in onset and shorter lasting that the former (Paper 2) Peripheral adrenergic mechanisms were only slightly impaired at the time of maximal hypotensive effect (Paper 3) After treatment with α MDA or α MNA, peripheral stores of NA are depleted at least as much as after α MD but this depletion is not accompanied by a reduction in blood pressure (Paper 2, Brunner *et al* 1966, 1967) In view of these findings, central nervous mechanisms must be taken into account for explaining the antihypertensive effect of α MD An action on the peripheral sympathetic system might contribute to the final result although appearing insufficient alone. Previous studies have shown that administration of drugs into a vertebral artery in anaesthetized cats may be used to reveal centrally mediated effects of vasoactive drugs (v Zwieten, Bernheimer and Hornykiewicz 1966, Reis and v Zwieten 1967 Sattler and v Zwieten 1967) This method was employed in a series of experiments. The results are reported in Paper 4

In cats under chloralose anaesthesia, a small dose of α MD (20 mg/kg) was infused into the left vertebral artery This procedure resulted in a pronounced slowly developing decrease in systemic arterial pressure which was maximal after about 3 hours. In cats similarly prepared, the same dose of α-MD infused intravenously had no significant effect on arterial pressure This was also true of two other types of control experiments in which the dextro isomer of α MD (20 mg/kg) or 0.9 per cent saline was infused into the vertebral artery A large dose of α MD (200 mg/kg) infused into a systemic vein seemed to lower the blood pressure slightly after 3 hours but the change was not significant Tissue monoamine levels were also studied in these experiments and three hours after the infusion of α-MD 20 mg/kg into the vertebral

artery there was a significant although moderate reduction of brain NA and DA while brain 5-HT and heart NA remained normal. Intravenous infusion of the same dose of α MD showed a depletion of these amines which in every case was similar to that observed after infusion into the vertebral artery. Infusion of D-α MD had no effect on any of the amines examined. In an attempt to reveal possible regional differences in the lowering of brain monoamines by α MD (20 mg/kg) after the two types of administration, the lower brain stem and the forebrain were analyzed separately in some experiments. No difference between the effect of intra-arterial and intravenous infusion of α-MD was observed. In a few experiments, the level of α-MDA in the brain was also measured. Both types of infusion of the small dose of α MD gave rise to similar concentrations of α MDA.

Since infusion of saline or D-α MD into the vertebral artery had no effect on the blood pressure in identically designed experiments, this would indicate that the effect of L-α MD was specific. It should be pointed out, however, that it is not known whether in the cat D-α MD penetrates the blood brain barrier to the same extent as does the L isomer. A specific action of L-α MD is also suggested by the gradual onset of the effect and the fact that its time course and relative magnitude was similar to that seen after single larger doses of the drug to conscious animals (see Paper 4). The possibility that the observed effect on blood pressure of α-MD was due to a potentiation of anaesthesia seems to be excluded by the fact that a much larger dose of α MD intravenously infused did not produce a corresponding effect on blood pressure.

The effects of α-MD on tissue monoamines were poorly correlated to the hypotensive action. Whole brain NA and DA were equally lowered and the accumulation of α MDA was similar after both types of infusion. When the lower brain stem was analyzed separately there was still no significant difference in the amine content after the two routes of administration. It may be that a more extensive and detailed analysis of various parts of the brain stem could have disclosed a correlation between the lowering of blood pressure and the decrease in amine content. However, it is also possible that the hypotensive action observed in the present experiments is not primarily related to changes in gross monoamine levels. Further, as shown in Paper 4, the time correlation between the effect of α-MD on blood pressure and the depletion of monoamines is poor, the hypotensive effect occurring at a time when only a small depletion of brain NA had taken place. Apparently, there exists in the brain a structure receiving its blood supply from the vertebral artery which is influenced by infusion of α-MD in such a way as to bring about a reduction in blood pressure. The determination of the nature and exact localisation of this effect requires further investigation. As stated in the introduction to this section, previous investigators have paid little attention to this possibility for the mode of action of α MD. Jaju, Tangri and Bhargava (1966) studied the effect of injection of small doses of α MD into the lateral cerebral ventricle or of topical application to the floor of the fourth ventricle in anaesthetized dogs. Both types of administration were reported to give

a gradual though short lasting fall in blood pressure and also inhibited the responses to central vagal stimulation and to occlusion of the common carotid arteries. Of considerable interest are also the results of a recent study by Boakes Candy and Wolstencroft (1968) NA applied by iontophoresis to neurons in the brain stem of decerebrate cats, was found to excite some neurons and to inhibit others. Both these actions could be mimicked by α-MNA although the excitatory effects of this amine were weaker than those of NA. Further after α MNA had been applied, the excitatory response to NA was reduced or abolished for up to 20 minutes. This antagonism of the excitatory responses of brain stem neurons to NA is of particular interest in view of the findings in Paper 4 providing a possible explanation for the action of α MD in those experiments.

Animal experiments as well as clinical experience with α-MD have revealed that a number of its effects may be attributed to impairment of central nervous functions. Examples of this are quoted in Paper 4 cf also Sourkes (1965) and Hamon and Henning (1967) The last-mentioned study showed that α MD significantly decreased a conditioned avoidance response (CAR) in cats. Further α MD prevented the amphetamine-induced restitution of CAR in reserpinized cats which indicates an insufficient transmission mechanism in neurons engaged in the maintenance of CAR. The significance of such actions for the hypotensive properties of α-MD is difficult to establish but it may be of relevance that, in therapeutic doses, α MD interferes with certain reflex adjustments of blood pressure. This is true of the overshoot in blood pressure following the Valsalva maneuvre in hypertensive patients (Dollery and Harington 1962, Dollery 1963) the cardiovascular adjustments to exercise (Sannerstedt, Varnauskas and Werkö 1962) the reflex vasoconstriction after a cold test or exercise in normal subjects (Mason and Braunwald 1964) and of the pressor responses to noxious stimuli in hypertensive patients (Shapiro and Kritcher 1964), all of which were impaired or blocked during treatment with α MD These findings may be explained by interference at various levels of central vasomotor control as previously mentioned. They may also be interpreted in terms of impaired monoaminergic transmission in the structures involved in blood pressure control Thus effect of α-MD may represent a mechanism of false transmission as well as other types of influence on the neuron separately or in combination. Since the reflexes mentioned involve both central and peripheral divisions of the sympathetic system, a peripheral sympathetic blockade may contribute Little is known of the influence of α MD on this part of the system in man Although being more effective in reducing blood pressure in the standing position, α-MD seems to be less prone to give orthostatic side reactions than the purely peripherally acting adrenergic blocking drugs guanethidine and ganglioplegics (Dollery and Harington 1962, Smirk 1963 Holtmeier and Heilmeyer 1965, Prichard *et al* 1968). Nasal congestion inhibition of ejaculation and other signs of peripheral sympathetic blockade also seem to be less commonly encountered after α-MD Observations of this kind may be taken to indicate that peripheral adrenergic mechanisms are relatively intact during therapy

with α-MD in keeping with the findings in animal experiments. The results of the investigations reported in this summary may then be of relevance to the clinical effects of α MD as well the hypotensive action of the drug in man may be at least partly due to interference with central mechanisms of blood pressure regulation Further work is required to ascertain the significance of such an assumption such clinical studies may possibly be performed following similar lines of investigation

SUMMARY

Several currently used antihypertensive drugs are known to interfere with the function in the sympathetic nervous system and also to influence the metabolism of the biogenic monoamines. The interrelations of such actions as well as their possible relationship to the therapeutic effect are in many instances poorly understood. The studies summarized in this paper were aimed at considering these aspects with particular reference to α methyldopa (α-MD)

α-MD depletes tissue stores of catecholamines mainly through a displacement of these amines by the metabolites of α MD i e. α methyl DA or α methyl NA or both This replacement of the normal transmitter by α methylated amines has been related to the antihypertensive properties of the drug by assuming that the metabolites substitute NA at the sympathetic nerve endings in the heart and the blood vessels, thus serving as so-called false transmitters. Since the α-methylated amines are less active on the adrenergic receptors than the endogenous transmitter the effectiveness of sympathetic impulses would be diminished thus leading to a fall in blood pressure. A number of basic requirements for this hypothesis may be set up e.g.

(1) prevention of the synthesis from α MD of possible false transmitters should abolish the hypotensive action
(2) a reasonable time relation should be demonstrable for the depletion of NA in peripheral nerves and the decrease in blood pressure
(3) since the compounds proposed as false transmitters are taken up by the adrenergic nerves and displace the adrenergic transmitter they should also be active in lowering blood pressure
(4) a parallelism should exist between the receptor activity of the assumed transmitter and the magnitude of the hypotensive response
(5) the function in peripheral sympathetic nerves should decrease in proportion to the lower activity of the false transmitter and this functional impairment should be clearly demonstrable at the time of maximal fall in blood pressure

The validity of these assumptions was tested in different types of experiments using the same animal species (rat) for both functional and biochemical studies.

(1) The formation from α MD of possible false transmitters was prevented by pretreatment of the animals with two DOPA decarboxylase inhibitors, seryl-2,3 4-trihydroxybenzylhydrazine (Ro 4-4602) and α-hydrazino-α-methyl β-(3 4-dihydroxy

phenyl) propionic acid (MK 485) Administration of Ro 4-4602 completely inhibited the hypotensive effect and markedly reduced the accumulation of α methyl DA in the heart and in the brain after α MD On the other hand pretreatment with MK 485 had no effect on the hypotensive response or on the accumulation of α-methyl-DA in the brain but prevented the formation of this amine in the heart as much as Ro 4-4602. It was concluded that decarboxylation of α MD in the central nervous system is a prerequisite for its hypotensive action (Paper 1)

(2) The time relations of the hypotensive effect and the depletion of NA in tissues were studied after administration of a single dose of α MD (Paper 2). A significant fall in blood pressure was observed after 1–12 hours at this time there was only a minor decrease in the peripheral NA stores and maximal depletion of NA did not occur until about 48 hours after the administration, *i.e* at a time when the blood pressure had returned to normal levels.

(3) Previous work has shown that α methyl NA is devoid of antihypertensive activity (Brunner *et al* 1966 1967) and the studies reported in Paper 2 established that this applied to α-methyl DA as well, in spite of a reduction of the heart NA content exceeding that caused by α MD at the time of maximal fall in blood pressure. However brain NA was not altered by treatment with α-methyl DA

(4) Like α MD the closely related compound α methyl-*m*-tyrosine (α MmT) depletes NA from the stores through displacement by its decarboxylated amine products These substances possess considerably less receptor activity than the amines arising from α MD By the concept of false transmission as outlined above it would therefore seem that α MmT should be more potent than α MD in lowering blood pressure However on administration in equivalent doses to normal as well as hypertensive rats, α-MmT was found to lack anti-hypertensive properties (Paper 2).

(5) The function in peripheral sympathetic nerves was studied at the time of maximal fall in blood pressure after a single dose of α MD (Paper 3). At most a slight functional impairment was observed. This is in contrast to e g. reserpine and epsilon aminocaproic acid which in equi-hypotensive doses, have been found to produce an almost complete block of sympathetic transmission It seems that this discrepancy can only be explained by assuming that α MD in addition to a possible slight peripheral sympathetic blockade, also influences central blood pressure regulation. The results summarized above thus seemed to point to the existence of an important action of α MD on the central nervous system and it was thought of interest to investigate this component further A small dose of the drug was slowly infused into a vertebral artery in anaesthetized cats, resulting in a gradual and significant lowering of mean arterial blood pressure (Paper 4) Infusion of the same low dose of α-MD into a systemic vein did not affect blood pressure, neither did infusion of saline

or the dextro isomer of α MD into a vertebral artery These findings support the view that the hypotensive action of α MD is at least in part, of central nervous origin. The contribution of an action on the peripheral division of the sympathetic system cannot be excluded but is apparently of little importance at least in the rat. It would thus appear that in order to be relevant to the mechanism of action of α-MD the theory of false transmission must be extended to include central neurons. Further experiments are required to settle the question whether this is so or if the transmitter involved is α-methyl DA or α methyl-NA or both.

ACKNOWLEDGEMENTS

The investigations summarized here were performed during the years 1965–1968

To my teacher Professor Arvid Carlsson I owe my sincere thanks for his constant readiness to discuss and criticise problems and results in a positive spirit his unfailing interest and support have made this study possible

My sincere thanks are also due to Dr Nils-Erik Andén for his invaluable criticism throughout this work and for countless discussions concerning the problems dealt with in this summary

I would also like to express my gratitude for many stimulating discussions to Drs Bengt Åblad and Gillis Johnsson who first aroused my interest in cardiovascular pharmacology

Tor Magnusson and Georg Thieme, Research Engineers, have not only drawn all the illustrations in this summary and in the individual papers but have also given invaluable help and criticism in various other ways.

The technical assistance in the work reported here as well as in most of my other publications was provided by Miss Inger Pettersson. Her patient skill and accuracy in performing biochemical analyses and animal operations have been of utmost importance for this study and I thank her warmly

To all other colleagues in the Department I want to express my sincere thanks for their most stimulating discussions and encouraging interest in the subject.

I am indebted to Miss Ulla-Karin Ahnsberg, Miss Christina Cruse and Mrs Elly Kihl for their kind help and patience with the manuscripts. Stylistic correction was kindly provided by Drs L. and S Butcher

I especially thank my family for their constant encouragement and support.

The studies were supported by research grants from the following sources Faculty of Medicine, University of Göteborg, Göteborg, Läkemedelsindustriföreningen, Stockholm Svenska Sällskapet för Medicinsk Forskning, Stockholm Swedish National Association against Chest and Heart Diseases, Stockholm Swedish State Medical Research Council, grant No B68-14X 155-04B Wenner-Grenska Samfundet, Stockholm.

I am indebted to the following companies for generous supplies of drugs F Hoffman-La Roche and Co Ltd, Basel, Switzerland through Dr A. Pletscher (Ro 4-4602) AB Hässle, Göteborg through Dr H. Corrodi (α methyldopamine) McNeil Laboratories, Inc. Fort Washington, Pa., U.S.A. (McN A 343) Merck, Sharp and Dohme International through Erik Lindblom and Co KB Stockholm (α-methyldopa and MK 485) Swedish CIBA Stockholm (Serpasil®)

Preface

This study of thermoregulation during exercise is part of a series of investigations dealing with different aspects of the same topic, parts of which have been published earlier The main findings from these papers are discussed in the General Discussion in connection with the results from the present study

The series consists of the following papers:

1 Nielsen, B and M. Nielsen, Body temperature during work at different environmental temperatures. *Acta physiol. scand.* 1962 *56* 120–129

2. Nielsen, B and M. Nielsen, On the regulation of sweat secretion in exercise. *Acta physiol scand* 1965 a. *64* 314–322.

3 Nielsen, B and M. Nielsen, Influence of passive and active heating on the temperature regulation of man. *Acta physiol scand.* 1965 b *64* 323–331

4 Nielsen, B., Regulation of body temperature and heat dissipation at different levels of energy- and heat production in man. *Acta physiol. scand* 1966. *68* 215–227

5 Nielsen, B., Thermoregulatory responses to arm work, leg work and intermittent leg work. *Acta physiol. scand.* 1968 *72* 25–32.

Acknowledgements

I wish to express my gratitude to Professor Marius Nielsen, Head of the Laboratory for the Theory of Gymnastics B The first papers were published in collaboration with him and his never failing interest in my work, his advice and discussions were invaluably helpful. Professor Erling Asmussen of the Laboratory for the Theory of Gymnastics A read the manuscript and gave advice and helpful criticism. Mrs Else Merete Skræm assisted through 7 years in the whole experimental procedure, performed the analyses and part of the calculations. In addition she drew part of the graphs, did the photographical work on the figures and typed the manuscript. I am greatly indepted to her for her skilful and reliable assistance. Assistant Professor at the Danish Technical University P O Fanger kindly made it possible for me to have the data treated at the Northern Europe University Computing Center where Mr Karsten Schmidt, M.sc. performed the statistical analyses. The subjects willingness to take part, over several months, in the sometimes strenuous and unpleasant experiments is greatly appreciated. The Transocomp 288, 12-channel recorder was placed at my disposal by the Carlsberg Foundation. Mrs and Mr W G Wilkoff kindly revised the English text.

List of symbols

Temperatures in C

A bar over a symbol denotes mean value of the quantity

T	ambient air temperature.
T_{ds}	deep skin (intracutaneous) temperature.
$T_{(ds\ s)}$	average temperature differential between deep and surface temperature in the skin.
T_m	muscle temperature.
T	operative temperature, measured as the mean of walls and air temperature, since both were nearly the same
T_{es}	esophageal temperature.
T_{re}	rectal temperature.
T	skin surface temperature.
T_{ty}	tympanic membrane temperature.

Quantities for the heat balance equation expressed in kcal/hr

M	metabolic energy liberation ($V_{O_2} \times 4.9 \times 60$)
W	external work (kpm/mm $\times$ 1/427 $\times$ 60)
$H = M - W$	total heat production.
$(C + R)$	convective plus radiation heat exchange (positive for net loss)
E_l	evaporative heat loss from lungs.
E_{sw}	evaporative heat loss from skin sweat.
$E = E_l + E_{sw}$	evaporative heat loss (water loss g/hr $\times$ 0.582)
S	storage of body heat (positive for net heat gain by the body)

Miscellaneous

A_D	DuBois Area, body surface area m^2
HR	heart rate, beats/min.
h_c	combined heat transfer coefficient for radiation and convection kcal/hr $\times$ m^2 $\times$ ° C.
K	conductance of the peripheral tissues kcal/hr $\times$ m^2 $\times$ ° C (cf p 16)
$\dot{Q}$	cardiac output l/min.
$\dot{Q}$	skin blood flow l/min.
R_s	thermal resistance of skin ° C $\times$ hr/kcal.
Sw	sweat rate g/hr
$\dot{V}o$	oxygen uptake l/min.

Introduction

In a study of heat dissipation during uphill and downhill walking on a motor driven treadmill (B Nielsen 1966), it was found that in conditions where the skin temperature is the same the body regulates the sweat rate so that the heat dissipation equals the total heat production, in spite of differences in the level of internal body temperature and the mechanical events in the muscles.

It was suggested that the thermoregulatory centre obtains information on the rate of heat production through thermoreceptors "measuring" the temperature at some definite depth in the skin as proposed by Kerslake (1955) and Blockley (1966) The rationale for this concept is that the temperature in the skin below a thermal resistance must be increased proportionally to the heat flow through the tissues. Another possibility is that thermal receptors, placed at different depths in the skin, could be stimulated by thermal gradients across the skin, in proportion to the heat flow and, hence to the rate of heat production (Bazett 1949 1951) Thirdly it has been postulated (by Robinson et al. 1965) that thermal receptors in the muscles or in the veins draining the working muscles provide information to the heat dissipating centre.

The present study was designed to evaluate the above mentioned hypotheses. A method was worked out for the measurement of 1) local temperature gradients in the skin, 2) the average deep skin temperature, and 3) the average deep to surface skin temperature differential. In addition the muscle temperature in *vastus lateralis* was measured in one series of experiments.

The study is divided into three experimental parts, chapters II–IV which are discussed independently followed by a general discussion of thermoregulation during work.

Chapter two is a pilot study of the local thermal gradients measured in the skin on the ventral surface of the thigh, and on the chest. The changes in these gradients with variations in both heat production (different work loads) and environmental temperature were studied, in order to determine the depth at which an average deep skin temperature should be measured.

Chapter three consists of a study of "average deep skin temperature" in relation to sweat rate (sweat rates between 50 and 600 g/hour) at 3 metabolic levels at various environmental temperatures.

Chapter four describes the changes in "average deep skin temperature" average deep to surface skin temperature differences, and muscle temperature in relation to heat dissipation during positive and negative work. By walking or bicycling uphill (+) or downhill (−) the proportion of total heat production to metabolic energy liberation can be varied.

Chapter I

METHODS

The instrumentation in the present study is nearly identical to that used in our earlier studies and has been described in detail (B Nielsen and M. Nielsen 1962 1965 a B Nielsen 1966) Therefore, only a short survey of the methods and the estimated accuracy of the measurements is presented here.

The temperature measurements. The temperatures were measured with copper-constantan thermocouples. For each thermocouple a calibration curve was constructed. The calibration was performed in a stirred thermoregulated waterbath, with the single thermocouples tied to the bulb of a mercury thermometer The reference thermocouples were similarly fastened and kept in a thermos bottle. The thermocurrent was read on a Cambridge Spot Galvanometer or recorded on a 4-channel recording galvanometer (Kipp Micrograph BD 1) The calibrations were repeated for each environmental condition, and were frequently checked. The *rectal temperature* in 4 depths (T_{re}) and the deep *esophageal temperature* (T_{oe}) were measured with the thermocouples described by B. Nielsen and M Nielsen (1962) The measurements are considered to be accurate to ± 0 025° C. During the experiments the esophageal temperature was recorded continuously on the Micrograph while the rectal temperature, measured every 5 min, was calculated from the readings on the Cambridge Spot Galvanometer

The *skin surface temperature* (T_s) was measured either with a skin thermocouple or by a radiation receiver (B Nielsen and M. Nielsen 1965 a)

The *average skin surface temperature* (T_s) was obtained by weighting the 15 single measurements of T according to the size of the corresponding skin area (Hardy and DuBois 1938 a) The error on the single skin surface measurement is less than 0 10° C.

Deep skin temperatures The temperature in the skin (T_{sk}) was measured with copper-constantan thermocouples made by Ellab., Copenhagen. The last 10 cm of the measuring probe consisted of only one copper core (0 045 mm diam.) and one constantan core (0 15 mm diam.) covered by "thermolacquer" The total outer diameter was 0.25 mm the exposed thermosensitive junction being 0.5 mm long.

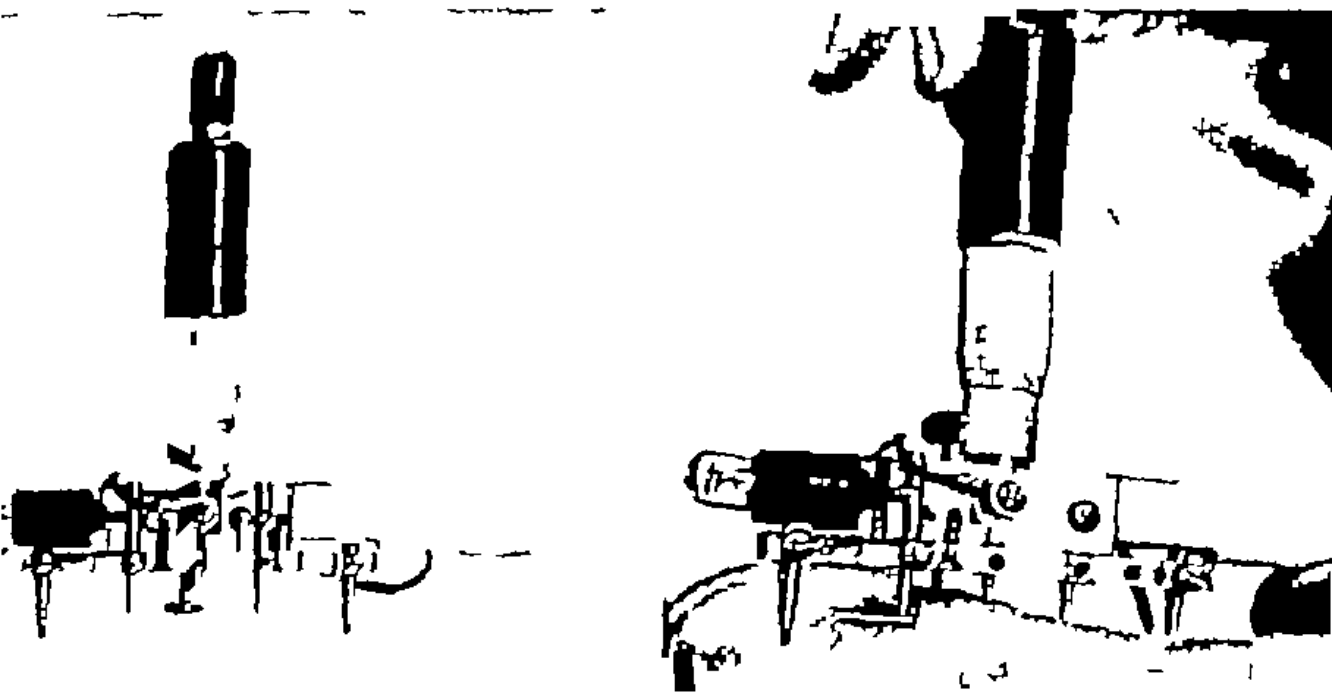

Fig 1

Left. Micrometer for measuring the distance between the intracutaneous thermocouple and the skin surface. Right. The micrometer placed on the needle—through which the thermocouple is inserted—in position for the measurement.

The thermocouple was inserted into the skin through a hollow needle (inner diam. 0.3 mm, outer diam. 0.5 mm) The procedure was as follows: A skinfold was picked up with the fingers and the hollow sharpened needle was pushed through the skinfold so that it protruded on both sides. The skin was then allowed to slide back into place. A micrometer provided with 2 grooved tips which could be placed on the cannula across the pierced skinfold, was placed on the needle (cf. Fig. 1) The micrometerscrew was then advanced until contact with the skinfold was obtained. This closed an electric circuit and lit a signal lamp. The reading on the micrometer at this point gave the vertical distance from the needle below the skinfold to the skin surface.

After this measurement the skin thermocouple was pushed through the needle; the needle was removed and the thermocouple was pulled back so that its tip lay midway between the two holes in the skin made by the needle. The thermocouple was then fixed in place with adhesive tape.

It is estimated that the depth of the thermocouple in the skin can be measured by this method with an accuracy of between 1/10 and 1/4 of a mm.

The skinfold thickness at the sites of measurement was measured with a

standard Harpenden skinfold caliper With some training it was possible to place 4 thermocouples in depths ranging from 0 8 mm to half the double skinfold thickness within an area of 2 × 2 cm (chap II)

The temperatures were continuously recorded on the above mentioned recording galvanometer (chap II and III) or on a Transocomp potentiometer recorder* (chap IV)

The single deep skin temperatures, calculated from the Micrograph record using the constructed calibration curves are considered accurate to ± 0 025° C, while within ± 0.1° when recorded with the Transocomp. (Accuracy ± 0.5 % for full scale deflexion, 50 C) The intracutaneous thermocouples were tested for errors due to heat conduction through the wires, but even a 10° C difference between the water surrounding the tip and the base of the 10 cm exposed wires did not influence the value recorded from the thermocouple.

The *average deep skin temperature* (T_{d_a}) was measured with thermocouples in 7 places (chest, abdomen, shoulder upper arm and forearm, thigh and calf) The skinfold thickness was measured at these 7 sites, and the needles through which the thermocouples were inserted were placed with the mid part at a *depth of half the skinfold thickness* The distance from the skin surface to the needle was measured with the apparatus described above. After insertion, the thermocouples were secured with tape as described The average deep skin temperature (T_{d_a}) was calculated as the simple average of the seven measured temperatures. There was no visible sign of skin irritation around the deep skin thermocouples, and the surface temperature above them was only slightly different from corresponding areas (subj TD average of 60 measurements. + 0 67° on the chest, and − 0.22° on the shoulder)

The *average temperature differential* across the skin ($T_{(d_a - s)}$) was calculated as the difference between T_{d_a} and the simple average of the seven of the fifteen skin surface temperatures which were measured exactly above the intracutaneous thermocouples.

Muscle temperature (T_m) was measured in 2 of the 3 subjects in the study reported in chapter IV Immediately after the work was stopped, a needle thermocouple (diam. 0.5 mm) was inserted 2.5 cm into the thigh in *vastus lateralis* The thermocouple was kept in 39° water till it was used. The temperature recording (Kipp Micrograph) was stable after $^1/_2$–1 min and did not change during the observation period of $^1/_2$–1 min The muscle temperature measurements are accurate within 0 05° C.

The external work. In the experiments reported in chapter II and

obtained through a grant from the Carlsberg Foundation.

III the subjects worked with 60 rev./min on the Krogh bicycle ergometer in which the saddle had been replaced by an armchair

In the treadmill experiments (chap. IV) the subjects walked or bicycled on an ordinary bicycle with direct transmission on the inclined treadmill uphill or downhill. (In the last mentioned situation the subject resisted the acceleration of the pedals) In the bicycle experiments the speed was kept constant at 8 1 km/hr The bicycle was geared so that the frequency of pedaling was 60 rev./min. The work load could be varied by changing the slope of the treadmill and by placing extra weights on the bicycle (1 2 or 3 × 11.5 kg) In the experiments where the subject walked or ran the speed was varied while the slope was kept constant at + or − 10°

The weight loss in the experiments was measured by the Krogh balance (Krogh and Trolle 1936) the error on the determinations being less than 5 g. The ergometer used in the experiments described in chapter II and III was suspended from a Krogh balance (M. Nielsen 1938) so that a continuous registration of the weight loss could be obtained. In the treadmill experiments the weight loss was determined from the weighings before and after the 45 min experimental period (cf p 39)

The sweat secretion (Sw) was calculated from the total weight loss by subtracting the respiratory losses due to evaporation and gas exchange.

The respiratory gas exchange was determined by the Douglas bag method, and air samples were analysed in duplicate on the Scholander apparatus (Scholander 1947)

The metabolic energy liberation (M) was calculated from the oxygen uptake using a caloric value of 4 9 kcal pr 1 oxygen, and the *total heat production* (H) was found by subtracting the caloric equivalent of the external work (W) (1 kpm = 1/427 kcal) from M

In the treadmill experiments (chap. IV) the total heat production during the experiment was calculated according to the formula.

H = M − W for positive (uphill) work and
H = M + W for negative (downhill) work,

where H is the total heat production in kcal/hour M is the metabolic energy liberation in kcal/hour and W is the external work converted to heat in kcal/hour The work was calculated as. $G \times v \times \sin \alpha$. G = weight of subject (or subject + bicycle + weights) in kg, v = speed m/min, α = inclination of the treadmill in geometrical degrees.

Skin blood flow Changes in skin blood flow as indicated by changes in the *conductance* of the peripheral tissue (K) (Burton 1934 Hardy 1937 Winslow et al. 1937) was calculated for the last 15 min of the experiment as

$$k = \frac{H - E_l - S}{\left(\frac{T_{rs} + T_{ee}}{2} - T\right) A_D} \quad \text{kcal/hr} \times \text{m}^2 \times {}^\circ\text{C}.$$

The modification $\frac{T_{rs} + T_{ee}}{2}$ instead of T_{rs} has been applied since it was found that during leg work T_{rs} was higher (0.2 – 0.4° C) than T_{ee}, probably due to heating of a large part of the pelvic cavity by blood returning from the working muscles (B Nielsen and M Nielsen 1962)

The ambient conditions *Air temperature* (T_a) was obtained from 2 mercury thermometers hanging behind and in front of the subject, and wall temperature was measured with a radiation receiver (B Nielsen and M. Niel- 1965 a) Since the walls and the air had nearly the same temperature, the *operative temperature* (T_o) was calculated from these temperatures as $\frac{T_{wall} + T_a}{2}$ T was measured 3 times during the last 30 min of the experimental period. The relative humidity was determined by an aspiration psycrometer

The experiments described in chapter two and three were carried out in a climatic chamber (B Nielsen and M Nielsen 1962) which could be maintained at any desired temperature level between 5° and 44° ± 1/4° C. The treadmill experiments (chap IV) were performed in a temperature controlled room kept at T 22½° ± 1° C

III, the subjects worked with 60 rev./min on the Krogh bicycle ergometer in which the saddle had been replaced by an armchair

In the treadmill experiments (chap IV) the subjects walked or bicycled on an ordinary bicycle with direct transmission on the inclined treadmill uphill or downhill. (In the last mentioned situation the subject resisted the acceleration of the pedals) In the bicycle experiments the speed was kept constant at 8 1 km/hr The bicycle was geared so that the frequency of pedaling was 60 rev./min. The work load could be varied by changing the slope of the treadmill and by placing extra weights on the bicycle (1 2 or 3 × 11.5 kg) In the experiments where the subject walked or ran, the speed was varied while the slope was kept constant at + or — 10°

The weight loss in the experiments was measured by the Krogh balance (Krogh and Trolle 1936) the error on the determinations being less than 5 g. The ergometer used in the experiments described in chapter II and III was suspended from a Krogh balance (M. Nielsen 1938) so that a continuous registration of the weight loss could be obtained. In the treadmill experiments the weight loss was determined from the weighings before and after the 45 min experimental period (cf p 39)

The sweat secretion (Sw) was calculated from the total weight loss by subtracting the respiratory losses due to evaporation and gas exchange.

The respiratory gas exchange was determined by the Douglas bag method, and air samples were analysed in duplicate on the Scholander apparatus (Scholander 1947)

The metabolic energy liberation (M) was calculated from the oxygen uptake using a caloric value of 4 9 kcal pr 1 oxygen, and the *total heat production* (H) was found by subtracting the caloric equivalent of the external work (W) (1 kpm — 1/427 kcal) from M

In the treadmill experiments (chap IV) the total heat production during the experiment was calculated according to the formula.

H = M — W for positive (uphill) work and
H = M + W for negative (downhill) work

where H is the total heat production in kcal/hour M is the metabolic energy liberation in kcal/hour and W is the external work converted to heat in kcal/hour The work was calculated as $G \times v \times \sin \alpha$. G = weight of subject (or subject + bicycle + weights) in kg, v = speed m/min, α = inclination of the treadmill in geometrical degrees.

Skin blood flow Changes in skin blood flow as indicated by changes in the *conductance* of the peripheral tissue (K) (Burton 1934 Hardy 1937 Winslow et al. 1937) was calculated for the last 15 min of the experiment as

Both the skin thermocouple and the radiation receiver gave a stable reading of skin surface temperature within 6–15 sec after being placed against or above the skin. However even these short applications affected the levels of deep skin temperatures (the temperatures generally decreased 0 1°–0.5°) in the region below the measured area for several minutes. The number of surface temperature measurements was therefore reduced to a minimum, and the values given in the graphs represent the average of only 3–5 measurements taken at intervals of about 5 minutes during the last half hour of the 1–1½ hours exposure to the given environment and activity level.

Twentyfour experiments on 4 subjects were carried out. No fundamental differences due to the variations in skinfold thickness were noticed

Subject	Average skinfold thickness mm		Number of exper
	Chest	Thigh	
J W	8.9	9.5	7
M C	13 6	13.6	7
K H N	4 7	6.8	6
G M	14.5	12.2	4

Results

Temperatures at different depths in the skin. In experiments where a thermal equilibrium could be established (as demonstrated by attainment of a constant level of internal temperatures) the highest deep skin temperatures ($T_{d.s}$) were, as expected, generally measured at the deepest sites (Fig. 2) In some experiments, however the temperature did not increase regularly with increasing depth, but showed reversals in the gradients. This phenomenon may have been due to a dislocation of the thermocouple during the work period or caused by contact of the thermocouple with minor bloodvessels in the skin. During rest in moderate warm and warm conditions the tissue layers studied received heat from the surface. (The temperature decreased with depth, Fig. 4)

The effect of different environmental temperatures on the temperature gradients in the skin is illustrated in Fig. 2 and in Fig. 3 In the last mentioned graph the differences from the surface temperature at various depths are shown. Each curve represents the gradient of a single experiment in conditions of heat equilibrium. At a constant work load

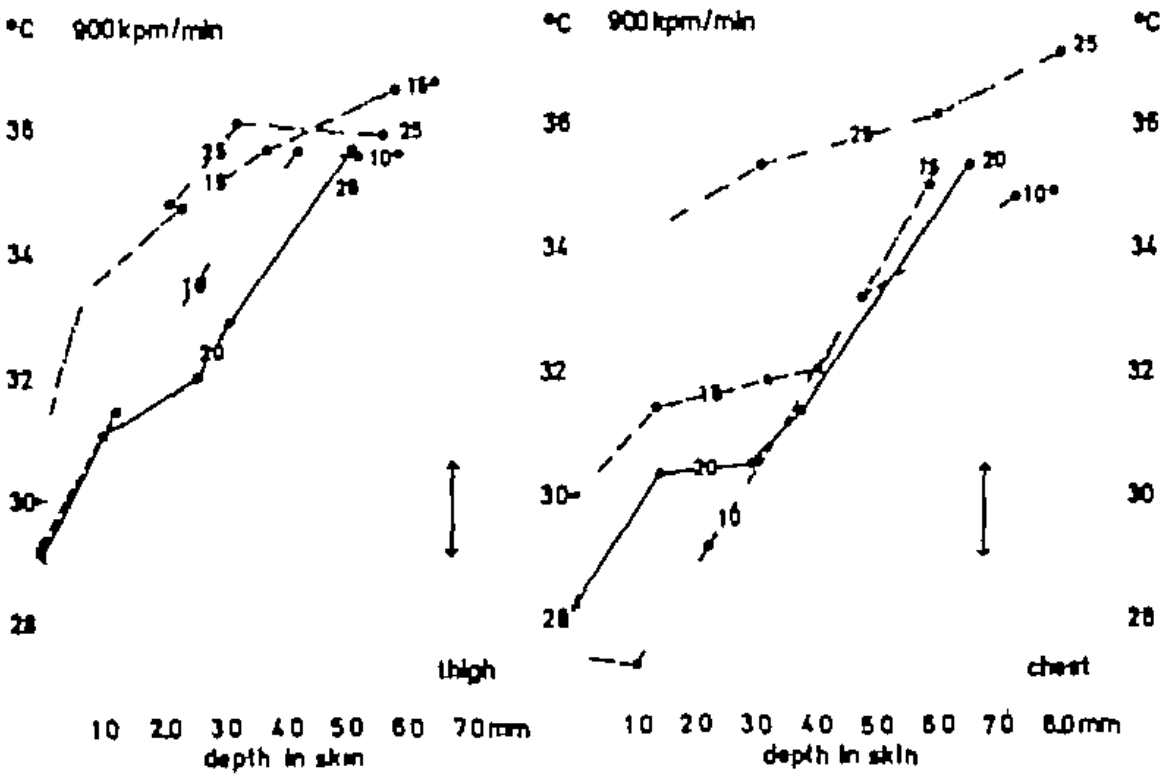

Fig 2

Temperatures at the skin surface and at various depths in the skin of the thigh (left) and the chest (right), during stable conditions of work at 10 15 20 and 25 operative temperature. (Single experiments). ↕ denotes ½ skinfold thickness. Subj. MC. Work intensity 900 kpm/min.

the increase in temperature with depth in the skin is generally smaller the higher the environmental temperature. (The 20° experiment deviates somewhat from the general pattern) This effect seems to be due to a temperature increase in all skin layers (Fig. 2) but the increase is greatest in the more superficial layers.

Increases in the rate of heat production produced by a higher work load also effects the temperature gradients in the skin. In Fig 4 the temperature gradient across the skin is seen to increase as the work intensity rises. The changes are brought about mainly by a temperature rise in the deepest skin layers. However the variations from one experiment to the next in surface temperature above the 4 thermocouples are too great to allow definite conclusions to be drawn as to which temperatures, deep or superficial, are changing the most.

Apparently no systematic difference exists between the temperatures of the two chosen skin areas the chest or the thigh

Discussion

The intracutaneous temperature rises with increasing depth in the tissue. This finding is in good agreement with the results of Bazett and McGlone (1926, 1927) Mendelson (1936) Pennes (1948) and Reader and Whyte (1951) The very steep reversed gradients with 0.3–0.5° C temperature change for 0.5 mm change in depth in the most superficial (0–2 mm) skin layers, noticed by these authors, were not found in the present experiments. One source of error in the present study was that the skin areas in which the 4 intracutaneous couples were placed showed a slight flush and were 1–2 degrees warmer than the corresponding areas on the other side of the midline of the body However it is believed that in conditions of heat equilibrium the values for the different external temperatures and metabolic rates nevertheless are comparable and that the changes observed with different conditions also reflect those occuring in the undisturbed skin areas. When only one intracutaneous thermocouple was used in each skin area (cf p 15) no sign of irritation was noticed.

It appears, that the gradient across the skin is generally *smaller* the *warmer* the environmental conditions. This finding is in agreement with the more extensive studies of Bazett and McGlone (1927) and Reader and Whyte (1951)

Further also changes in the level of activity have a strong effect on the gradient, which becomes steeper with increasing work rate and heat production.

The skin on the thigh over the working muscles (bicycle ergometer) and the skin on the chest behaved in similar ways, and no special effect of blood returning from the working muscles through superficial veins (Cooper Randall and Hertzman 1951 cit. by Robinson 1963) has been noted.

The confirmation of the existence of even very steep gradients (up to 8°) in the skin and subcutaneous tissues in some situations draws more attention to the theory of Kerslake (1955) He calculated an average deep skin temperature and found a correlation between this calculated value and sweat rate in various experimental conditions of rest and work. In our earlier studies (B Nielsen and M. Nielsen 1965 a) we found that at a given sweat rate the average skin surface temperatures were very much lower (5–10°) during work when compared to rest values. This means that if sweat rate is controlled *solely* by the temperature of nerve endings situated deep in the skin (Kerslake 1955 Blockley 1966) these endings must be placed at a depth where the temperature in certain conditions exceeds that of the surface about 5–10 i.e. in the very deepest part of the tissue layer studied in the present paper

If the temperature in the deeper layer of the skin should play any part in the thermoregulation, it must contain thermosensitive receptors. In the studies of Bazett et al (1927 1930) Bazett (1951) Oppel and Hardy (1937) it was presumed that the receptors concerned with thermal sensation and thermoregulation were the "warm" and "cold spots" which could be correlated with Ruffini and Krause endorgans. These structures seemed to lie at depths of 0.3–0 6 mm and 0 15–0.20 mm respectively (Bazett et al. 1927 1930) These values are in good agreement with the receptor depth they calculated from thermal conductivity and temperature-sense reaction time and have later been confirmed by the electrophysiological studies of thermal sensations by Hensel and Zottermann and their coworkers, cf Hensel (1952) These receptors seem to be placed far too superficially to serve as the "deep skin temperature" receptors involved in the thermoregulation according to Kerslake's theory (1955) However the existense of morphologically distinguisable thermal receptors in the skin has not been verified (Zottermann 1959 Winkelmann 1960 Hensel 1966) —Evidence of Lele et al. (1954) Weddell et al. (1954) and Weddell and Miller (1962) seems to show that such specialized thermoreceptors do not exist in the common skin areas and that thermal sensations may be achieved from free nerve endings widely distributed but arranged in distinct layers through the tissue down to the subcutaneous border (Weddell and Miller 1962 Melzack and Wall 1962)

In conclusion it may be said that the present experiments and modern neurophysiological evidence seem to justify a study of the temperature measured as deeply as possible in the skin + subcutaneous tissues. The "average deep skin temperature" i.e. the average of measurements from different sites (chest, abdomen shoulder upper arm and forearm, thigh and calf) may then be evaluated with respect to its possible role in the regulation of sweat secretion in rest and work.

Chapter III

AVERAGE DEEP SKIN TEMPERATURE AND THE REGULATION OF SWEATING AND SKIN BLOOD FLOW

Sweat secretion during work occurs at a mean skin temperature ($\bar{T}$) which is much lower than the threshold of about 35° C for thermal sweating during rest. In certain conditions the differences in $\bar{T}$ between work and rest were found to be more than 10° C for the same sweat rate (B Nielsen and M Nielsen 1965 a) the skin temperature being lower when the work rate was higher

If the rate of sweat production during both rest and work is controlled solely by the temperature of nerve endings situated in the skin (Kerslake 1955) these receptors must lie as deep as possible so that the work and rest values of temperature coincide. This argument also follows from the results presented in chapter II which showed that the highest temperatures were found in the innermost skin layers in all subjects, even when their subcutaneous fat layers were of different thickness (table p 19) It was therefore decided to measure T_{d_i} as the average of the highest possible temperatures found in the tissues studied, namely the temperature measured at a depth corresponding to half the skinfold thickness rather than at a fixed depth. The "average deep skin temperature" (T_d) (cf. methods p 15) was measured during rest and work at different environmental temperatures in conditions for which the sweat rate was between 50g/hour and 600 g/hour in order to evaluate the possible role of T_{d_i} in the regulation of heat dissipation and skin blood flow

Procedure

The subject arrived in the morning, changed to shorts and entered the climatic room which the day before had been set to the desired temperature He inserted the rectal and esophageal thermocouples and then rested in the ergometer chair while the intracutaneous thermocouples were put in place An electric fan directed towards the chest of the subject produced an air movement of 0.5–1 m/sec at chest height it was started at the beginning of the actual experimental period in the cold and cool environments but was kept on also during the preparation period in warm conditions. In this way

he usually spent 1 hour at the experimental environmental temperature before the experiment started. The experiment lasted 60 min during which the subject rested or worked at a constant rate while the measurements were taken The weight loss, esophageal temperature and average deep skin temperature of trunk (3 localities) arm (2 localities) and leg (2 localities) were recorded continuously T_{re} was measured and pulse rate counted at 5 min intervals $\bar{T}$ and wall and air temperatures were measured 3 times during the last 30 min of the 60 min experimental period. After about 45 min of work samples for the determination of the respiratory gas exchange were collected and the relative humidity in the chamber was determined with an aspiration psycrometer

The experimental data presented in the graphs represent the values in stable conditions, i. e. the average of the values obtained from the 45th to the 60th min of the experimental period.

Subjects: Two of the three subjects in this study MC and KHN are the same as used in the temperature gradient studies, chapter II. Their data are presented below Max. V_{O_2} was estimated from the heart rate at submaximal work loads ($\dot{V}_{O_2}$) extrapolated to V_{O_2} at heart rate 196 (Asmussen and Hemmingsen 1958)

Subj.	Age yrs	Weight kg	Height cm	A_D m	Est max. $\dot{V}_{st}$ l/min	N of exp.
T D	19	70	189	1.94	3.0	20
K H N	21	65	181	1 83	4.2	13
M C	21	83	176	1.99	3.5	6

Results

Variations in sweat rate and skin temperature were produced by exposing the subject to different environmental temperatures at 3 metabolic levels (rest at 30 35 and 44° C work 540 kpm/min at 20 25 and 35° C and work 900 kpm/mm at 10 20 and 30° C)

In Fig. 5 and 6 the sweat rate is plotted against the mean skin surface temperature ($\bar{T}_s$) and the mean deep skin temperature ($\bar{T}_{ds}$) for subject TD and KHN It appears that the relationship between sweat rate and skin temperature is different for the 3 metabolic levels, the sweat rate being greater for a given $\bar{T}$ at higher work loads as found earlier The same separation is seen for the sweat rate/deep skin temperature relationship

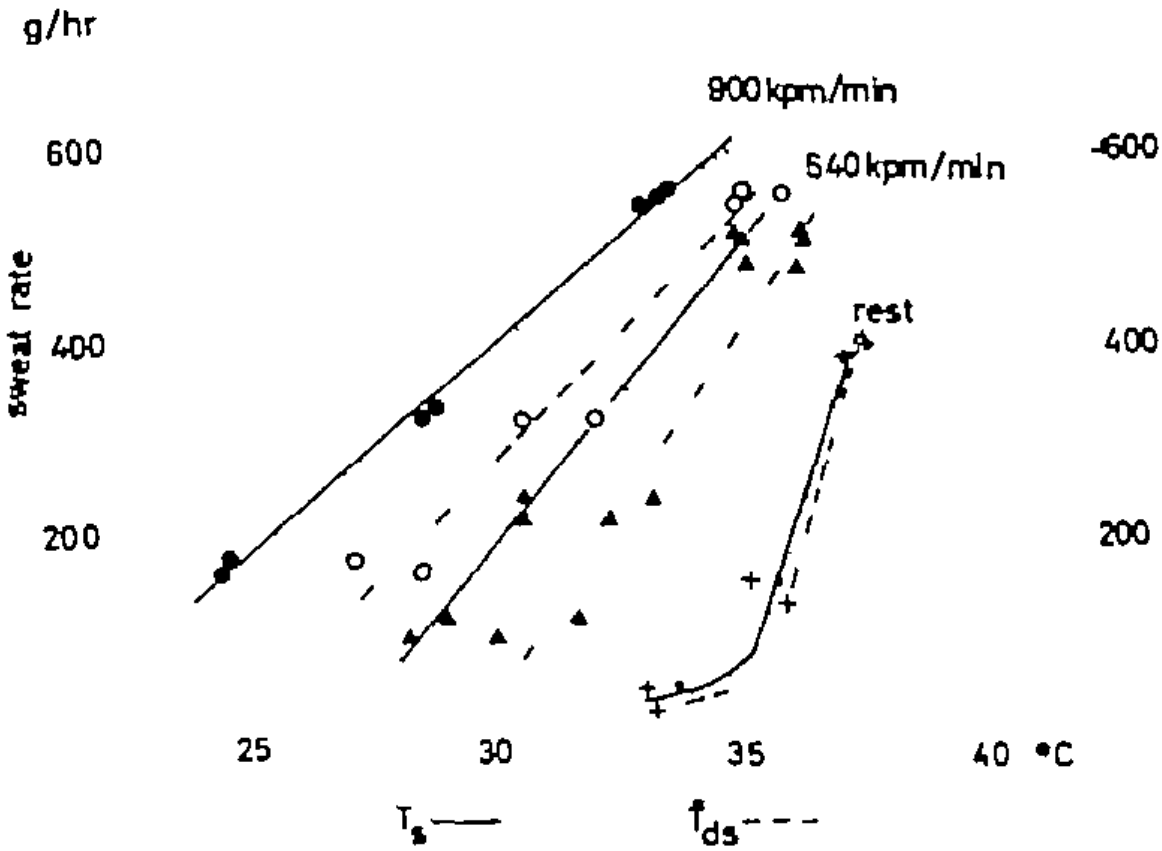

Fig 5

Steady state sweat rate plotted against mean skin temperature ($\bar{T}$ —— closed symbols) and average deep skin temperature (T_d - - - - open symbols). Subj. TD

3 metabolic levels { ○ 900 kpm/min ($\bar{T}$ = 10, 20 30°) ▲ △ 540 kpm/min ($\bar{T}$ = 20, 25 35) + rest ($\bar{T}$ = 30, 35 44)

Fig. 7 shows the sweat rates and the esophageal temperatures for the 3 metabolic levels in two subjects. $\dot{S}w$ for each condition varies from about 100 to about 600 g/hr with only small changes in internal temperature. The esophageal temperature (T_{es}) is increased in proportion to the metabolic rates. In all the rest experiments and also at the low work level for subject KHN the temperature is drifting towards higher values in the more stressful environments.

In Fig. 8 the average "steady state" sweat rate ($\dot{S}w$) is plotted against T_d The relationship varies with the metabolic rate.

The average skin surface temperature ($\bar{T}$) is linearly correlated with ambient temperature independent of the metabolic level. This relationship is shown in Fig. 9 and 10

The calculated heat loss by convection and radiation (C + R) is plotted against the difference between the skin surface temperature and the operative

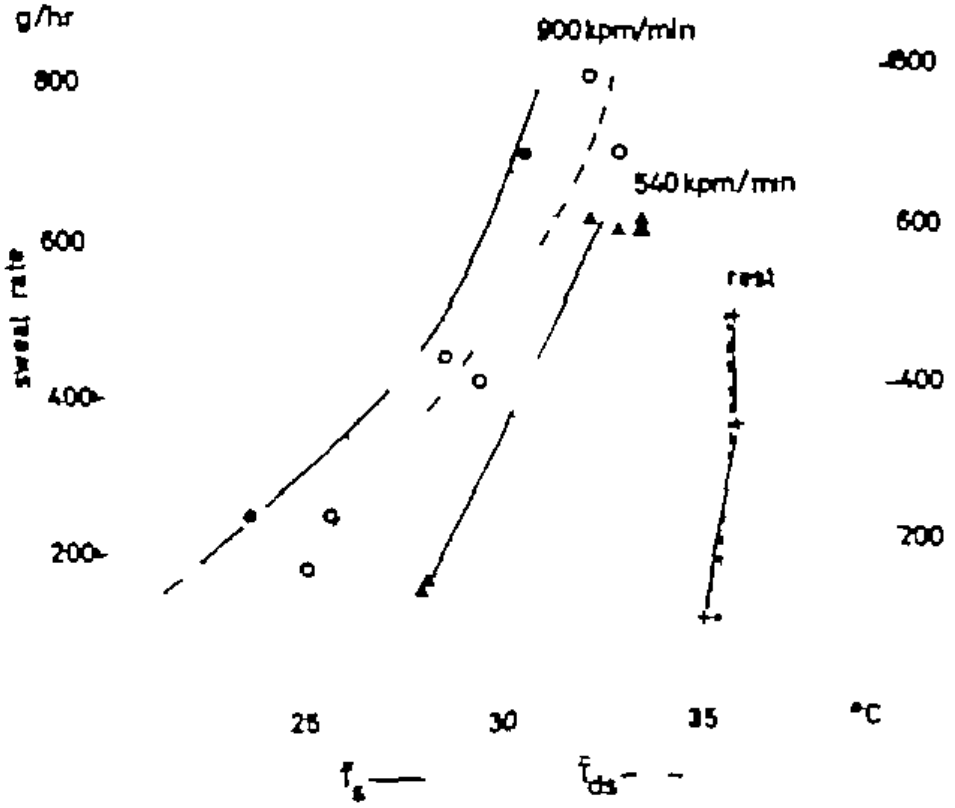

Fig. 6

Steady state sweat rate plotted against mean skin temperature ($\bar{T}$ ——, closed symbols) and average deep skin temperature (T_{ds} – – – – open symbols). Subj. KHN

3 metabolic levels { ○ 900 kpm/min ($\bar{T}$ = 10, 0, 30) ▲ △ 540 kpm/min ($\bar{T}$ = 20 and 35) + rest ($\bar{T}$ = 30, 35, 40°)

temperature ($\bar{T} - T_a$) in Fig. 11. The slope of this curve gives the combined heat transfer coefficient (h_c) for the two subjects. It amounts to 14.3 kcal/hr–m²– C for TD and 13.5 kcal/hr–m²– C for KHN.

When, as in Fig. 12, the heat loss by convection plus radiation (C + R) is plotted against $T_{(ds,\ a)}$ another nearly linear relationship results. The slope of these lines may be used to estimate the heat flow by conduction through the skin (see p. 33). A value of 12 kcal/hr–m²–mm– C for TD and 23 kcal/hr–m²–mm– C for KHN for heat conductivity can be estimated. (Average depth to measurements in skin TD: 3.6 mm, KHN: 2.4 mm).

With the assumption that all heat transported to the skin surface by the blood is given off by evaporation in the experimental conditions of this study and that the blood enters the skin at T_{ar} and leaves it at $T_{ar} - 2\ (T_{ar} - T_{ds})$ (see p. 35) the skin blood flow can be estimated. The skin circulation calculated in this way is plotted against skin surface temperatures in Fig. 13.

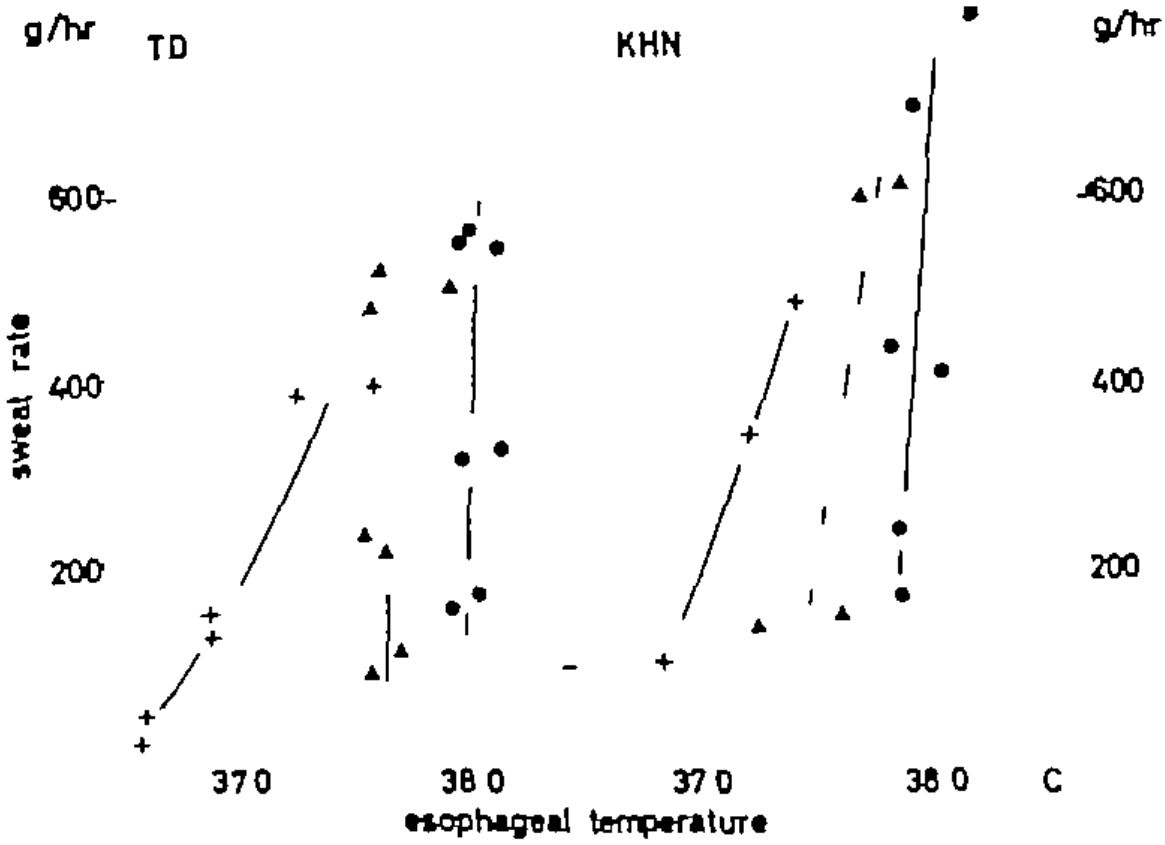

Fig 7

Steady state sweat rate in relation to deep esophageal temperature. 3 metabolic levels: 900 kpm/min 540 kpm/min ▲ and rest + Left: Subj. TD Right. Subj KHN

For comparison, the changes in skin blood flow expressed by the conductance of the peripheral tissues is shown in Fig. 14 These two expressions of skin blood flow are plotted against one another in Fig. 15 Finally in Fig. 16 the thermal resistance of the skin $R_s = \frac{T_{(d\quad)}}{H}$ viz. the temperature differential per unit heat flow through the skin, is plotted against surface skin temperature.

Discussion

The interesting theory of Kerslake (1955) is not supported by the present experimental data. Even when measurements were made in the level where temperatures were highest, i.e in the deepest layers of the subcutaneous tissues (chap II) the relationship between "deep skin temperature" and sweat rate was found to vary at the 3 metabolic levels (Fig. 5 and 6) In Kerslake's theory it was supposed that the thermal resistance, i.e. the temperature dif

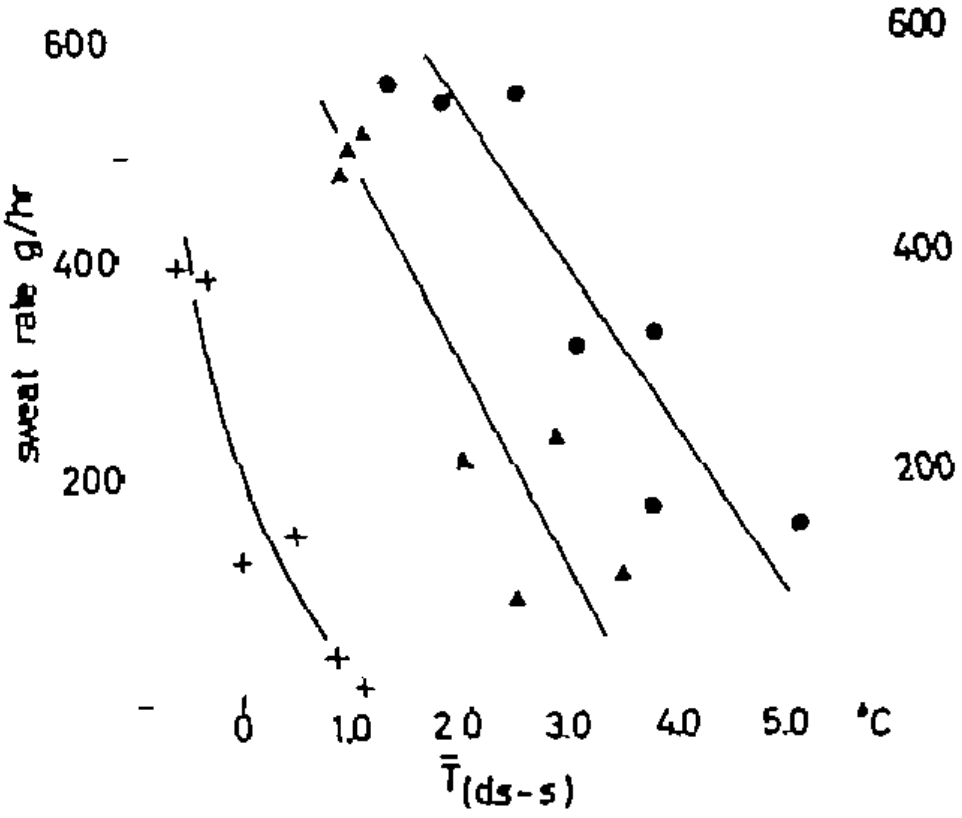

Fig 8.

Sweat rate versus $\bar{T}_{(ds-s)}$ at 3 metabolic levels: 900 kpm/min ● 540 kpm/min ▲ and rest + Subj. TD

ferential per unit heat flow between the hypothetical deep receptor and the surface, was constant. Thus, the temperature of the deep skin receptor would increase over the surface skin temperature as the product of the heat flow through the skin and thermal resistance. The present experiments (cf. Fig. 5) show that for the same rate of heat flow (same work rate) the total peripheral thermal resistance from the surface to a depth of half the skinfold thickness decreases with increasing surface temperature (Fig. 16). In Blockley's (1966) calculations of deep skin temperatures, a decrease in the peripheral thermal resistance with increases in surface skin temperature was presupposed. The thermal resistance calculated in the present experiments (Fig. 16) where T_{ds} is measured shows different values for the same $\bar{T}$ at the 3 metabolic levels. The maximum value of 0.012° C-hr/kcal, obtained by extrapolating the curves in Fig. 5 to surface skin temperatures equal to sweat rate zero (cf. Fig. 16) is identical for the 3 metabolic levels. The range is of the same order of magnitude as Kerslake's 0.013–0.017° C hr/kcal for different subjects and Blockley's 0.006–0.019° C-hr/kcal which increases with decreasing skin tem-

Mean skin temperature at various levels of environmental (operative) temperature, 3 metabolic levels: 900 kpm/min • 540 kpm/min ▲ rest + Subj. KHN

perature. However it is evident from the present experiments that no average deep temperature in tissues superficial to muscle and bone is equal in rest and work for the same rate of sweat secretion.

The mean temperature differential across the skin $T_{(d_s)}$ is different at the same sweat rate for the three metabolic levels (Fig. 8) At the first sight, this finding seems to rule out the assumption of *Bazett (1949 1951) that* temperature gradients in the skin supply information on heat production for the regulation of sweating. However the differential measured in the present study is believed to be the maximum difference existing between the surface and the cutis + subcutis. Although unlikely it is possible that the gradients in more superficial layers of the skin, e. g. in bloodless layers, are the same for equal sweat rates.

Neither of the differences $(T_{co} - T_s)$ $(T_{co} - T_{ds})$ nor $T_{(d_s)}$ shows the same relationship to sweat rate for the three metabolic levels. However the *possible interaction between core temperature (hypothalamic temperature)* and deep skin temperature or temperature gradients across the skin may be considered as stimulus for the regulation of sweat secretion and skin circulation. Multiple regression correlations for T_{co}, $\dot{T}$ and Sw *for* T_{co}, T_{ds} and Sw and for T_{co}, $T_{(d_s)}$ and Sw are presented in an appendix, p. 59

The mean skin surface temperature (T_s) was found to be a linear function of ambient temperature (Fig. 9 and 10) This correlation agrees with earlier findings (e. g. Winslow and Gagge 1941 Robinson 1949 B Nielsen and M. Nielsen 1965 a) In conditions in which the subject can attain thermal equilibrium with the environment, the skin temperature was found to be independent of the activity level and of the sweat rate (Fig. 9 and 10) The skin surface temperature is determined partly by the conductive heat flow and the thermal resistance between the thermoregulated core and the skin surface and partly by the relationship between the total heat flow from the core to *the skin surface and the amount of heat dissipated to the environment.*

The total heat flow from the *core* to the *skin surface* takes place as conduction and as convection due to blood flow

$$H_{cond} = k(T_{core} - T_s)$$
$$H_{conv} = \dot{Q} \times c \times (T_{art} - T_{venous})$$

where.

H_{cond} = conductive heat transfer in the peripheral tissues.
H_{conv} = convective heat transfer in the peripheral tissues.
k = conductive coefficient of the peripheral tissues.
$\dot{Q}$ = skin blood flow l/min.
c = specific heat of blood.

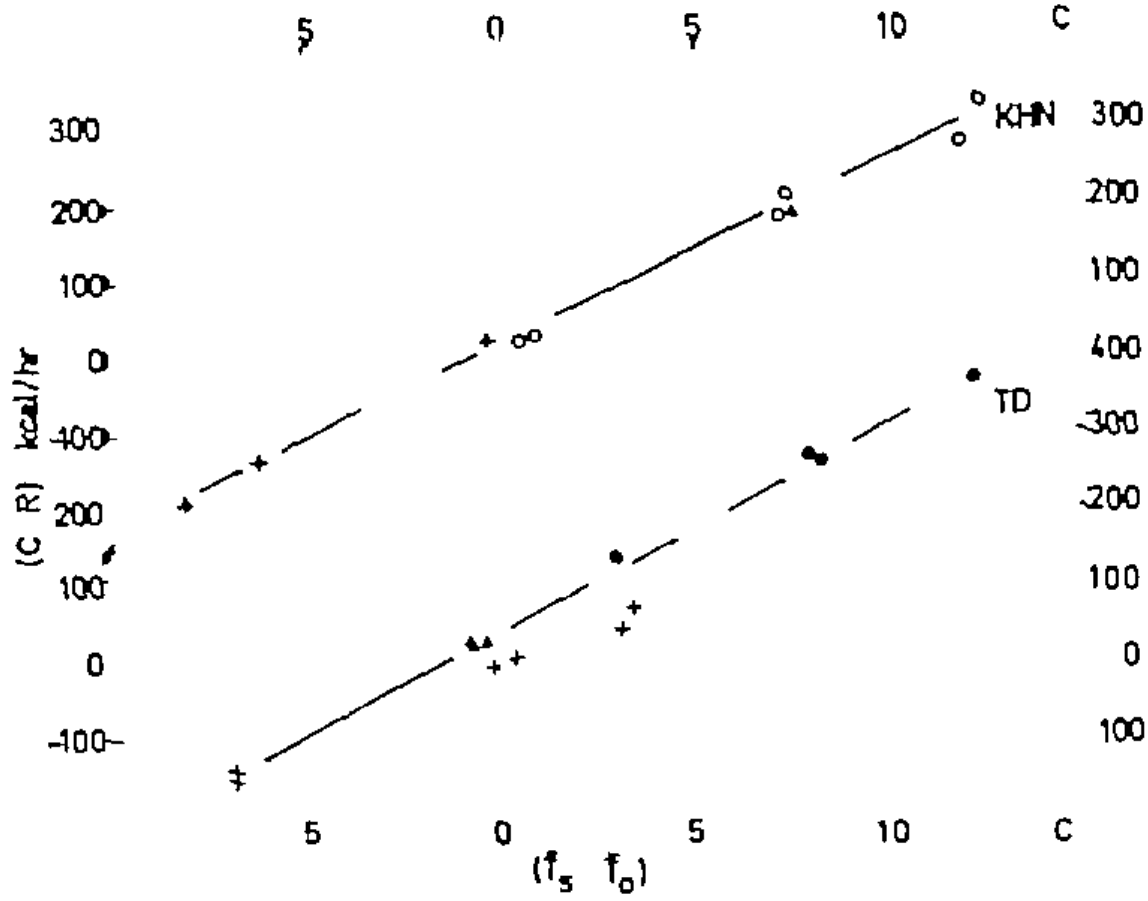

Fig 11

		TD	KHN
3 metabolic levels	900 kpm/min	•	○
	540 kpm/min	▲	△
	rest	+	◇

The heat loss from the *surface* takes place by convection radiation and evaporation. In thermal equilibrium heat production = heat loss, and hence

$$k(T_{core} - \bar{T}) + \dot{Q} \times c \times (T_{art} - T_{venous}) = h_o(\bar{T} - T_a) + E_{sw}.$$

As found in the present study when $\bar{T}$ is a function of $\bar{T}$ independent of sweat rate and total heat production it follows that for a constant environmental temperature $C + R = h_o(\bar{T} - T_a)$ remains constant and $k(T_{core} - \bar{T}_s)$ is practically constant. Therefore, the amount of heat brought to the surface by the skin blood flow must be exactly counterbalanced by the evaporative heat loss. Variations in heat production result in changes in the amount of heat delivered to the skin by the blood (convective transfer). By the criterion of the constant skin temperature, this same amount of heat must be dissipated by evaporation of sweat.

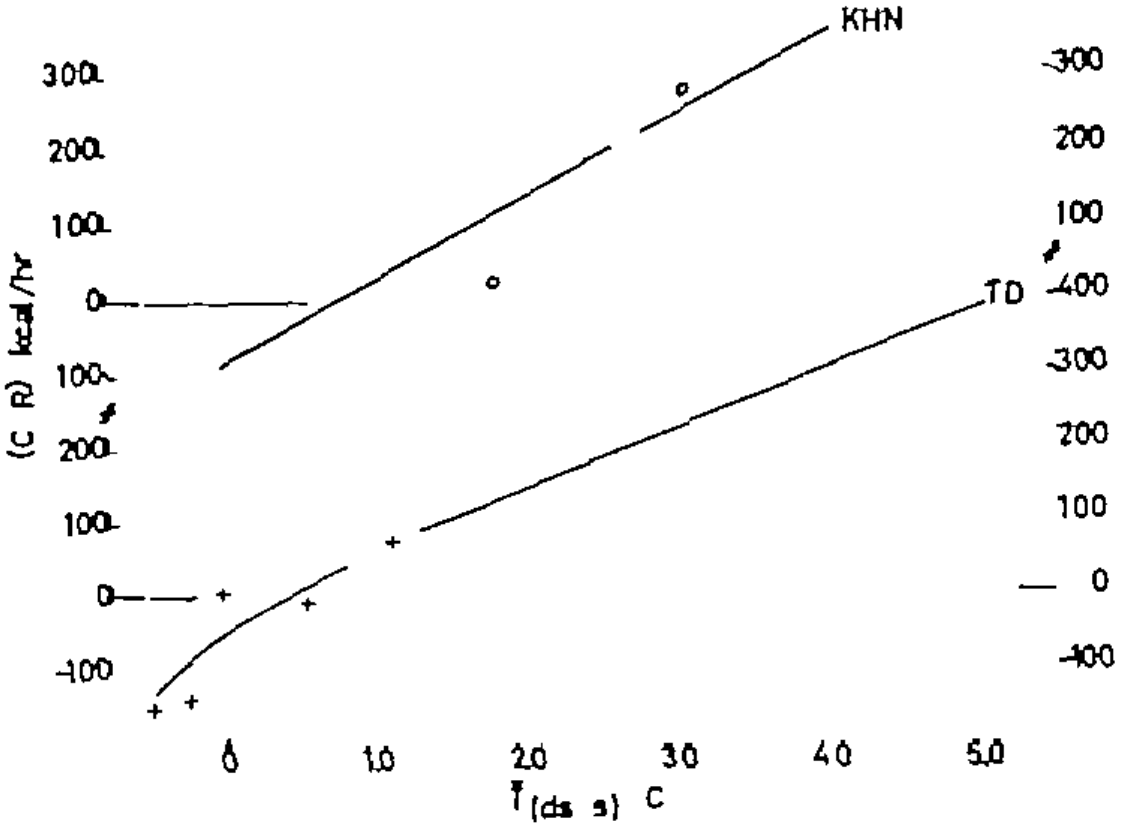

Fig 12.

(C + R) heat loss plotted against $T_{(dis\ s)}$ Two subj: Above: KHN below TD

		TD	KHN
3 metabolic levels	900 kpm/min	•	o
	540 kpm/min	▲	△
	rest	+	◇

How this coordination of convective heat transfer by the skin blood flow and sweat secretion is brought about is unknown. Bradykinin mechanisms may be involved in the fine adjustment of blood flow to the sweat gland activity (Fox et al 1958)

When the sweat rate is zero at the lower limit for thermal equilibrium, the skin blood flow is also very nearly zero (cf. Fig. 13 and 14) The total heat transfer to the skin then takes place as conduction across the skin ($H_{cond} = k_t(T_{sk} - T_s)$) and the heat is dissipated from the skin to the environment by convection plus radiation ($H_{conv} = h_c(T - T_s) = (C + R)$)* Since the skin surface temperature remains constant and independent of increases in heat production and sweat rate, it follows that increases in heat production

*Should be (C + R) + insensible perspiration, but the relative small value of the latter 10–20 kcal/hr may permit its omission in the following considerations.

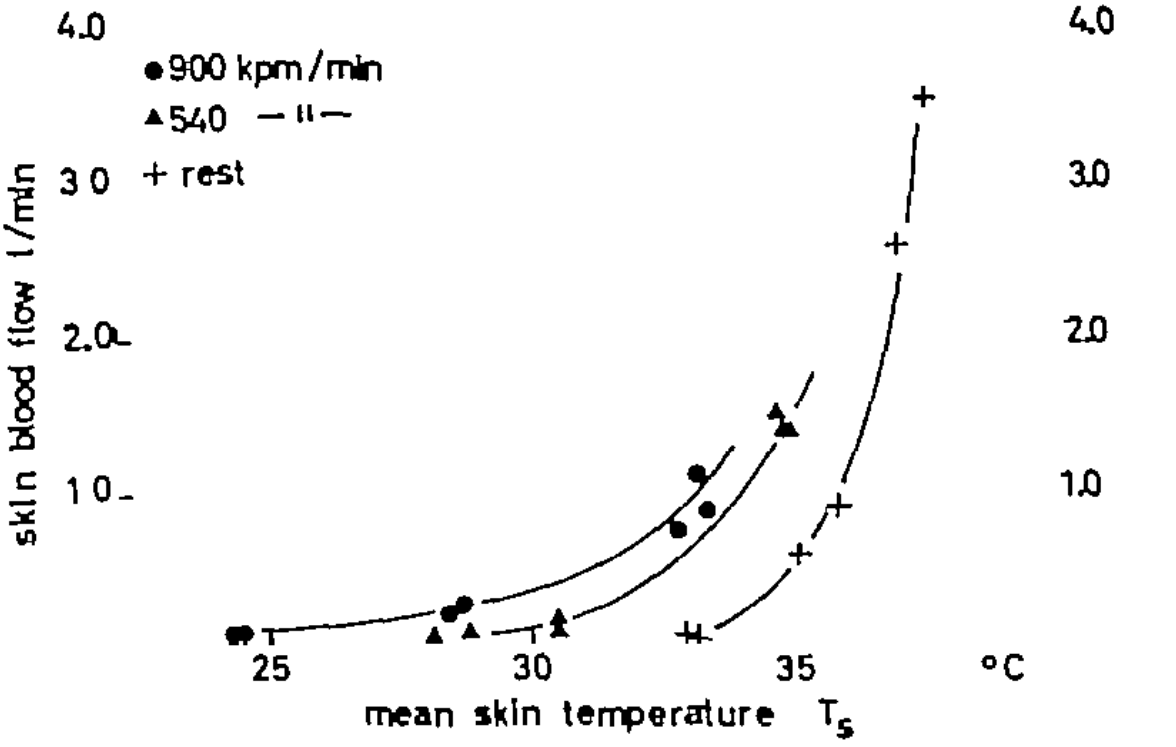

Fig 13

above the lower limit of equilibrium must cause an increase in convective heat transfer (skin blood flow) equal to the increase in evaporative heat loss, while the conductive heat transfer still equals the (C + R) heat loss.

If this explanation is sound, then a plot of (C + R) versus $T_{(sk\ s)}$ (Fig. 12) can be used to calculate the conductive heat transfer in the skin. The slope of the $(C + R)/T_{(sk\ s)}$ line is then the conductive heat transfer coefficient for the peripheral tissues. The values for 2 subjects are 41 kcal/hr–m²–° C (subj TD) and 52 kcal/hr–m²–° C (subj KHN)

The above mentioned conclusion that the amount of heat given off by evaporation is equal to the heat transferred to the skin by the blood flow also permits calculation of skin blood flow in such experiments in a new way cf. Fig. 13 It is assumed that the arterial blood entering the skin from the core has the same temperature as the aortic blood, which is considered to be equal to deep esophageal temperature (Cooper and Kenyon 1957) The venous blood leaving the skin has given off heat at the epithelial borderline so that its temperature at this stage is probably very close to T_s. Returning through the skin and subcutis the venous blood is rewarmed, receiving heat from the tissues and perhaps by countercurrent exchange with the arteries.

The temperature of the "shell" tissue must lie between the temperature of the arterial and venous blood, which runs into and out of the shell When measured in the layer nearest to the thermoregulated core (i.e. in a region very little influenced by heat conductance) the tissue temperature should be equal to the average between the arterial and the local venous blood temperature. It is further assumed that in heat equilibrium the deep skin temperature (T_{d_s}) as measured in the present experiments represents this tissue temperature, i.e. $T_{d_s} = \frac{T_{es} + T_{venous}}{2}$ Thus T_{venous} (the temperature of the blood which enters the core) becomes $2\ T_{d_s} - T_{es}$. The skin blood flow may then be calculated as

$$\dot{Q} = \frac{E_{sw}}{2(T_{es} - T_{d_s}) \times 1\,0 \times 60}$$ where:

$\dot{Q}$ = skin blood flow in l/min
E_{sw} = sweat heat loss kcal/hr*
T_{es} = esophageal temperature
T_d = mean deep skin temperature
1 0 = specific heat of blood in kcal/l–° C.

Results from subj TD are presented in Fig. 13

The very high calculated skin blood flow of 3.5 l/min during rest at 45° (T = 37°) is of the same order of magnitude as the "approximately 2 l/min–m²" reported by Robinson (1963) Horvath et al. (1964) and Koroxenidis et al. (1961)

Both during rest and in the two working conditions the heart rate increases with rising environmental temperature. This change from lowest to highest environmental temperature was 30 beats/min at rest while 15 beats/min in the work experiments. Assuming a constant stroke volume of 120 ml in exercise, this HR response would produce an increase in cardiac output ($\dot{Q}$) of (120 ml × 15) = 1 8 l/min during work, and, with a resting stroke volume of 80–100 ml, an increase in $\dot{Q}$ of (80–100 ml) × 30 = 2.4–3.0 l/min in the rest experiments. Experiments of Rowell et al. (1966 1967) however show that the increased skin circulation due to thermal stress superimposed on exercise is attained by a reduction in splanchnic and renal blood flow with a constant or even reduced $\dot{Q}$ due to a diminished stroke volume, in spite of the increased heart rate.

* In conditions where heat is *received* from the environment ($T > T_s$) the received external heat is subtracted from E_{sw}, since this heat is not transported to the skin surface by the blood.

A comparison of the calculated blood flow with the conductance of the peripheral tissues, Fig. 15 for the same experiments shows that the two calculated indexes of skin blood flow are remarkably similar The same is found for subj KHN The deviation from the "45° line of identity" at the higher values of skin blood flow may be the result, if the blood at very high flow rates is not cooled to skin temperature as presumed in the calculation of conductance.

The intercept on the conductance axis for skin blood flow zero is 15 kcal/hr–m² in the work experiments and 10 kcal/hr–m² for the rest experiments in Fig. 15

These minimum values of conductance are in good agreement with those reported in the literature (cf. Robinson 1963) The finding that the minimum value during work is greater than in rest also corresponds with earlier studies (e. g. Pugh and Edholm 1955) where the determinations were made in water In these studies the rectal temperature decreased much faster during work

than at rest in cold and cool water (cf also Keatinge 1961 and Craig and Dvorak 1968) This difference in rate of cooling is ascribed to cold vasodilation for the very cold conditions but no explanation seems to be given for the moderately cold 15–25° conditions. It may be suggested that the elevated values of minimum conductance during work are due to the higher ratio of "core" to "shell" This increased ratio favouring heat loss—must be the outcome of the increased heat production and blood flow in the working muscles.

In air, the temperature of the muscles during rest has been shown to fall to low values especially in cold environments (Buchtahl, Höake and Lindhard 1944 Saltin et al. 1968) Therefore, this same explanation may also be valid for the higher minimum conductance during work in the less uniform and less easily defined air environment.

Chapter IV

DEEP SKIN TEMPERATURE, MUSCLE TEMPERATURE AND THE REGULATION OF SWEATING DURING POSITIVE AND NEGATIVE WORK

When external work is performed the amount of heat liberated in the body is less than the total energy output. This is the case when a person performs positive work, e. g. walks or bicycles uphill. When walking or bicycling downhill, i. e. doing negative work, potential energy is converted to heat in the muscles, and the total heat liberation becomes greater than the metabolic energy liberation. In a recent study of thermoregulation during uphill and downhill walking (B Nielsen 1966) it was demonstrated that the core temperature increases to levels proportional to the metabolic energy liberation and not proportional to the heat production. The sweat secretion, however increased in proportion to the amount of heat liberated in the body in spite of differences in the level of core temperature.

Thermoreceptors placed at an appropriate depth below the surface could be stimulated in proportion to the heat flow through the skin and hence to the total heat production in the body (cf. p 11 and 22) A study of the deep skin temperature and the gradient across the skin during positive and negative work,—i. e. in conditions where, the ratio of total heat production to metabolic energy liberation (and body temperature) is varied,—might help to explain the correlation found between sweating and heat production.

Procedure

The subject, dressed in shorts and shoes, was fitted with the thermocouples and started to work at the fixed speed and inclination. During the walk/run experiments 2 big fans directed towards the subject's chest and back produced an air movement of 0 75 m/sec (chest) and 1–1.5 m/sec (shoulder) No fans were used in the bicycle experiments. Every 5 min the rectal temperature was measured and the heart rate (HR) was counted. After a preliminary warming up period of 25 min he stepped off the treadmill and sat down on the Krogh balance for the first weighing. This pause lasted $1^1/_2$–2 min. The subject returned to the treadmill and continued the work (walking

or bicycling) for the 45 min experimental period. During this period T_{re} and HR were measured every 5 min, while the deep skin and esophageal temperature were recorded continuously $\dot{V}$ was measured at the 30th, 37th and 42nd min and the wall temperature at the 30th and 42nd min

Expired air was collected in the Douglas bag at about the 40th min of work.

After the 45 min experimental period the subject stepped off again and sat down for the weighing as quickly as possible after stopping.

In experiments where the muscle temperature was measured, the thermocouple was inserted in the muscle as soon as the subject sat on the seat of the balance. After this the thermoneedle was withdrawn and the subject weighed. The weighing thus was delayed less than 2 min.

Three male subjects were used KHN (who also took part in the experiments reported in chapter II and III) and BJ bicycled uphill and downhill, while BI walked and ran on the treadmill. Their data are presented in the table below

Subj	Age yrs	Weight kg	Height cm	A_D m	Est. max. $\dot{V}O_2$ l/min	Number of exp.
KHN	21	65	181	1.83	4.20	16

Cf. p. 25

Results

In Fig. 17 the time relationships of the measurements are shown for subj BI It appears that in the experimental period a temperature equilibrium is practically achieved Values obtained from the last 15 min of this period are those presented in the following graphs.

The oxygen uptake in relation to work intensity in uphill (positive) and downhill (negative) bicycling is presented in Fig 18 As shown earlier e. g. by Abbott, Bigland and Ritchie (1952) and Asmussen (1952) the oxygen consumption is only slightly increased with greater loads during negative work. The same relationships for walking are shown for another subject in Fig. 19

The heart rate was 15–25 beats/min higher in negative work than in positive work at the same oxygen uptake. The pulmonary ventilation was only slightly higher in negative work than in positive work at the same $\dot{V}_{O_2}$

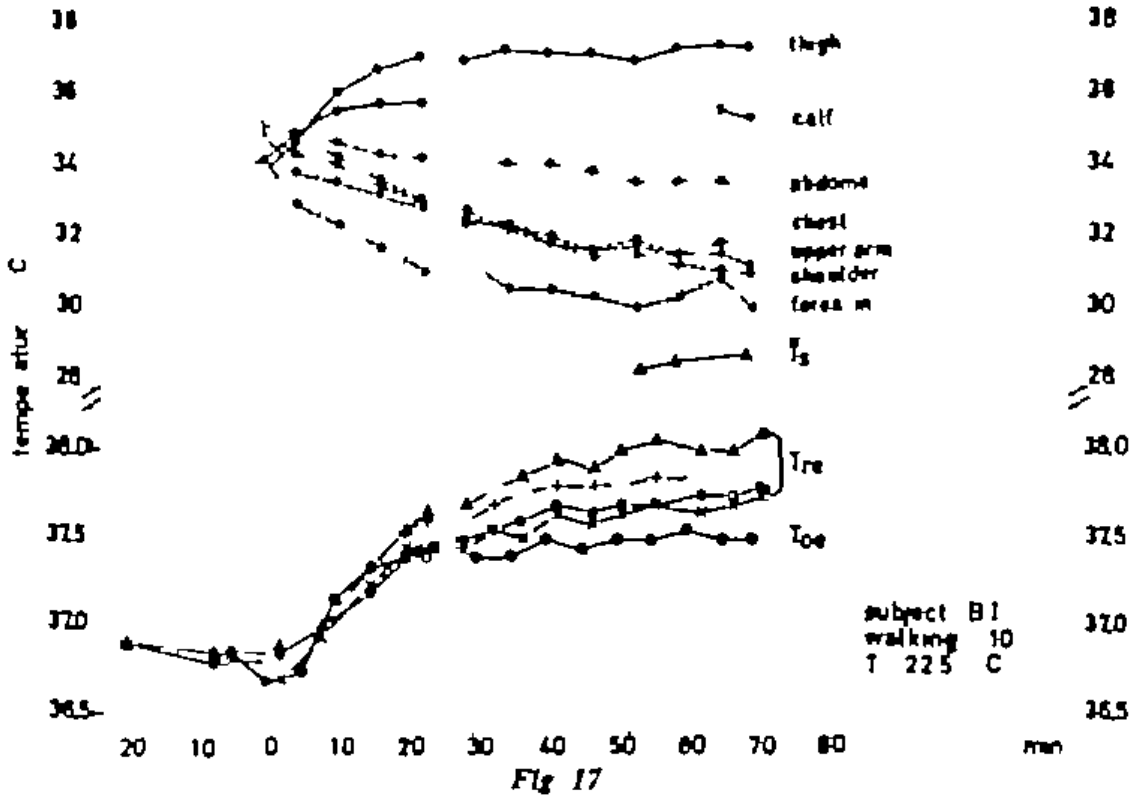

Fig 17

The time relations of the 7 single intracutaneous temperatures, $\bar{T}$ (▲), T_{re} at 4 depths (+ 27 cm, ○ 22 cm, × 17 am and △ 12 cm) and T_{oe} ( ) during the 25 min warming-up period and the 45 min experimental period. Pause for weighing between the 25th and 26.5th min. Subj. BI, downhill −10° speed 6.48 km/hr HR 116 $\dot{V}_{O_2}$ = 1.31 l/min, total weight loss 600 g/hr T_{re} at 73 min: 38.85 C.

In all 3 subjects the skin temperatures decreased with increasing metabolic rate. The relationships between T_s, T_{d-s}, T_{re} and metabolic energy liberation (M) and total heat production (H) are illustrated by the results from subject BJ in Fig. 20 and BI in Fig 21 The 3rd subject shows similar results.

The relationships between internal body temperature and M and H are shown in Fig. 22. This data reconfirms that the plateau level of esophageal temperature is a function of the metabolic energy liberation and not of the total heat production

In Fig. 23 (subject KHN) the temperature differential across the skin is plotted against M and H respectively In all subjects the relationship to H is nearly the same for uphill and downhill work

The slope $\frac{T_{(d-s)}}{H}$ has the dimensions of a thermal resistance, C–hr/kcal degrees temperature differential per unit heat flow The slope is 0 0045° C–hr/kcal for KHN in positive and 0 0068° C–hr/kcal in negative work For

BJ it is 0 0086° C–hr/kcal for positive work and 0 0060° C–hr/kcal in negative work, and for BI 0 0095° C–hr/kcal for positive and 0 0050° C–hr/kcal in negative work. Their average ½ skinfold thicknesses, i. e. the skin layer across which this gradient is accumulated are: KHN 2.4 mm, BI. 4.4 mm, and BJ 5 9 mm. The correlations of $T_{d\ \ }$) with M are different for uphill and downhill work as seen in Fig. 23 The sweat rate (Fig. 24) also shows nearly the same relationship to H in both positive and negative work, while its relationship to M is different in the 2 cases. There are much higher sweat rates in negative work at the same metabolic energy liberation

In Fig. 25 sweat rate is plotted against esophageal temperature (T_{es}), average skin surface temperature (T_s) average deep skin temperature (T_{ds}) average temperature differential $T_{(ds\ s)}$ across the skin, and muscle temperature (T_m) At the same rate of sweat production, only core temperature (esophageal) and muscle temperature are different in positive and negative

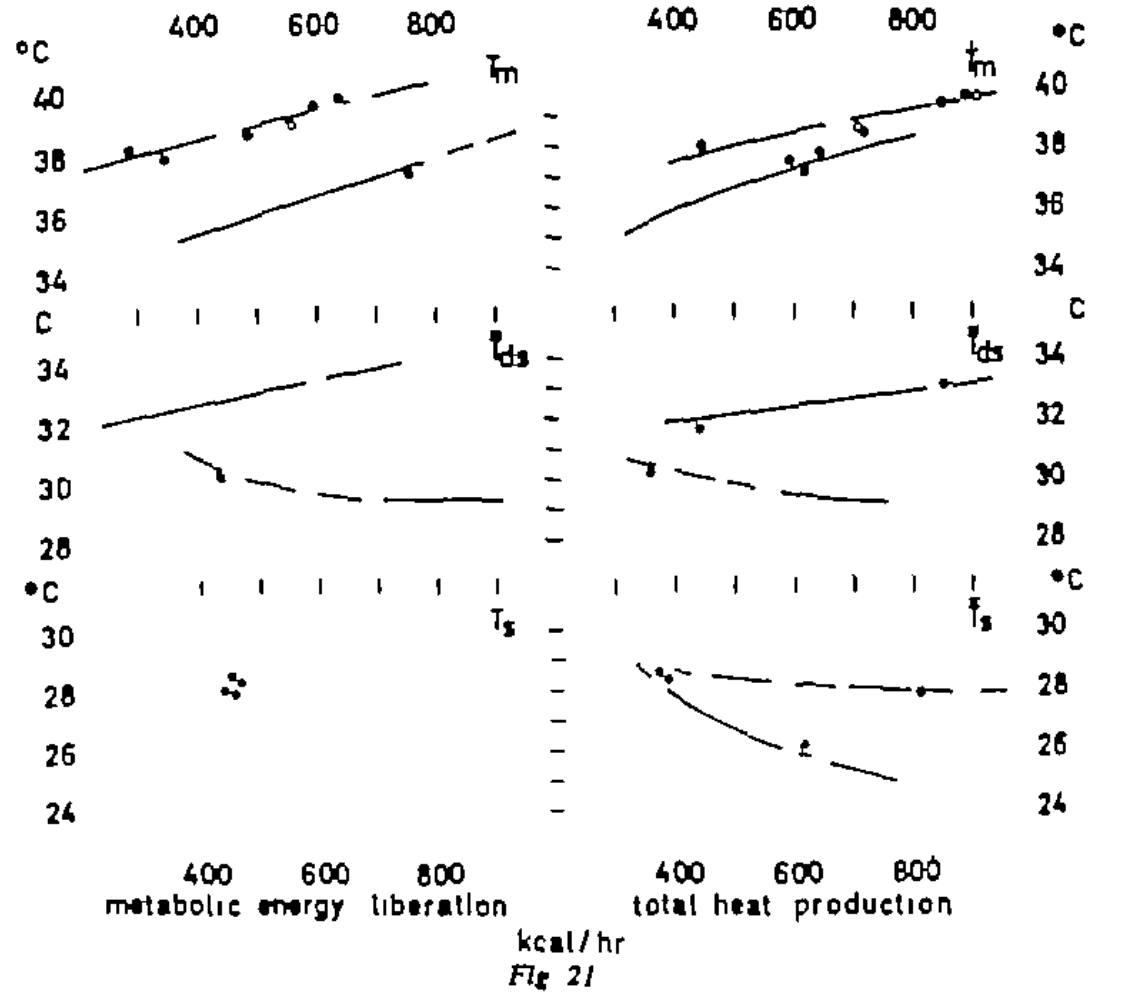

Fig 21

work Esophageal temperature is lower and muscle temperature higher in negative work (compared to positive work) In subject BI (Fig. 26) T and T_d as well are different for the same sweat rate in positive and negative work In all 3 subjects there is a positive correlation between sweat rate and the temperature differential across the skin with the values for positive and negative work scattering around the same line

Discussion

The procedure adopted in the present study was the same as that used in a recent study (B Nielsen 1966) of temperature and sweat regulation dur ing positive and negative work The main results from the earlier study were:

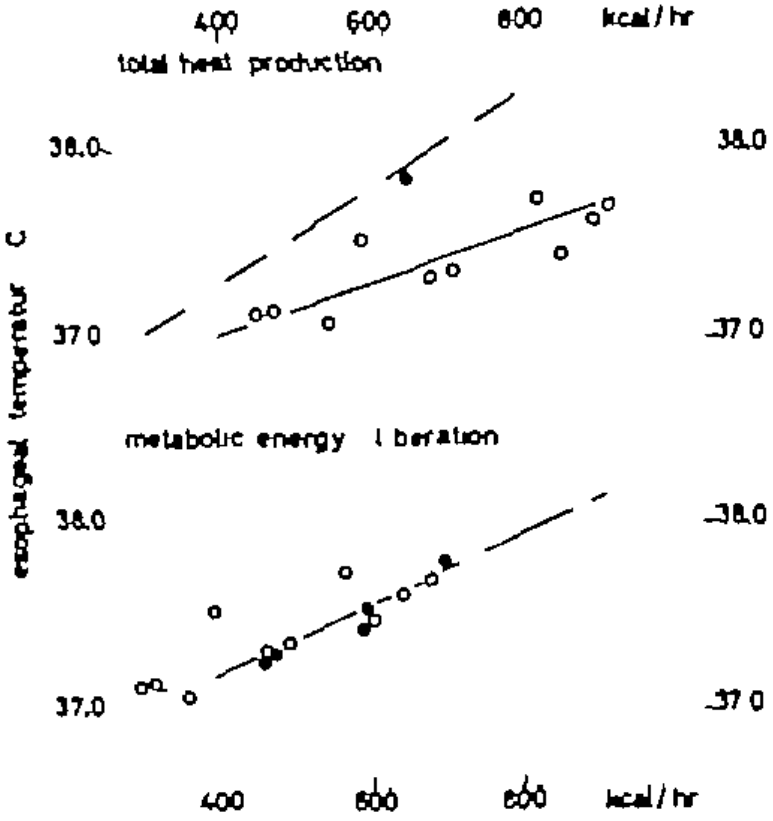

Fig 22

The correlation of esophageal temperature (T_{oe}) with total heat production (above) and with metabolic energy liberation (below). Subj. BI Walking. Positive work • negative work ○ T 22.3

1) that the level of internal body temperature is determined by the metabolic rate and 2) that the rate of sweat secretion varied in proportion to the total amount of heat liberated in the body in spite of differences in the level of internal body temperature. These findings were confirmed and will not be discussed at any length The experiments led to the question of how information on total heat production can be obtained by the temperature regulation centres. In the present study it was intended to measure temperatures in the deeper skin layers and in the muscles which might act as stimuli for thermal receptors at these sites. It must, however be remembered that the existence of such thermal receptors has not been histologically proven. (See chap. II)

One complicating factor in the present experiments is that, although the room temperature was the same in all experiments, the skin surface temper

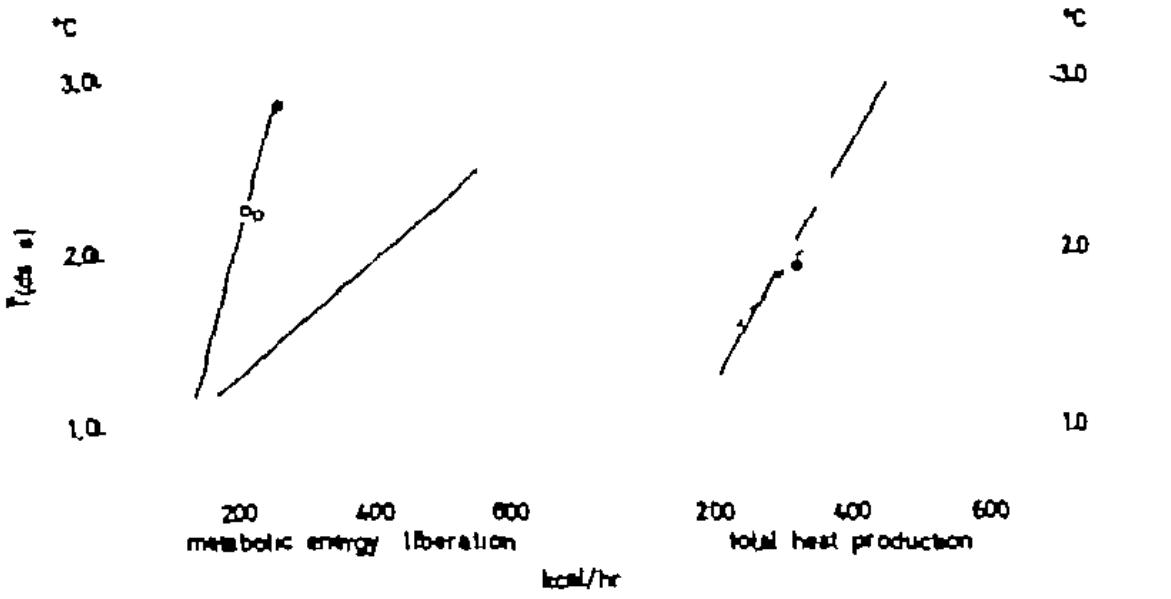

Fig 23

$T_{(d,\ a)}$ plotted against *metabolic energy liberation (left) and total heat production* (right). Subj. KHN Bicycling. Positive work • negative work ○ T 22.4

ature was not constant, but declined with increasing energy metabolism (Fig. 20 and 21) This must mean that, as the metabolic rate rises sweat production increases *more* than the heat transfer to the skin by the blood flow (cf. chap. III) Perhaps the *increasing demand for blood to the working muscles* with higher work intensities is met by a gradual reduction of the proportion of blood available for thermoregulatory purposes. Such a relationship of T to work load was not found in the experiments reported in chapter III and by B Nielsen and M Nielsen (1965 a) This discrepancy may exist because these earlier work experiments were performed in a sitting position working with the legs horizontal as opposed to the nearly vertical position when walking or bicycling on an ordinary bicycle as in the present series of experiments. In the sitting (legs horizontal) position the heart rate was found to be lower for the same work load, presumably due to less pooling of blood in the legs with a consequently better diastolic filling of the heart (M Nielsen and Fridrichsen 1939) Cardiac output ($\dot{Q}$) is less for the same oxygen uptake if blood is pooled in the legs (e.g. Asmussen and Christensen 1939 Bevegård, Holmgren and Jonsson 1960 Bevegård et al. 1966 Bevegård and Shephard 1967) This reduction in $\dot{Q}$ may cause a redistribution of the peripheral circulation favouring muscle blood flow with a concomittant reduction in skin-blood flow As seen in Fig. 20 and 21 the skin surface temperature (T_s) in these subjects decreases about 2° when the metabolic energy liberation is almost tripled. A similar although smaller decrease of $T_{d,}$ is also observed.

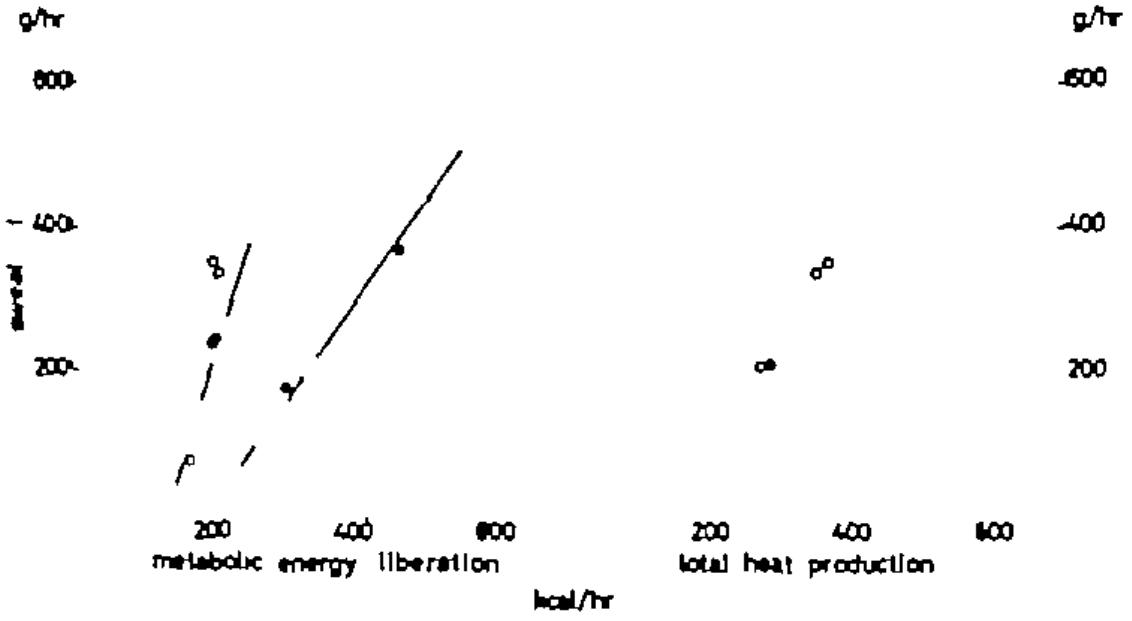

Fig 24

Sweat rate plotted against metabolic energy liberation (left) and total heat production (right). Subj. BJ Bicycling. Positive work • negative work ○ T 22.4

Values of T for positive and negative work, however fall on the same line. The small differences (1–2½°) in skin surface temperature between the positive and negative work experiments when compared at the same rate of *total heat production* (Fig. 20 and 21) are probably the reason for the slightly lower sweat rate at comparable heat productions in the downhill experiments (Fig. 24) The increments in (C + R) heat loss as calculated from $h_c \times (T - T_a)$ are apparently exactly compensated by a decrease in sweating

At the same rate of total heat production the deep skin temperature (T_{ds}) also is *higher* in the negative work experiments. Therefore, the correlation of sweat rate with total heat production Fig. 24 can hardly be explained as a result of stimulation of deep skin temperature receptors alone (Kerslake 1955 cf. p. 11 and 22)

The deep-to-surface temperature differential, $T_{(ds\ -\ s)}$, seems to be closely correlated with total heat production (Fig. 23) and is nearly the same in positive and negative work. As Fig. 25 and 26 show the sweat rate is positively correlated with $T_{(ds\ -\ s)}$ the values for positive and negative work scattering around the same line. In other words, $T_{(ds\ -\ s)}$ might be assumed to be an index of the stimulus to the sweating mechanisms. However this assumption conflicts with the results from chapter III which showed that an *increase* in $T_{(ds\ -\ s)}$ i. e. when the surface skin temperature decreased during exposures to colder environments, is accompanied by a *decrease in sweat rate*

The muscle temperature, which has been considered a factor in the sweat

regulation by several authors (Robinson et al. 1965 Stolwijk and Hardy 1966 a, Saltin and Hermansen 1966 Saltin, Gagge and Stolwijk (1968)) was different for uphill and downhill work, compared at both the same rate of metabolic energy liberation and at the same total heat production (Fig. 20 and 21) The data confirms the findings of Saltin et al. (1968) that the local muscle temperature is the net result of the regional heat balance i. e. roughly the balance between the amount of heat liberated in the muscle and the heat transported by the blood flow However in the present experiments the rectal temperature (or T_{es}) and the muscle temperature do not differ by a constant value as in Saltin et al. s experiments. In negative work the muscle temperature was much higher than in positive work at identical core temperatures (i. e. metabolic rates, Fig. 22) cf. Fig. 20 and 21 It must therefore be concluded that muscle temperature cannot be the stimulus that correlates sweat rate with total heat production, since it differs for the same rate of total heat production in positive and negative work (Fig. 20 and 21) In the appendix p 59 a statistical treatment of the data is presented.

Chapter V

GENERAL DISCUSSION

The thermoregulatory system of the human body allows it to maintain thermal equilibrium within wide limits of external and internal heat loads. In thermal equilibrium of rest or exercise, the heat gains and heat losses are balanced by adjustments in skin circulation and sweat secretion. These adjustments are supposed to be monitored by central and peripheral drives. But it is not yet known where and how the information necessary for the regulated interplay of these drives are gathered.

Most investigators discuss the possibility of some interaction between two factors, core temperature and skin surface temperature, for the regulation of sweating and skin blood flow (e. g Robinson 1949 Belding and Hertig 1962, Cooper et al. 1964 Beamont and Bullard 1965 B Nielsen and M Nielsen 1965 a and b Wyndham 1965 Hardy and Stolwijk 1966 Stolwijk and Hardy 1966 b Wurster McCook and Randall 1966, Stolwijk, Saltin and Gagge 1968) The results of the experiments with positive and negative work (B Nielsen 1966 and chapter IV) however cannot be explained unless an additional factor correlated with the rate of heat production is also included. In the following paragraphs the regulation of the core temperature, the skin temperature, and the regulation of heat dissipation will be discussed separately

The core temperature. M. Nielsen demonstrated in 1938 that the increase in core temperature during work within wide limits is independent of the external conditions for heat loss and concluded that the increase is not due to a failure of the heat dissipating mechanisms but that it is a controlled rise determined by the metabolic rate. This finding has since been confirmed by Robinson (1949) Eichna et al. (1950) Wyndham et al. (1952) Lind (1963 a, b)

However the value of the rectal temperature as index of the regulated body temperature has been disputed (cf reviews by Grant 1951 and Hardy 1961) Mead and Bonmarito (1949) for instance, found that the rectal temperature measured simultaneously at different depths under various conditions of warming or cooling of the body showed considerable differences. In 1962 therefore, B Nielsen and M Nielsen studied the rectal temperature measured

in four depths and compared it with the temperature measured in the esophagus. It was found that during work only small and unsystematic differences existed at different depths in the rectum The temperature gradient along the esophagus was considerable, but measured just above the diaphragm it was uninfluenced by changes in external conditions. During legwork the deep esophageal temperature, T_{es}, was 0.2–0 4° lower than T_{re}, while during arm-work they were equal. It was therefore concluded that T_{re} is elevated due to heating of a large part of the pelvic cavity by venous blood returning from the working muscles. Benzinger (1959 1960) claimed that tympanic temperature, T_{ty} was the best index of core temperature, since it was thought to mirror the hypothalmic temperature. B Nielsen and M. Nielsen (1965 a) found T_{ty} to be 0 4–0 6° C lower than T_{re} and also lower than T_{es}. But all three core temperatures reached plateau values during work independent of the environmental conditions inside a wide range.

In other words during work the temperature of the whole body core increases to new levels, the height of which is a function of the work load. The studies of B Nielsen (1966) and chapter IV further show that the increase in core temperature is independent of the heat liberation connected with the working condition and is only correlated with the metabolic rate. This is a direct confirmation of the therory of M Nielsen (1938) that the increase in temperature during work is a regulated rise.

I. Astrand (1960) and Saltin and Hermansen (1966) demonstrated that the increase in body temperature is proportional, not to the absolute values of metabolic rate, but to the relative work load, i e. to the percentage of the individual's maximum aerobic capacity This finding also agrees with the results of Clasing and Laumann (1968) who in 20 trained and 20 untrained subjects working with the same heart rate of 130 beats per min obtained exactly the same rectal temperature, in spite of widely different work loads and metabolic rates.

How this regulation of the core temperature to higher plateau values during work is brought about is still unknown The mechanical events in the muscles do not seem to influence the level of body temperature attained during work, since variations in the speed of running or in the forces produced by the muscles, for instance in positive and negative work had no effect on the relationship of core temperature level to metabolic rate.

Irradiation of impulses from the motor cortex to the temperature regulating centre in the brain has been proposed as a possible "work factor" responsible for some of the functional changes occurring during work, e. g. to the respiratory centre (Krogh and Lindhard 1913 Asmussen et al 1943 1965) and to the sweat regulation centre (Robinson 1949 Beaumont

and Bullard 1963) However Kitzing and Bleichert (1965) using partial blocking of the neuromuscular system with curare during exercise, found no change in deep esophageal temperature with this procedure, which is presumed to increase the cortical activity together with the subjective feeling of strain Also, when work performed with a small muscle group the arms, was compared to leg work, the esophageal temperature level was found to be the same function of the metabolic energy liberation in spite of the very different neuromuscular conditions that must exist in the two kinds of exercise (B Nielsen 1968)

Since direct cortical or mechanoreceptor impulses do not seem to be important work factors regulating the deep temperature in exercise, it may be thought that chemical factors are involved in the controlled increase in body temperature during work It is generally accepted that the increase in temperature which occurs during a fever is produced by the action of chemical compounds, "pyrogens" These substances have recently been shown to act on quite well defined areas in the anterior hypothalamus (Cooper et al. 1967) the same areas as those involved in thermoregulation. Cabanac, Stolwijk and Hardy (1968) showed that pyrogens inhibit the activity in "warm" neurons and increase that in "cold" neurons in the rabbit's brain stem. In 1964 Feldberg and Myers suggested that thermoregulation is mediated through the release of certain amines, serotonin and noradrenaline in the hypothalamus. These amines, which are found in high concentrations in the hypothalamic area, are perhaps released continuously and the body temperature may thus be determined by the balance between these substances. They further proposed that the actions of pyrogens and antipyretics may be explained as an interference with this system Since this "chemical" theory was forwarded, a large number of studies of the action of these amines in different species have been published (Cooper et al 1965 Bligh 1966 a, Feldberg, Hellon and Myers 1966 Andersen Jobin and Olsson 1966 Cunningham, Stolwijk, Murakami and Hardy 1967 Findlay and Robertshaw 1967 Banerjee et al 1968) showing rather divergent results, interspecific differences, and reverse effects of larger and smaller doses of the same substances (cf the reviews of Cooper 1966 and Bligh 1966 b) Myers and Sharpe s (1968) recent experiments with rhesus monkeys, on the other hand, seem to show unambiguously that the natural occuring changes in the concentration of these substances can evoke thermoregulatory reactions Cooling a donor monkey and transfusing perfusate from the anterior hypothalamus to a corresponding site of a recipient monkey produced fever in the latter Conversely heating the donor produced a temperature fall in the recipient.

It still remains a question whether these experiments only show that the

transmittor substances from terminals of the neurons involved in thermoregulation are effective when placed in the appropriate area, or whether they give evidence for the "chemical" temperature regulation theory i. e. that the concentration of these substances in the hypothalamus actually determines the body temperature. If Feldberg and Myers (1964) are correct it is possible that the temperature elevation during work also can be effected through the interference of some chemical agent, liberated in proportion to the aerobic processes in the muscles. Interacting with serotonin and noradrenalin or interfering with their release in the hypothalamic area, this agent would have an action similar to that ascribed to the pyrogens in fever This hypothetical agent is not simply a pyrogen because acetylsalisylates have no effect on the "work fever" (Downey and Darling 1962) The combined effects of work and fever on body temperature seem to be additive (Fox and Macpherson 1954 Macpherson 1959 Grimby 1962)

How the plateau values of core temperature are related to the individual s maximum aerobic capacity (I Astrand 1960 Saltin et al. 1966) also remains unclear It may be that these phenomena are related to circulatory functions. For instance the total blood volume, maximum stroke volume, and maximum cardiac output shows a high positive correlation to the individual's maximum aerobic capacity (P -O Astrand 1952 Astrand et al 1964 Holmgren and Astrand 1966) and all of these change with training. A greater core-to-surface temperature differential, as that found when the same work is performed by an untrained subject, will increase the conductive heat transfer to the environment and consequently decrease the demand for skin blood flow thus leaving more blood for the working muscles. When on the other hand, submaximal work is performed in a hot environment, the increased demand for skin blood flow causes a reduction in muscle blood flow so that the work becomes more anaerobic (Williams et al. 1962, Klausen et al. 1967) These problems need further investigation including a systematic study of core and skin temperatures, cardiac output, heart rate, and peripheral blood flow and their relation to physical performance capacity

There has been speculations upon the reasons for the regulated elevation of core temperature Since the demonstration (M Nielsen 1938) that the rise is not due to a failure of the heat dissipating mechanisms, it has been suggested, that the increment in body temperature might serve to increase the body's capacity for work. Asmussen and Bøje (1945) demonstrated that the ability to perform a short maximal work was improved considerably when the core temperature was elevated, either by "warming up" exercise or by passive heating.

The increase in temperature may also serve other purposes, Hammel

(1968) for instance, assumed that the increase was necessary for activating the thermal regulator because the inputs from the peripheral receptors alone would be insufficient. The same view was held by Bradbury Fox, Goldsmith and Hampton (1964)

The discussed regulated plateau values of core temperature during work are independent of the environmental conditions as long as thermal equilibrium with the environment can be maintained. When the environmental stress becomes greater than what can be compensated for by the heat dissipation mechanisms, the core temperature increases (Robinson 1949 Lind 1962, 1963 a, b, Leithead and Lind 1964 Wyndham et al. 1966) The range of the temperature independent zone varies with the subject s state of training and acclimatization.

Conversely in extremely cold environments the core temperature may decrease during work It has been found that the metabolic rate remains almost unchanged during light work in a cold environment, even when the core temperature decreases (Kitzing 1966 Kitzing, Kutta and Bleichert 1966 1968) It would seem that shivering in the non working muscles is insufficient to increase the metabolic rate enough to maintain the normal work temperature.

The skin surface temperature. The temperature of the different areas of the body surface in a warm environment is relatively uniform while in colder environments the more distal parts have lower surface temperatures than the proximal areas, such as the trunk and the head. (Hardy and DuBois 1938 b Stolwijk Saltin and Gagge 1968) The average surface temperature i.e. the single measurements weighted according to the area they represent (Hardy and DuBois 1938 a) shows a linear correlation with the ambient temperature. This relationship was independent of the metabolic rate, internal temperature, and rate of sweating (Winslow and Gagge 1941 Robinson 1949 B Nielsen and M. Nielsen 1965 a, Snellen 1966, Stolwijk Saltin and Gagge 1968 Mitchell et al. 1968 chap III) In other types of work (cf chap IV) $\bar{T}$ decreases slightly with increasing metabolic rate. Therefore, heat exchange by convection and radiation to the environment is also nearly independent of metabolic rate, sweat rate, and core temperature, and dependent predominantly on the ambient temperature.

The skin temperature is the result of a balance between the heat *supplied* to the surface from the body core by conduction and by convection due to blood flow and the heat *lost* from the surface to the environment. For environmental conditions above the "zone of vasomotor regulation" (Hardy and Söderström 1938) and for the metabolic levels studied in the present investigation (chap III) there is a very close coupling of the changes in skin

blood flow and in sweat rate. This interrelation occurs in such a way that the amount of heat transported by the blood to the skin surface equals the amount of heat dissipated through the evaporation of sweat. In other words, the skin surface temperature at thermal equilibrium probably depends on the temperature fall across the skin due to the conductive heat transfer from the thermoregulated constant core to the environment through the thermal resist ance of the peripheral insulating tissues. In other types of work (bicycling with the legs down instead of horizontal) the above mentioned interrelation of sweating and skin blood flow is slightly altered. Perhaps the upright position causes a redistribution of the circulation favoring the working muscles at the expense of the skin blood flow The decrease in T with increasing metabolic rate (1/2° C per 100 kcal/hr) could then be explained

The control of heat dissipation The concept of a regulated deep body temperature implies as stressed by Hammel in his review (1968) that "the regulated temperature" is checked against some reference. When a difference from the desired level occurs, a response tending to reduce the deviation is elicited. This response would mean a change in heat dissipation, brought about through changes of skin blood flow and sweat rate. The sensory inputs necessary to elicit the response that controls this balance have been the subject of a great number of papers (conf. reviews by v Euler 1961 Hardy 1961 Bligh 1966 Hammel 1968) and a complete survey of the literature will not be attempted here.

As mentioned, most authors agree that there is an interaction between central and peripheral sensory inputs. (Robinson 1949 Belding and Hertig 1962, Robinson et al. 1965 Wyndham 1965 Hardy and Stolwijk 1966, Stolwijk and Hardy 1966 a and b, Hammel 1968) Benzinger (1959 1960) and Benzinger et al. (1963) maintain that only hypothalamic temperature (expressed by T_{hy}) is of importance for the regulation of heat dissipation, although a certain inhibition from peripheral receptors may interfere at lower skin temperatures. However in experiments with a wider range of work rates and environmental temperatures B Nielsen and M Nielsen (1965 a) were not able to confirm Benzinger's hypothesis.

The interaction between the peripheral and central drives is often described in terms of *control theory* (Hardy 1961 1965) with *proportional control* as the best model for the dominant part of the thermoregulatory responses.

The variables in the equations are usually 1) hypothalamic temperature assumed to be the regulated temperature (for the discussion as to which temperature is the regulated temperature, cf. Hammel 1968) which is compared to some sort of intrinsic reference, and 2) the average skin surface tempera-

ture, which is compared to a "set temperature" for the skin (Stolwijk and Hardy 1966 a) The proportionality constants and the combinations of the two terms vary In some models the core and skin terms are added, (Stolwijk and Hardy 1966 b, Stolwijk, Saltin and Gagge 1968) and in others they are multiplied by one another (Stolwijk and Hardy 1966 a, Hardy and Stolwijk 1966)

According to Hammel et al. (1963) Jackson and Hammel (1963) Hellstrøm and Hammel (1967) and Hammel (1968) the "set point" of the controlling system, defined as the hypothalamic temperature at response zero, may be changed by a variety of factors such as skin temperature, state of awakeness, exercise etc. Their conclusions result from observations that the actual hypothalamic temperature in dog and monkey is more or less unchanged between situations where panting or shivering are elicitied. The controlling system thus is assumed to operate by adjusting the set point temperature so that the error signal is achieved with minimal changes in the hypothalamic temperature. However Jackson and Hammel's (1963) work experiments may just as well be interpreted by postulating, that during work an extra stimulus is added to those already existing, since no point on their curves relating panting to hypothalamic temperature during work was found to fall to the left of the "set point" of the corresponding curve for the resting condition. Hammel's theory also fails to explain how and why the body temperature during work increases to the *same plateau value* independent of ambient temperature.

Hammel's concept of temperature regulation is an attempt to answer the most difficult problem in the other models of sweat regulation, i. e. how to combine the thermoregulatory responses for working and resting conditions. For all "comparable conditions" of rest and work, the sweat rate is always much higher during work (Robinson 1949 1962, Minard and Copman 1963) A hypothetical "work factor" has therefore been introduced in many control models in order to explain the regulation of sweating. This "work factor" may be thermal, e. g. muscle or venous temperature, (Robinson et al 1965 Stolwijk and Hardy 1966 a, Saltin, Gagge and Stolwijk 1968) or it may be non-thermal, e. g. a neuromuscular factor (Robinson 1949 Beaumont and Bullard 1963)

Experiments with passive heating through diathermia (B Nielsen and M Nielsen 1965 b) and treadmill experiments with positive and negative work (B. Nielsen 1966 and chapter IV) showed that the sweat rate and skin blood flow varies in proportion to the summated rate of heat produced and induced in the body For a given skin temperature the sweat rate and conductance varied proportionally to changes in the heat production in spite of

widely different levels of internal body temperatures (T_{re}, T_{es}) and neuromuscular conditions.

The possibility of thermal receptors, stimulated by the rate of heat flow in the deeper parts of the skin below a thermal resistance (as proposed by Bazett 1951 and Kerslake 1955) is evaluated in chapter III and IV of the present study. It seems that neither "average deep skin temperature" nor muscle temperature can be the sole stimulus to the sweating mechanisms. However one cannot exclude the possibility that the stimulus to the sweating mechanism may consist of an interaction of the inputs from the skin surface, deep skin receptors and muscle temperature receptors with a central temperature information (cf. appendix p. 59). Such additional effect of for instance muscle temperature is suggested by Robinson et al. (1965), Stolwijk and Hardy (1966 a), Saltin, Gagge and Stolwijk (1968). Perhaps the only way of evaluating the summated thermal inputs to the thermoregulatory centre is to measure the changes in average body temperature calorimetrically as proposed by Snellen (1966).

Since the heat balance equation provides the best prediction of the sweat rate in stable conditions of both rest and work, a simple thermostatic control could be responsible for the sweat rate in these conditions. It may justly be presumed that, like the rectal, esophageal and tympanic temperatures, the temperature of the hypothalamic centres for thermoregulation also changes to new levels in proportion to the oxygen uptake. It may then be assumed that in stable conditions of rest or exercise the hypothalamic temperature, determined by the metabolic rate, is used as reference temperature for an on–off control of sweating. Any disturbance of the thermal equilibrium would eventually produce a change in temperature in the hypothalamus itself.

It can be argued that since no change in core temperature (T_{re}, T_{es} and T_{ty}) can be demonstrated during work at 5, 20 and 30° ambient temperature in man (B. Nielsen and M. Nielsen 1962, 1965 a) or during positive or negative work at the same metabolic energy liberation (B. Nielsen 1966 and chapter IV) such a control mechanism would need an even greater sensitivity to changes in temperature than that found in experiments with direct measurement and manipulations of hypothalamic temperatures (cf. v. Euler and Söderberg 1958, Jackson and Hammel 1963, v. Euler 1964, Hammel et al. 1963, Hellström and Hammel 1967). However the "gain" of the hypothalamic control system may be underestimated in such experiments. If there exist extra-hypothalamic receptors for deep body temperature (as demonstrated by for instance Hallwachs, Thauer and Usinger 1961, Hallwachs, Hupfer and Thauer 1961, Simon, Rautenberg and Thauer 1964, Thauer 1964, Simon, Rautenberg and Jessen 1965, Jessen et al. 1967, Jessen 1967

Bligh 1963 Brück and Wünneberg 1966) which can influence the hypothalamic centre, then, in experiments where the heat dissipation is increased by an artificial increase of the local hypothalamic temperature, the "deep thermoreceptors" elsewhere in the body would register a temperature fall and, through a negative feedback would tend to counteract the stimulus from the hypothalamic thermoreceptors (cf. Hammel 1968 p 692) Even if the hypothalamus is not as highly sensitive to its own temperature as presumed above, the small temperature fluctuations which must occur under natural conditions, due to slight deviations between heat production and heat dissipation, could provide the stimulus to the sweat regulation. Through the *dynamic* responses from hypothalamic and extracerebral thermal receptors in the core and perhaps also from the skin (Hensel and Boman 1960) the sweat rate might be adjusted, even though no deviation in deep temperature for a constant oxygen uptake can be detected. This theory implies, as mentioned above, an adjustment in core temperature corresponding to the oxygen uptake, which is not explained by the theory

The stimulus to the sweating mechanism in transient states appears to be at least partly non thermal. The onset and cessation of sweating when work is started and stopped seem to take place before any thermal changes have time to occur Beaumont and Bullard (1963) report that sweating is increased within 1.5 sec after the beginning of work Furthermore, the rate of increase in sweating at the start of work was found to be proportional to the work load. (Beaumont and Stier 1965)

The only temperatures that have a time constant at the onset of work of the same order of magnitude as sweating are the temperature in the working muscles (Robinson et al. 1965 Saltin, Gagge and Sto wijk 1968) and the temperature of the blood in the femoral vein draining the working muscles (Robinson et al. 1965)

Appendix

The "steady state" values of Sw T_{oe}, T_{re}, T_{dre}, $T_{(dt\ \ re)}$ and T_{re} from the experiments in chapter III and IV was tested in the following models:

1 $Sw = f(T_{oe}, T_{re})$
2 $Sw = f(T_{oe}, T_{dre})$
3 $Sw = f(T_{oe}, T_{(dt\ \ re)})$
4 $Sw = f(T_{oe}, T_{re})$
5 $Sw = f(T_{oe}, T_{re}, T_{dre}, T_{(dt\ \ re)}\ T_{re})$

Model 5 in Table I is the model which gives the best linear fit to the experimental values in the sense that it is chosen as to minimize the emperical realdual standard deviations SE_1

Assuming that the relationships are linear $Sw/100 = c + a_1(T_{oe} - 30) + a_2(T_{re} - 30) + a_3(T_{dre} - 30) + a_4T_{(dt\ \ re)} + a_5(T_{re} - 30) + \varepsilon$ (ε is the random fluctuation component) the estimates for the multiple regression parameters c, a_1, a_2 a_3, a_4 and a_5 for four subjects were computed. The values are presented in Table I

The statistical analyses show that for the values from the experiments in chapter III with 3 metabolic levels and various ambient temperatures the sweat rate can be satisfactory explained by model 1 the multiple correlation coefficient being 0 95 and SE_1 0 63 for TD and R = 0 95 and SE_1 = 0 81 for KHN Table II shows that the influence of the other measured temperature factors are insignificant; indicating that no relevant information on sweat rate is contained in these variables. Correspoodingly the best description, model 5 for the experiments in chapter III turns out to be equal to model 1 It is further confirmed that model 1 is insufficient in predicting the sweat rate for BI and BJ in the positive–negative work experiments, chapter IV (R = 0 84 and 0 72 and SE_1 0 83 and 1 69) Table II shows significant influence of at least one of the variables, T_{dre}, $T_{(dt\ \ re)}$ and T_{re}

Model 2 is almost equivalent to 1 in expressing the sweat rate for the experiments in chapter III and for subject KHN and BJ in chapter IV while for subject BI this model provides a better prediction.

The predictions of sweating from model 3 are not essentially superior to those obtained with model 2. All in all the experiments from chapter III are described better with model 2 and those from chapter IV better by model 3

Model 4 explains only 76 % of the variations in Sw in subj BJ while in BI T_{es} and T_m both play a significant role the two of them together having a R value of 0 85 and SE_1 1.28

As mentioned the fifth model is selected as the best in predicting Sw Table II shows that in the uphill–downhill experiments (chap. IV) at least one of the three variables T_{ds}, $T_{(ds\ )}$ or T_m has a significant influence on the description of the sweat rate, but for each of the 3 subjects a different variable is the most important (Table I model 5)

The conclusion to be drawn from the statistical analyses is that the changes in T_{es} and $\dot{T}$ (model 1) do not explain sufficiently the variations in sweat rate in all the studied conditions Extra information may be obtained by including T_{ds}, $T_{(ds\ )}$ and T_m No one of these last mentioned temperature factors can be singled out as being the most important, due to the individual variation. This finding may mean that the sweat rate is determined by the summated input from thermal receptors in all parts of the body and that the prediction of Sw is improved the more temperature factors we measure. Or perhaps, the information held in T_{ds}, $T_{(ds\ )}$ and T_m only reflects changes in some other factor e. g rate of heat production which is not included in the present analysis.

The computed multiple regression parameters c, a_1 a_2, a_3 , and a_5 and their standard deviations, SE, computed from the xperiments described in chap. III (p. 24) and chap. IV (p. 39) R = multiple correlation coefficient. SE_1 = standard deviation of the residuals from the estimated model, measured in (1/100) g/hr n = number of experiments. Four subjects: TD KHN BJ and BI.

Summary

Two theories for the regulation of sweating (Bazett 1951 and Kerslake 1955) are based on the idea that temperature receptors placed at a certain depth in the skin are stimulated by heat, both of *external* origin, i. e. environmental temperature and *internal* origin, i. e. the degree of muscular activity which is proportional to the heat production To evaluate these theories on an experimental basis, a method is worked out by which the temperature at different depths in the skin and subcutaneous tissues can be measured.—In *Chapter I* p. 13 a survey of the applied methods is presented.

In *Chapter II* (p 18) a series of experiments is described in which the temperature is measured at 4 depths between the skin surface and a depth corresponding to "1/2 skinfold thickness" (i. e. at approx. 1 2, 4 and 6 mm s depth) Experiments at various external temperatures in rest and during work showed that the temperature generally rose with increasing depth in the tissues. Differences in temperature between the surface and "1/2 skinfold thickness" of up to 8 were found. The differential across the skin was *larger* when the environmental temperature was *lower* and widened further with increasing heat production. It was therefore decided to measure an average of the highest possible temperatures in the studied tissue layers viz. "average deep skin temperature (T_{d_a}) measured at "1/2 skinfold thickness at upper arm, forearm, chest, abdomen, shoulder thigh and calf. Changes in T_{d_a} with different conditions of rest and work would be of interest for the discussion of the two above mentioned theories.

In *Chapter III* (p 24) therefore, the variations in T_{d_a} with different environmental temperatures are investigated. Results from experiments during rest and at 2 work intensities, 540 kpm/min and 900 kmp/min, are presented. At identical sweat rates in rest and work, the same average temperature could not be found at any depth superficial to muscle and bone. This means that *the sweat secretion cannot be regulated solely by the stimulation of thermal receptors in the deep layers of the skin*

The average skin surface temperature (T_s) was found to be determined by the environmental temperature, independent of the rate of sweating and heat production and identical for rest and work. From this finding it is concluded

that *the amount of heat transported to the skin surface by the skin blood flow must be exactly equal to the amount of heat which is given off by the evaporation of sweat* The heat lost by convection and radiation is transported to the skin by conduction through the peripheral tissues It is therefore assumed that the skin blood flow may be calculated from T_{d_s}, esophageal temperature (T_{oe}) and sweat heat loss (p 35) The calculated values agree with the variations in skin circulation expressed as "conductance"

In *Chapter IV* (p 39) T_{d_s} and the temperature in the thigh muscle, m. vastus lateralis, (T_m) are studied during bicycling and walking, or running on a treadmill By having the subject work uphill (positive work) or downhill (negative work) the proportion of metabolic energy liberation (M) to total heat production (H) can be varied For positive work we have H = M − external work (W) while for negative work H = M + W The possible correlations of sweat rate with various measured temperatures (T_{oe}, T_{re}, $T_{d_{re}}$, $T_{(d_s\ s)}$ and T_m) are discussed. The only parameter with which the sweat rate had the same positive correlation in both positive and negative work was $T_{(d_s\ s)}$ This temperature difference might therefore be assumed to be an index of the stimulus to the heat dissipation mechanisms. However this idea must be discarded in the light of the relationships between sweat rate, T_d and T_{oe} found in chapter III. The changes in muscle temperature with changes in total heat production are different for positive and negative work so *muscle temperature cannot be the stimulus that correlates sweat rate with heat production*

In *Chapter V* the general discussion (p. 50) deals with the presently available information on temperature regulation during muscular exercise. *The deep body temperature* reaches steady state values proportional to the metabolic rates, independently of the temperature of the environment within wide limits, and independently of the heat production in the body These temperature levels are not a function of the absolute values of metabolic rate (oxygen uptake, V_{o_2}) but are proportional to the relative demands on the organism (to % of V_{o_2} max) How this adjustment takes place is unknown. Various theories for the setting of body temperature, e. g. during fever are mentioned.

It may be concluded that *the average skin surface temperature* (p 54) is determined predominantly by the environmental temperature. $\bar{T}$ seems to be nearly independent of work intensity rate of heat production and core temperature in conditions where thermal equilibrium with the environment can be attained. This independence exists because the heat flow to the skin surface via skin blood flow is linked with the heat dissipation by sweat evaporation in some unknown way

Thirdly *the regulation of heat dissipation* is discussed (p 55) Within the temperature zone where thermal equilibrium can be reached, the heat loss by sweat evaporation in rest and work equals the total heat production less the heat loss due to convection and radiation in spite of differences in the levels of deep body temperature. Various theories for the interaction between deep and superficial temperatures in the regulation of sweating are mentioned. None of these theories seem to explain the observed correlation of sweat rate with heat production during steady state of rest and work It is suggested that *the sweat secretion in these stable conditions is regulated from the thermal balance* Any disturbance in thermal equilibrium would produce temperature changes somewhere in the body (hypothalamus, skin etc.) from where thermal receptors, perhaps through their strong "dynamic" responses, might feed information back to the thermoregulatory centre. Reflex adjustment of sweat rate would then reestablish the thermal equilibrium.

In the appendix (p. 59) a statistical treatment of the data is presented. Multiple correlation equations have been calculated for the correlations of the sweat secretion with the measured temperature factors.

Dansk Resumé

En række tidligere publicerede undersøgelser over reguleringen af legemstemperaturen og svedsekretionen under muskelarbejde havde som resultat, at temperaturreguleringscentret må kunne registrere den varmeproduktion, som finder sted i organismen. Svedsekretionen og blodgennemstrømningen i huden ændres proportionalt hermed, uafhængigt af den dybe legemstemperatur og uafhængigt af de mekaniske forhold i musklerne.

To teorier for reguleringen af svedsekretionen (Bazett 1951 og Kerslake 1955) bygger på den idé, at termoreceptorer beliggende i en vis dybde i huden skulle kunne stimuleres af varmepåvirkning dels udefra (ydertemperaturen) – og dels indefra (ved muskelarbejde) og derfor påvirkes proportionalt med varmeproduktionen. For at prøve disse teorier experimentelt, er der udarbejdet en teknik, der gør det muligt, med termoelementer at måle temperaturen i forskellige dybder i huden og underhuden. – *Første kapitel* (s. 13) giver en kortfattet oversigt over de anvendte metoder.

I *andet kapitel* (s. 18) beskrives en række forsøg, hvor der foretages temperaturmålinger i 4 dybder mellem hudoverfladen og en dybde svarende til $^1/_2$ hudfolds tykkelse (dvs. i ca. 1, 2, 4 og 6 mm's dybde). En række forsøg ved forskellig ydertemperatur dels i hvile, dels under muskelarbejde viste at temperaturen steg indefter i huden. Temperaturforskelle på op til 8° mellem overfladen og $^1/_2$ hudfolds dybden blev målt. Gradienten over huden blev *større* jo lavere ydertemperaturen var og desuden jo større varmeproduktionen var. Det konkluderes, at under hensyn til at man endnu ikke histologisk har kunnet påvise placeringen af termoreceptorerne i huden vil en undersøgelse af temperaturen målt så dybt som muligt i huden dvs. i $^1/_2$ hudfolds dybde kunne være af interesse til belysning af de ovenfor omtalte teorier for reguleringen af svedsekretionen. T_{d_m}, den gennemsnitlige d hudtemperatur bestemmes derfor som gennemsnittet af temperaturen i $^1/_2$ hudfols dybde på overarm, underarm, bryst, abdomen, skulder og lår.

I *tredie kapitel* (s. 24) er undersøgt, hvorledes T_{d_m} forholder sig ved forskellige ydertemperaturer dels under siddende hvile, dels ved to

tensiteter 540 kpm/min og 900 kpm/min Det konkluderes – at under forhold hvor svedsekretionen er ens – er der ingen steder i de væv der ligger mere perifert end muskler og knogler hvor man har samme T_{d_s} i hvile og under arbejde. Dvs. *svedsekretionen kan ikke styres alene udfra påvirkning af termoreceptorer i hudens dybere lag*

Den gennemsnitlige hud-overflade temperatur (T) fandtes, i overensstemmelse med tidligere undersøgelser at være bestemt af omgivelsernes temperatur og uafhængig af svedproduktionen, varmeproduktionen og af, om forsøgspersonen var i hvile eller arbejdede. Heraf kan sluttes, at *den varmemængde der med blodstrømmen transporteres til hudens overflade nøjagtigt svarer til den ved svedfordampning afgivne* mens den ved konvektion og stråling afgivne varmemængde transporteres fra det indre af kroppen til hud overfladen ved ledning gennem de perifere væv Det antages derfor at hudens blodstrøm kan beregnes udfra T_{d_s}, oesophagus temperaturen (T_{oe}) og svedfordampningen (s. 35) De beregnede værdier er overensstemmende med de variationer i blodstrøm, der kan beregnes som »conductance«

I *fjerde kapitel* (s. 39) undersøges T_{d_s} og desuden temperaturen i lårmusklen m. *vastus lateralis* (T_m) – under gang og løb og ved cykling – dels opad, (positivt arbejde) og dels nedad bakke (negativt arbejde) – på et løbebånd. Herved kan forholdet mellem energistofskiftet (M) og varmeproduktion (H) varieres. Ved positivt arbejde har man, at H = M – ydre mekanisk arbejde (W) og ved negativt arbejde, H = M + W Svedproduktionens mulige afhængighed af forskellige temperaturfaktorer (T_{oe}, T_m, T_{d_s}, $T_{(d_s\ oe)}$ og T_m) diskuteres. Kun til $T_{(d_s\ \ )}$ udviser svedproduktionen den samme positive afhængighed både for positivt og negativt arbejde. $T_{(d_s\ \ )}$ kunne derfor tænkes at være et udtryk for stimulus til varmeafgivelsescentret. Men det må afvises i betragtning af de relationer mellem svedproduktionen, $T_{(d_s\ \ )}$ og T_{oe}, som fandtes ved forsøgene i 3 kapitel. *Heller ikke muskeltemperaturens ændringer med variationer i varmeproduktionen kan accepteres som udtryk for det stimulus der tilpasser svedsekretionen efter varmeproduktionen.*

I *femte kapitel* den generelle diskussion (s. 50) opsummeres de til dato opnåede resultater for termoreguleringen under muskelarbejde. Det fastslås at *den dybe legemstemperatur* (s. 50) indstilles efter stofskifteintensiteten, ilt optagelsen i organismen, mens den inden for vide grænser er uafhængig af omgivelsernes temperatur og varmefrigørelsen i organismen Desuden er det temperaturniveau som organismen opnår under arbejde proportionalt, ikke med den absolutte iltoptagelse men med den relative belastning af organismen (% af den maximale aerobe kapacitet) Hvordan denne omstilling finder sted vides ikke. Forskellige teorier om indstillingen af legemstemperaturen, bl. a. under feber omtales.

Om *huditemperaturen* (s. 54) kan man konkludere, at den hovedsagelig er afhængig af omgivelsernes temperatur men er ved visse arbejdsformer uafhængig af arbejdsintensitet, varmeproduktion og den dybe legemstemperatur i de ydertemperatur intervaller hvor varmebalance kan opnås. Dette skyldes, at varmetransporten med blodet til hudoverfladen, på ukendt vis, er koblet meget nøje til varmeafgivelsen ved svedsekretionen Til sidst diskuteres *reguleringen af svedsekretionen* (s. 55) Indenfor reguleringsområdet har svedsekretionen både i hvile og under muskelarbejde en størrelse svarende til den totale varmeproduktion minus den ved konvektion og stråling afgivne varmemængde, trods forskelle i dyb legemstemperatur Forskellige teorier for regulering af svedsekretionen udfra samspil mellem temperaturreceptorer forskellige steder i kroppens indre og i huden omtales. Ingen af disse teorier synes at kunne forklare den fundne afhængighed mellem svedsekretion og varmeproduktion *Det foreslås at svedsekretionen under »stationære tilstande« i hvile og arbejde reguleres udfra varmebalancen i organismen* Hvis varmebalancen forstyrres, medfører det straks temperaturændringer i kroppen. Herved stimuleres termoreceptorer i hypothalamus eller andre steder i kroppens indre og evt. i huden Det meget kraftige »dynamiske response« på selv små temperaturændringer kan måske reflektorisk, via varmeafgivelsescentret, ændre svedsekretionen så varmebalancen genoprettes.

I appendix et (s. 59) præsenteres en statistisk behandling af talmaterialet. Der er beregnet multiple korrelations-ligninger for svedsekretionens afhængighed af de forskellige målte temperaturfaktorer

Preface

This investigation was carried out in 1964—1968 at the Institute of Physiology University of Aarhus, and at the Institute of Medical Physiology B University of Copenhagen. I thank the members of these institutions, particularly the directors, Professor J C. Skou, M.D., D M Sc., and Professor Poul Kruhoffer M.D D.M.Sc., for ideal working conditions.

I am greatly indebted to: Professor Skou for rousing my interest in research and for basic instruction in scientific methods, Professor Kruhoffer for post-graduate training in physiology as well as for constructive help, inspiration and encouragement throughout the present investigations L. James Brown for revision of the English Drs E. Boye, A. B Craig Jr., N Juel Christensen, I Dahn, E. H. Lanphier, N A. Lassen, O I Nissen, N Nørrø, H. Rahn, K. Tonnesen, L. Vanggaard, H. Westling, and H. Wetterqvist for help with various problems Engineer Jacob Fredelund Nielsen, H Christiansen, E. Hansen and John Jonson for help with electronic and mechanical problems Mrs. Jytte Zeppelin, Miss Grete Nielsen, and Miss Hanne Ring for skilled technical assistance Mrs. Inge Jakobsen and my wife Eva, for never tiring secretarial assistance.

The work was supported by grants from Statens Almindelige Videnskabsfond 'Fonden til Lægevidenskabens Fremme P Carl Petersens Fond' and 'Rask—Ørsteds Fond

Introduction

While serving as a medical officer in the Navy in 1964 I was placed in charge of Danish crews undergoing submarine escape training in a tank (Fig 1). On my arrival at the training school, which is at the Norwegian Naval Base in Haakonsvern at Bergen, a Norwegian confrere told me about 4 recent, serious accidents that had occurred in the tank after routine breath-hold diving and sometimes after free escape from a chamber simulating a sunken submarine some of the divers had experienced nausea, dizziness, eructation, fatigue, pain and even paralysis. No satisfactory explanation could be offered for these complications, and to regard them as manifestations of decompression sickness would have been incompatible with the general consensus of opinion, according to which 'Decompression sickness is virtually impossible for the skin diver because he cannot submerge deep enough or remain long enough under water to take up a troublesome amount of nitrogen—unless he has access to a supply of air at depth" (Lanphier in Submarine Medicine Practice 1956—p 259). Neither could the complications be ascribed forthwith to so-called "diving bradycardia of man (*e.g.*, Scholander 1962, Wolf 1965), because it was not known whether such bradycardia can become severe enough to arrest cardiac activity and cause sudden death. After a personal interview with the men who had had these complications, I suspected that decompression sickness might after all be the culprit.

In the light of the considerations set forth above the present investigations were started in an attempt to elucidate the basis of:

loss of consciousness and drowning in association with breath-hold diving

the bradycardia observed among human breath-hold divers and

the alterations in limb blood flow cardiac output and blood pressure occurring during breath-holding under various experimental conditions.

BREATH HOLD DIVING IN A 20 M DEEP SUBMARINE ESCAPE TRAINING TANK

PART I

METHODS

CHAPTER 1

Methods used in respiratory physiology

2. ALVEOLAR AIR SAMPLING

Samples of expiratory air, after a "Haldane cough" were delivered to the apparatus shown in Fig 2 The apparatus consisted of a brass T-tube (22 mm I.d.) The left arm was fitted with a detachable mouthpiece the right, with a 1000 ml breathing bag (A). In the vertical part of the T was a rubber stopper, penetrated by a piece of rigid polyvinylchloride (PVC) tubing carrying a football bladder for the alveolar sample (B) The dead space of the apparatus was 43 ml.

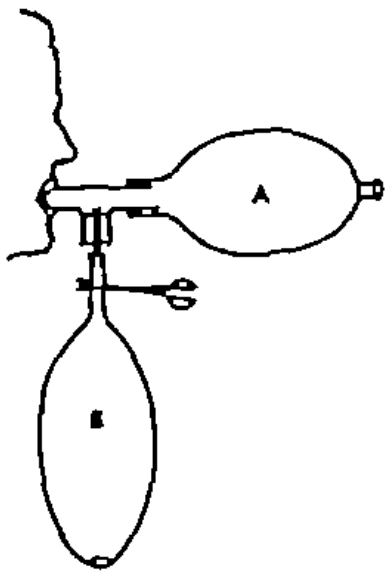

Fig 2. Equipment for obtaining samples of alveolar air A, breathing bag for dead space wash out B football bladder for collecting sample of expired air

When the subject expired into this apparatus, with or without the mouthpiece, the breathing bag (A) expanded and when it was full, the final part of the expired air approximately one liter filled B With this device it was also possible to obtain expiratory air samples during breath-hold diving in a training tank (Fig 1) During deep dives the total lung volume decreased roughly proportionally to the rise in ambient pressure, with consequent compression of the gases in the lungs. A breathing bag of only 500 ml instead of the 1000 ml was therefore used to wash out the dead space of the subject. The subject put the apparatus to his mouth while he was totally immersed in water the apparatus thus had practically no dead space. In such experiments it was not necessary to respire the contents of the bag A, because after delivery of the sample at the bottom of the tank, the subject swam immediately to a diving bell at approximately the same depth (Fig 1).

The samples of alveolar air were analyzed as soon as possible, and mostly within one hour. Analysis, at various intervals, of aliquots of a given air sample showed a fall of 1—3 mm in the carbon dioxide tension (P_{CO_2}) in one hour, but no alteration of the P_{O_2} level.

b SCHOLANDER'S MICRO-ANALYZER

The composition of the calibration gases was checked with a Scholander micro-analyzer. Duplicate analysis showed agreement within ± 0.02 % for O_2 and for CO_2. The micro-analyzer was also used for analysis of alveolar air samples and for samples from Douglas bags, when the number of samples to be analyzed was small. When the number was large, electrodes were used (see c.). The micro-analyzer was built by the author and differed somewhat from Scholander's (1947) The vernier of the micrometer had divisions of 0 001 mm, instead of only 0 01 mm. A Van Liew (1961) adapter was used, but the two cannulae were glued together so that the adapter consisted of a single unit and was therefore easier to handle.

c. ELECTRODES

Humidified samples were analyzed simultaneously in a polarographic Clark oxygen cell and a Severinghaus P_{CO_2} electrode. The two electrodes were thermostatically controlled (37°C) and connected to a pH meter with a gas monitor (Radiometer) Before each series of measurements two point (O_2 10 and 18 % CO_2 3 and 8 %, approximately) gas calibration was

repeated until stability was achieved. As a rule, only one sample was examined between two consecutive calibrations. Readings were made at exactly 60 (P_{O_2}) and 120 (P_{CO_2}) seconds after the introduction of the gas or the blood sample. The flow was kept at a fixed rate of one or two bubbles per second. The measuring precision was determined by treating the sets of calibration gas readings before (D_1) and after (D_2) the analysis of a given sample as duplicate samples. The SD was calculated from $\sqrt{(D_1-D_2)^2/2n}$. The mean difference between duplicate samples was 0.07 and 0.1 mm, SD $\pm$0.38 and 0.65 mm, n=56 and 62, for P_{O_2} and P_{CO_2}, respectively.

In preliminary experiments a medical gas analyzer (Beckman) with a CO_2 pick up and a physiological gas analyzer (Beckman) with a P_{O_2} electrode, were used. The values indicated by these meters were traced on a U.V. recorder (ABEM, type 'Ultralette'. Fig. 7).

d. GAS VOLUMES

Volumes of expiratory air were delivered to conventional Douglas bags and measured with two dry low resistance gas meters. Inspired and expired volumes were measured by having the test subjects breathe through an air-tight Ruben valve, directing the inspired air through one gas meter and the expired air through another. When 50 liters of air was sucked or blown through two gas meters the recordings differed by $\pm$50 ml at most ($\pm$1 %).—Also vital capacities (VC) were measured with the dry gas meters. The values found in a given subject were reproducible with an accuracy of $\pm$0.1 liter.—The residual volumes (RV) were calculated from the VC and the ratio between RV and VC given by Schaefer (1955). In one of the subjects the RV found with the helium dilution method and a Godart expirograph was 1.4 liters (STPD) which agreed well with the calculated value of 1.45 liters. In many respects the Godart expirograph resembles the light weight spirometer designed by Bernstein & Mendel (1953).

The air-tightness of various respiratory valves (von Döbeln, Ruben, Dräger werke Lübeck) was examined. The Dräger valve is generally used in connection with a self-contained underwater breathing apparatus. During the examination the inspiratory side of a valve was closed and connected to a transducer (Statham, type BB). Instead of being connected to a mouthpiece the valve was connected to a source of compressed air with an intermediate safety outlet. A constant flow of air passed through the valve and out at the expiratory side of the valve. In this system a significant pressure increase on the inspiratory side of the valve indicates a back flow *i.e.*, failure of the valve. The air passing through the valve was given

a statical pressure of 250 mm H_2O on the input side. In 6 von Döbeln valves, one Dräger valve, and two Ruben valves examined, a similar pressure developed at the inspiratory side and thereby indicated leakage. Five of the 6 Dräger valves examined showed no leakage. In another test of the air tightness of the 14 valves (Table 1) the expiratory side of the valve was sealed with a rubber stopper, penetrated by a tube connected to a water manometer and a transducer. The inspiratory side was immersed 1 cm in a water bath. A test subject expired into the valve with creation of the pressures shown in Table 1 before air bubbles escaped through the water bath. This procedure failed to produce any backflow in the 6 Dräger valves over the pressure range of zero to 400 mm H_2O (Table 1). These findings show that none of the types of valves examined are always tight, but that the Dräger valve is the most acceptable one. On the other hand, the dimensions of the Dräger valve—although better than the other two types—are suitable only for low and moderate ventilation, and the Dräger valve should be provided with a septum also in the cylindrical part in order to eliminate the dead space.

Commercially available (Wilhelmsen, Ltd., Aarhus) thin-walled, flexible plastic tubes (*i.d.* 25.4—31.8—38.1—44.5—50.8 mm), with an intramural PVC-spiral and a smooth internal surface, proved better than the conventional, antistatic rubber tubes used for anesthesia, when gas meters, valves, Douglas bags, and other units were to be connected.

Rubber Douglas bags are heavy and require the use of an expensive stopcock. A serious disadvantage of these bags is that if a partial pressure

difference across the wall is allowed to operate for any appreciable time, gas molecules will diffuse through the wall. According to Carlowitch (1963) the permeability coefficient for gas molecules in certain polymers is 133×10^{-9} ml (STPD) $\times$ cm^{-2} area $\times$ mm^{-1} thickness $\times$ cm^{-1} Hg pressure difference $\times$ sec^{-1} at 298°K for CO_2 in rubber, a value 1330 times higher than that for CO_2 in polyethylene-terephtalate. The polyethylene compound is 50 times more permeable to CO_2 than polyvinylidene chloride, but the later cannot be used directly for bags because the two layers will adhere to one another. It was therefore decided to use polyethylene (PE), and suitable PE-bags were procured (Danish Plast Industry Haarlev) The bags were provided with a long neck so that they could be closed simply with a clamping screw and a stopcock could be avoided. Such bags were filled with air and lead plates were placed on them for days without any consequent measurable reduction in the volume of their contents. A rubber Douglas bag and a PE-bag of similar size and shape, were filled with similar portions of one and the same sample of expiratory air. Duplicate samples from each bag were then removed immediately and again two hours later The samples were analyzed in the micro-analyzer described above. The CO_2 concentration fell from 3 84 % to 3.46 % in the rubber Douglas bag (0 8 mm thick) and to 3 69 % in the PE-bag (the wall of which was 0.4 mm thick). The O_2 concentration increased from 16.43 % to 16.69 % in the rubber Douglas bag but was essentially unchanged in the PE-bag (16.43 %) —The PE-bags can be completely emptied by passing them through a mangle or simply by flattening them out. Talcum was not used to prevent adhesion of the walls of the bag.

e. INTRAPULMONIC PRESSURES

During breath-holding the intra-oral pressure was measured with a water manometer (Knowles et al. 1959). Both intra-oral pressure and, in water the pressure at the mid-axillary line were recorded via Statham transducers, on the U V recorder (Fig 7) The subjects were instructed to hold the glottis open during the breath-holds (usually 60 seconds) and to maintain a steady level of intraoral pressure by watching the water manometer or by voluntary relaxation of the respiratory muscles This procedure was used in most breath-holds in this study and the breath was usually held at the end of a deep inspiration (mean lung volume: 90 % of VC). The fact that the intra-oral (intra-pulmonic) pressure in such cases was often only slightly positive (0 to +5 mm Hg) indicates that the subjects were

apparently unable to relax completely Goggles enabled the subject to watch the manometer even during total immersion of the head when lying supine in water. Each subject has his own fairly characteristic pressure during relaxation.

The pressure measured at the mouth during breath-holding with the glottis open was taken as representative of that in the airways (Knowles et al. 1959) especially since the use of oesophageal balloons is inconvenient and of limited value (Mead & Milic Emili 1964).

CHAPTER 2

Methods used in circulatory physiology

A ELECTROCARDIOGRAPHY

In most of the experiments standard leads (one electrode on each limb) were used. These electrodes were used also when the limb was immersed in water. To insulate the electrodes when in the water a circular stainless steel plate was cemented into a piece of solid nylon and the insulated electrode lead was connected to the plate. The electrodes were protected from the water by placing them on the skin and holding them there by means of a rubber band. A shielded single conductor cable connected the subject with a recorder. In the preliminary experiments a three or six channel recorder (Elema-Schonander mingographs, types 51 or 81) was used. The simple device just described, could be placed on the limbs within 2 minutes, and the recordings obtained were just as good as those obtainable by more complicated systems, which required about one hour to secure the position of the electrodes before water immersion.

Electrocardiographs are equipped with a differential, high input impedance amplifier. When recording ECG with the electrodes underneath the water surface, the water provides an external shunt (with an assumed resistance of 500 ohms) between the sites of the body lying close to the electrodes. This shunt will reduce the voltage available for the electrocardiograph, creating artifacts and noise. These problems have been solved by using a recorder, with an input resistance much smaller than the water shunt resistance, and with a high current sensitivity namely the already available U V recorder (Type ABEM). For further details, see footnote.

FOOTNOTE:

The ECG potential differences are assumed to be produced by constant voltage equivalent generator with an electromotive force (E) equal to the voltage measured between two standard lead-off areas, with high input impedance recorder. The R wave in lead II, between the right arm and the left foot of a supine subject resting on land, was found to correspond to an electromotive force of approximately 1 mv (Fig. 3 A). If the subject is then immersed in water and still connected to the conventional ECG apparatus, water—being good conductor—will affect the potential difference prevailing between the lead-off areas (Fig. 3 B). Since R_{H_2O} is much smaller than 10 Kohms, the voltage available for the recorder device will be small fraction of E. The R wave will then be so small that it will be masked by noise, and it will not be possible to measure the heart rate. The ECG was therefore recorded with a mirror galvanometer with low input resistance (50 ohms) while the subject was immersed in water (Fig. 3 C). Since R_{H_2O} is

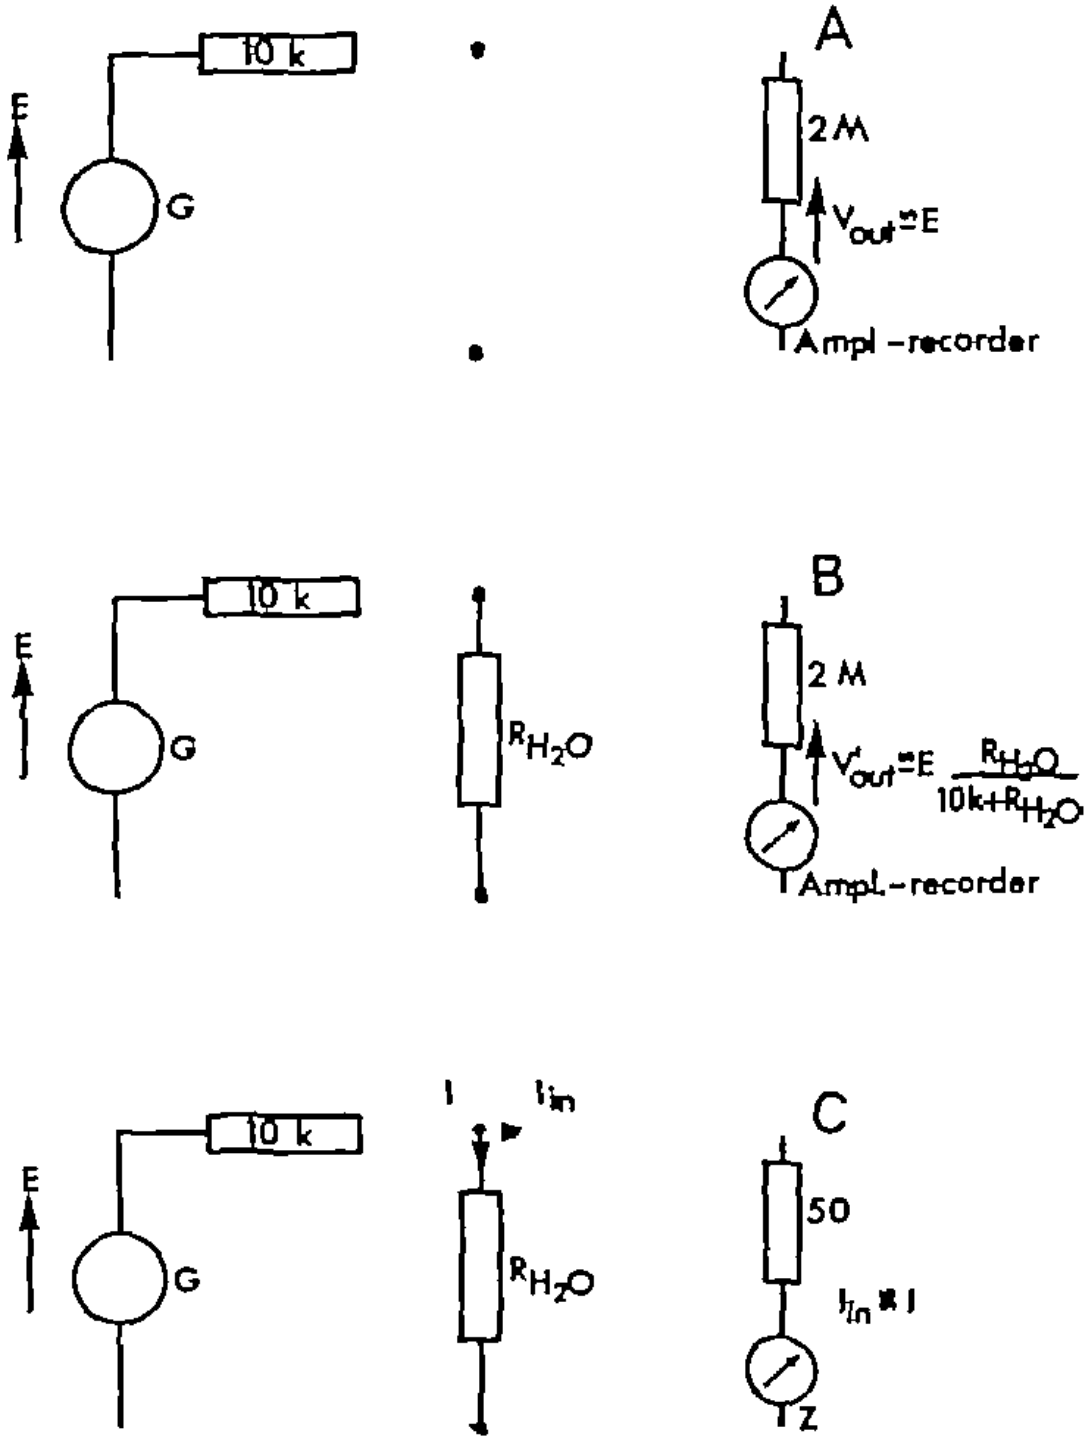

Fig. 3 ECG recording. The sum of the resistances of the two electrodes and the body

B DIRECT MEASUREMENT OF THE BLOOD PRESSURE

In the first part of the work Elema—Schonander pressure transducers (capacitance principle) were used together with mingograph type 81 During the final part of the work Statham transducers (strain gauge principle) were used with properly selected mirror galvanometers and the U V recorder. Usually the transducer model P 23 AA was used for arterial pressures, and P 23 BB for venous pressures. However when only a small volume displacement could be tolerated, the small model P 23 Dd was used for measuring arterial and central venous pressures. In the arrangement shown in Fig 4 the units are connected with sterilized tubes. Between the bottle of saline and the manometers was a so-called air tube a 60 cm long polyethylene tube with a 20 cm cannula. The transducer tube was 75 cm long, it had a 5 cm cannula, and Y-pieces varying in number with the number of transducers used at the same time, and it connects the bottle with the transducers. The blood pressure transducer was placed with its central axis in the same horizontal plane as the surface of the water in the manometer bottle with heparinized saline (Fig 4). The manometers were fastened to the wall one was a water manometer for calibration of the venous pressure transducers the other, a mercury manometer for calibrating arterial pressure transducers. They were connected to the bag of a sphygmomanometer in such a way that it was possible to create static pressures of 0, 5 10 20, 30 40, 50 100, 150, 200, and 250 mm Hg above the surface of the saline in the bottle, with only one air tube' Thus, only the bottle with sterilized saline the transducer tube' and the air tube' had to be

1 time as great as the internal resistance of the galvanometer, it is obvious that the major part of the current supplied from G will reach the recording device. If the ECG recordings are to be of conventional shape, current amplifier must be introduced between the electrodes and the critically damped galvanometer

is assumed to be 0 Kohms, G denotes a constant voltage equivalent generator I, the current from G I_{in}, the fraction of I flowing through the galvanometer; V_{out} and V'_{out}, the voltage available for the recording device All resistances are given in ohms.

A Conventional ECG apparatus with an internal resistance of Mohms, recording from a subject in air.

B Conventional ECG apparatus, recording from a subject lying up to neck in water (the resistance, R_{H_2O} is assumed to be 500 ohms).

C The (underdamped) galvanometer (Z type) system with low input resistance (50 ohms).

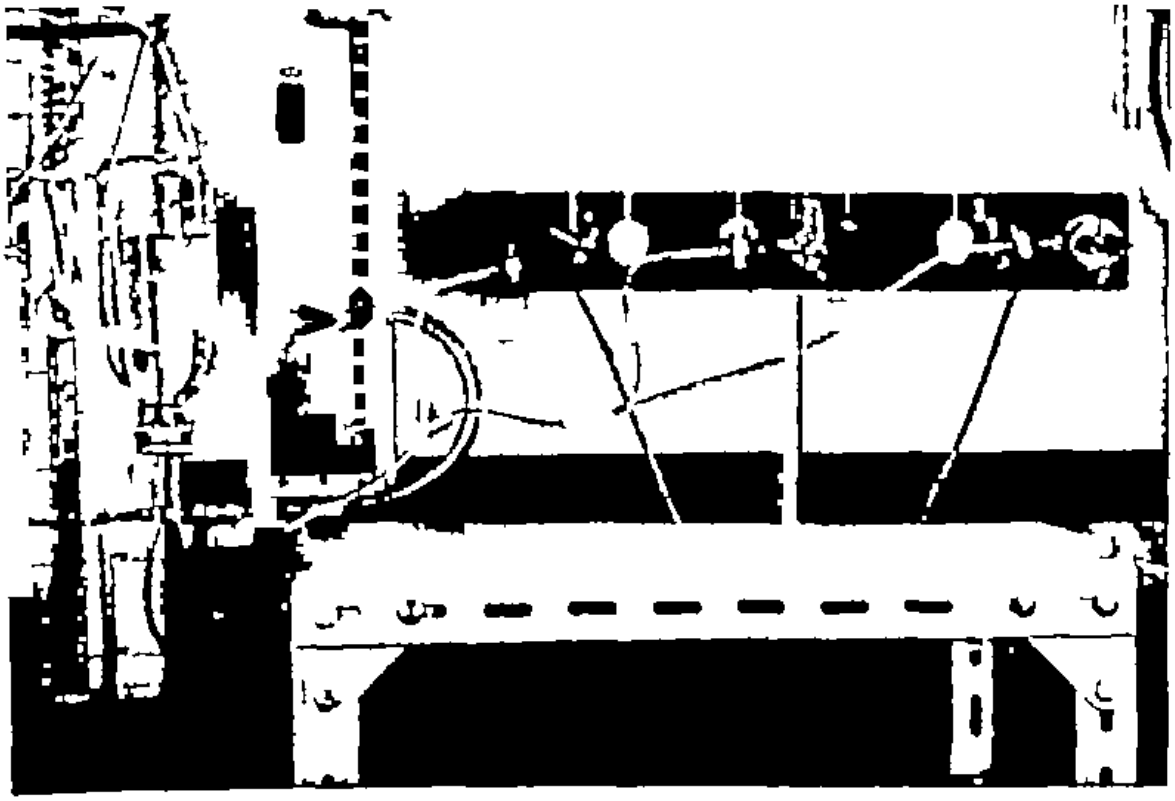

Fig. 4. Photograph of the pressure recording system.

changed from day to day (everything else remained unchanged) The transducers and stop-cocks were sterilized for 30 minutes in 60 % alcohol with 1 ‰ detergicide immediately before use, and flushed with sterilized saline. *Only heparinized saline was used (1250 I.U in 500 ml)* Polyethylene catheters (o d. 1 6 mm, i.d.. o 9 mm, length 6—50 cm) were placed in the brachial artery the basilic vein, and peripheral veins by the Seldinger technique (1953) "Intracat (Bardic) catheters were often used for recording the central and the peripheral venous pressure. Only Luer Lock fittings were used. A syringe was mounted on a stopcock on the transducer and up to 5 ml heparinized saline was used to flush the catheter in the course of the experiment (at most two hours)

Statham transducers of type P 23 BB and Dd with 6 cm long PE-catheters were examined regarding their response to a transient change in pressure. A "square wave generator" (Tybjærg Hansen 1949) was used. If the bore of the pist n and piston rod of the syringe is wide enough, this procedure is preferential to the other procedures described in the literature (*i.e.*, sucking with the mouth and after a short time, removing the tongue from the tube – exploding a condom etc.) With the "square wave generator' it

is possible to produce many pressure changes within a short time. The mirror of the galvanometer was placed at right angles to the direction in which the paper was fed. With the usual input voltage to the transducers Dd, a galvanometer deflection of 25 cm (30 cm broad paper) corresponded to 300 mm Hg. The examination was performed at the usual speed (12.15 cm/min) of the paper and at a speed of 245 cm/min. The transducer-catheter system responded so fast that no measurable time difference was found.

Tightness of the transducer-catheter system was checked with a pressure of 200 mm Hg immediately before recording of the biological pressure.

The volume displacement per unit of pressure increase (which is the reciprocal value of Tybjærg Hansen's (1949), "modulus of volume elasticity"), was determined with a calibrated capillary tube from August Krogh's latest microtonometer. According to the manufacturers, transducer Dd itself, has a volume displacement of 0.02×10^{-3} cm³ per 100 mm pressure increase (*i.e.*, a modulus of volume elasticity of 6.67×10^{9} dyn × cm^{-5}). This volume displacement is less than that of the optimal transducer studied by Tybjærg Hansen (thickness of membrane 35×10^{-4} cm, modulus of volume elasticity 3.4 to 4.5×10^{9} dyn × cm^{-5}, volume displacement 0.09 to 0.12×10^{-3} cm³/100 mm Hg). Our Dd transducer with the 6 cm catheter described above, had a volume displacement of 0.05×10^{-3} cm³/100 mm Hg (*i.e.*, a modulus of volume elasticity of 2.67×10^{9} dyn × cm^{-5}), which is thus very satisfactory.

In view of the above examination, and the fact that all the mirror galvanometers were critically damped, the peak systolic and the diastolic pressures recorded were presumably true measurements of those prevailing at the tip of the catheter. The "physiological reactance" (Fry 1960) is not dealt with here, because owing to the small volume displacement of the transducer-catheter system this factor must be of minimal importance compared with other pressure recording systems.

C. MEASUREMENT OF THE CARDIAC OUTPUT

With the use of the Seldinger technique (1953) under local anesthesia, a polyethylene catheter was introduced into the basilic vein, and the catheter tip was advanced to an intrathoracic position. Another catheter was introduced into the brachial artery. The indicator dilution technique used for determination of the cardiac output was essentially that described by Stewart—Henriques and Hamilton (Stewart 1897, Henriques 1913, Hamilton et al. 1948), but with a colourless and quickly eliminated indicator (bromsuphalein) in order to avoid possible discoloration of the skin by the frequent,

successive determinations. This indicator was first used for this purpose by Wassén (1956) who compared it with Evans Blue, and found no systematic difference between the cardiac output as measured with the two substances. In the present work Wassén's modification was employed, except for the injection technique described below All indicator dilution curves satisfied the extrapolation criteria of Dow (1956). At least 5 determinations were made to ascertain the slope of the descending limb of the curves. The $\dot{Q}$ was measured by the injection, through the catheter in the vein, of 3.0 ml of a bromsulphalein solution (50 mg/ml) from a cylinder mounted on a syringe with 20 ml physiological saline. The bromsulphalein and the saline was injected as rapidly as possible. This took 3 to 5 seconds, which implies that the 3 ml dye bolus was injected in 0 6—0 7 seconds. Blood samples were obtained from the arterial catheter every second for 30 successive seconds after the beginning of the injection. After the end of this period, arterial blood samples were obtained for gas and acid base analysis These samples were analyzed simultaneously in the above mentioned polarographic oxygen cell, in Severinghaus P_{CO_2} electrode and in a micro-electrode chain (Radiometer).

D PLETHYSMOGRAPHIC MEASUREMENT OF THE LIMB BLOOD FLOW

It might not be out of place to give a brief outline of previous studies in the field to facilitate understanding of the present investigation.

Historical comments

The first to use a plethysmograph was Francis Glisson (1677) who placed a musculous limb in a rigid walled chamber and utilized the principle that any swelling of the limb would displace the fluid from the rigid chamber to a system for volume measurements. In 1898 a Danish scientist measured spontaneous changes in volume of the forearm with a water filled plethysmograph (Lehmann 1898).

Venous occlusion plethysmography introduced by Brodie (1907), and modified by Hewlett & Van Zwaluwenburg (1909) provides a method for estimating the arterial inflow in organs and limbs. In recent years several improvements have been made. Lewis & Grant (1925) introduced the segmental plethysmograph during their famous work on reactive hyperæmia. Krogh, Landis & Turner (1932) described the pressure plethysmograph and important features of the plethysmographic method in general How important it is to keep the local temperature in the plethysmo-

graph constant is evident from Freeman's results (1935). On occlusion of the brachial veins the venous reservoirs in the hand fill quicker than those in the forearm, and blood passes from the distal hand veins into the forearm veins and thereby contributes to the increase in volume of the forearm (Grant & Pearson 1938). Arterial occlusion at the wrist was therefore introduced (Grant & Pearson 1938). Repeated resting blood inflow recordings over a period of half an hour were the same whether the circulation to the hand was continuously or only intermittently arrested (Grant & Pearson 1938). Kerslake (1949) produced evidence of a vasomotor reflex upon an arterial occlusion by a cuff around the wrist. This response was however short-lived and disappeared 90 seconds after the application of the occlusion (Hyman & Winsor 1961).

Greenfield & Patterson (1954) re-investigated the validity of the method of venous occlusion plethysmography. The apparent rate of blood inflow to the forearm (*i.e.*, the slope of the ascending plethysmographic line during the first seconds of venous occlusion) was found to be unchanged, even in the presence of a venous back-pressure sufficient to increase the resting forearm volume by anything up to 2 % (Greenfield & Patterson 1954). Since the increase in the volume of the forearm during ordinary venous occlusion plethysmography is less than 1 % there is no evidence for Gaskell & Burton's (1953) assumption that venous distention during the venous occlusion period causes a change in the apparent rate of blood flow.

Holling & Verel (1957) found a reduction in brachial arterial pressure and forearm blood flow when the arm was raised above heart level, the reduction in flow being greater than what would be expected if blood flow and the brachial arterial pressure varied linearly with one another. Some investigators measured the blood flow in a dependent limb (Gaskell & Burton 1953) or in one where the veins were distended for some other reason (Yamada & Burton 1954) but the validity of the method is questionable under these conditions (Greenfield 1960).

As far as forearm- and hand-plethysmography is concerned, a 45° abduction of the shoulder joint with a 130—150° flexion of the elbow joint was found to be the position inhibiting the arterial inflow to the smallest extent (Graf 1964 b).

Wallace (1958) found no significant difference between the apparent rate of blood flow to the forearm measured with a water pressure of 9—16 cm acting upon the forearm, and the flow obtained with a water head of 16—26 cm. According to Hyman et al. (1963) progressive increments in the pressure of an air plethysmographic cuff, decrease the total forearm blood flow this decrease probably occurring mainly in the intracutaneous

circulation against which the cuff exerts the greatest pressure. Graf & Rosell (1964 a) corroborated the above results and claimed that pressures less than 100 mm water do not measurably influence the arterial inflow rate. A decrease in forearm blood flow with increasing external pressure has also been found with the use of a water plethysmograph (Fewings & Whelan 1966).

Barcroft & Edholm (1943 1946) found that the water into which a forearm was to be immersed for plethysmography should preferably be 34 C, thus maintaining the local temperature of the skin practically equal to that of the adequately dressed forearm. The water plethysmograph acts as a thermostat on the skin and is generally maintained at 34 C in forearm plethysmography

Dohn (1956) has designed an air plethysmograph with several practical advantages. It consists of a 6 cm broad rubber cuff. Changes in the volume of the limb are assumed to cause proportional pressure changes in the air in the cuff, and the pressure changes are measured with a sensitive transducer. Though the compression of the air in the cuff in association with 10 seconds venous occlusion is not isothermic, the principle is acceptable in practice. But during an experiment the temperature within the rubber cuff slowly rises to reach a level between room and skin temperature. This rise is accompanied by a gradual increase in resting blood flow Thus comparison of blood flow values recorded with an air plethysmograph at different laboratories is warranted only if the local temperature beneath the cuff, the body temperature and environmental temperature are maintained at standardized levels, provided effects of such alterations are not the object of study

Graf (1964 a, b) carefully studied the accuracy of the venous occlusion method for blood flow measurements using Dohn plethysmographs. Graf (1964 a) mentions seven drawbacks of distal arterial occlusion during forearm blood flow measurements. Closure of the radial and ulnar arteries by the wrist cuff seems to produce such a change in the forearm vessels that it can hardly be regarded *a priori* as a natural system. As will later be apparent, the size of the apparent blood flow is not influenced by distal arterial occlusion. However prolonged arterial occlusion is unpleasant enough to warrant a search for another solution. Graf (1964 a) recommends simultaneous inflation of the distal occlusion and the proximal collecting cuff to the same venous occlusion pressure, but this produces a serious artefact due to displacement of tissue by the occlusion cuffs This makes it difficult to determine the initial slope. Therefore another procedure was developed (see later)

Venous occlusion plethysmography gives results in good agreement with those obtained by calorimetry (Cooper et al. 1949). Conrad & Green (1961) found that the plethysmograph and the electromagnetic flowmeter give corresponding values for a given flow

The results of venous occlusion plethysmography cannot of course be compared directly with those obtained by methods measuring a variable not linearly related to the overall blood flow *e.g.*, methods using thermal skin needles or disc oscillometry and accumulation or clearance of an indicator.

Plethysmography has been used not only for measurements of volume and blood flow but also in the assessment of capillary permeability (Krogh, Landis & Turner 1932) pulse wave velocity (Simonson & Nakagawa 1960) and venous tone and compliance (Wood et al. 1956)

Besides the above displacement plethysmographs, where a fluid (water or air) is displaced by the expanding tissue, also electronic plethysmographs have been used. Here only strain gauge plethysmography will be considered. —Several so-called "plethysmographs such as the "photo-plethysmograph" do not deserve the name since these devices do not measure the rate of volume increment or related variables at all (Hyman & Winsor 1961) —In 1953 Whitney introduced a new method for recording the relative change in girth of human limbs by means of a mercury in-rubber *strain-gauge*. According to this method, a narrow and very elastic rubber tube filled with mercury is wrapped round the limb and changes in its length are deduced from changes in the electric resistance. Assuming the limb to be a truncated cone and assuming equal reduction in thickness per unit length, the relative change in the limb girth will vary linearly with that in its volume.

Although venous occlusion plethysmography has survived major attacks through the years, and though it is still regarded as the best available method for measuring blood flow in an intact limb it is still questionable whether the venous occlusion is complete in all situations. The so-called blood flow may be the best approximation, but it is not necessarily the true blood flow especially not during dynamic muscular exercise, where the venous muscle pump can probably easily press out blood from under neath the venous occlusion cuff. However the resting blood flow as measured with a reasonably accurate venous occlusion plethysmograph, may not be far from the true blood flow

Other aspects of the history of plethysmography have been reviewed by Abrahamson (1944), Hyman & Winsor (1961), and Mune (1967).

Plethysmographic methods employed

Water plethysmography

In the course of the present work, the water plethysmographs were improved. The main improvements were 1) The use of a larger water surface and omission of the expansion chamber, 2) A minimal external water pressure on the limb segment, 3) Tailor made sleeves of extra thin rubber dam, 4) A stiff wide bore tube between the plethysmograph and the recorder

1 *Large water surface* The plexiglas plethysmograph consisted of a plethysmograph chamber proper, surrounded by a thermostatically controlled water jacket (Fig 5) The size of the water surface was an essential point in the construction of the chamber Dahn (1964) connected the plethysmograph chamber to an expansion chamber with a water surface area of 88 cm^2 and conclusively showed the advantage of the arrangement. The advantage is that a certain volume increase will only increase the height of the water column to a minimal extent (see 2). Therefore Dahn's principle was used in the present work, but the expansion chamber proved both unnecessary and undesirable. The water surface of the plethysmograph chambers of the present system was 140—200 cm^2 The transmission loss to the surroundings (*i.e.*, the difference between the true increase in limb volume and that recorded) was found minimal at all external water pressures used probably because the sleeves were made to measure and fitted well The transmission loss was determined as the difference (here mostly zero) between the recorder calibration with air and the water calibration (see later)

2 *Small external water pressure* The influence of different, external water pressures on the limb segment was studied. The blood flow was measured at 4 7 and 12 cm of water (measured from the axis of the limb segment). The upper part of the forearm segment was at the level of the sternal angle, and measurements showed no significant difference between the average resting forearm blood flow in this position, and in positions where the arm was lowered 3 cm or lifted 2 cm from this position. The position of the arm was as comfortable as possible (Graf 1964 b). The results are shown in Table 2. It is seen that the rate of relative volume increment was the same at 4 as at 7 cm of water whereas at 12 cm H_2O it decreased significantly Therefore, high water pressures, which have been used in numerous investigations on record, should be avoided. In the present system a water column of 4 or 7 cm was used throughout, and owing to the large water surface the rise in water pressure during venous occlusion was only 1—2 mm of water from the 4—7 cm level.

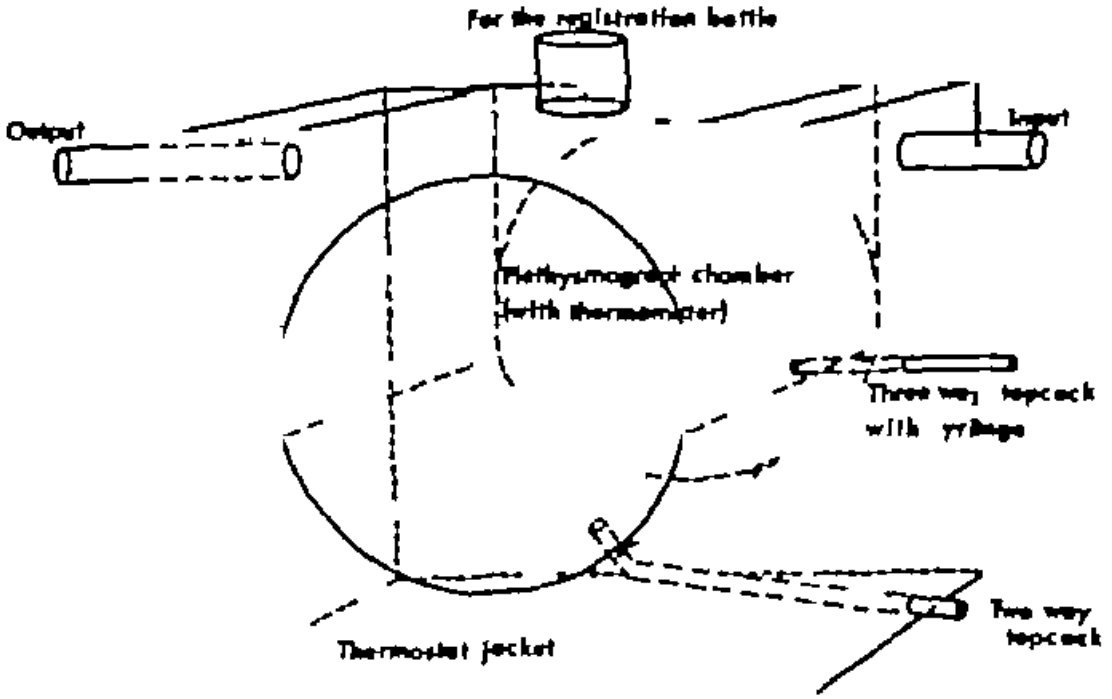

Fig 5 The plexiglas plethysmograph. Input—output for the water from the Heto thermostat to the thermostat jacket. The tube with the two-way stop cock is used to empty the chamber after an experiment. The three way stop cock with syringe is used for calibration. The registration bottle is connected to the plethysmograph chamber t the wide tube bove. The wide tube carries mark used when measuring the volume of the limb segment.

5 *Tailor made sleeves* The tailor made sleeve was cut out of extra thin hygienic dam (0.10—0.17 mm thick) and at each end it was fixed with latex glue to 4 mm thick, extra stiff rubber plates (Fig 6). The apertures

Table 1 Effect of the hydrostatic pressure.

Water pressure[1]	Percentage change in apparent blood flow[2]	Number of observations
4 cm	100 ± 2.4 %	32
7 cm	00 ± 1.6 %	34
cm	8 ± 3.2 %	33

The water pressure resting on the forearm segment is measured from the water surface to the mid axis of the forearm.

Mean values ± SE. The apparent resting blood flow was found essentially identical at 4 and 7 cm water pressure (this flow is called 100 %).

Plethysmographic methods employed

Water plethysmography

In the course of the present work, the water plethysmographs were improved. The main improvements were 1) The use of a larger water surface and omission of the expansion chamber 2) A minimal external water pressure on the limb segment, 3) Tailor made sleeves of extra thin rubber dam, 4) A stiff wide bore tube between the plethysmograph and the recorder

1 *Large water surface* The plexiglas plethysmograph consisted of a plethysmograph chamber proper surrounded by a thermostatically controlled water jacket (Fig 5) The size of the water surface was an essential point in the construction of the chamber Dahn (1964) connected the plethysmograph chamber to an expansion chamber with a water surface area of 88 cm^2 and conclusively showed the advantage of the arrangement. The advantage is that a certain volume increase will only increase the height of the water column to a minimal extent (see 2) Therefore Dahn s principle was used in the present work, but the expansion chamber proved both unnecessary and undesirable. The water surface of the plethysmograph chambers of the present system was 140—200 cm^2 The transmission loss to the surroundings (*i.e* the difference between the true increase in limb volume and that recorded) was found minimal at all external water pressures used probably because the sleeves were made to measure and fitted well. The transmission loss was determined as the difference (here mostly zero) between the recorder calibration with air and the water calibration (see later).

2. *Small external water pressure* The influence of different, external water pressures on the limb segment was studied. The blood flow was measured at 4 7 and 12 cm of water (measured from the axis of the limb segment) The upper part of the forearm segment was at the level of the sternal angle, and measurements showed no significant difference between the average resting forearm blood flow in this position, and in positions where the arm was lowered 3 cm or lifted 2 cm from this position. The position of the arm was as comfortable as possible (Graf 1964 b) The results are shown in Table 2. It is seen that the rate of relative volume increment was the same at 4 as at 7 cm of water whereas at 12 cm H_2O it decreased significantly Therefore, high water pressures, which have been used in numerous investigations on record, should be avoided. In the present system a water column of 4 or 7 cm was used throughout, and owing to the large water surface the rise in water pressure during venous occlusion was only 1—2 mm of water from the 4—7 cm level.

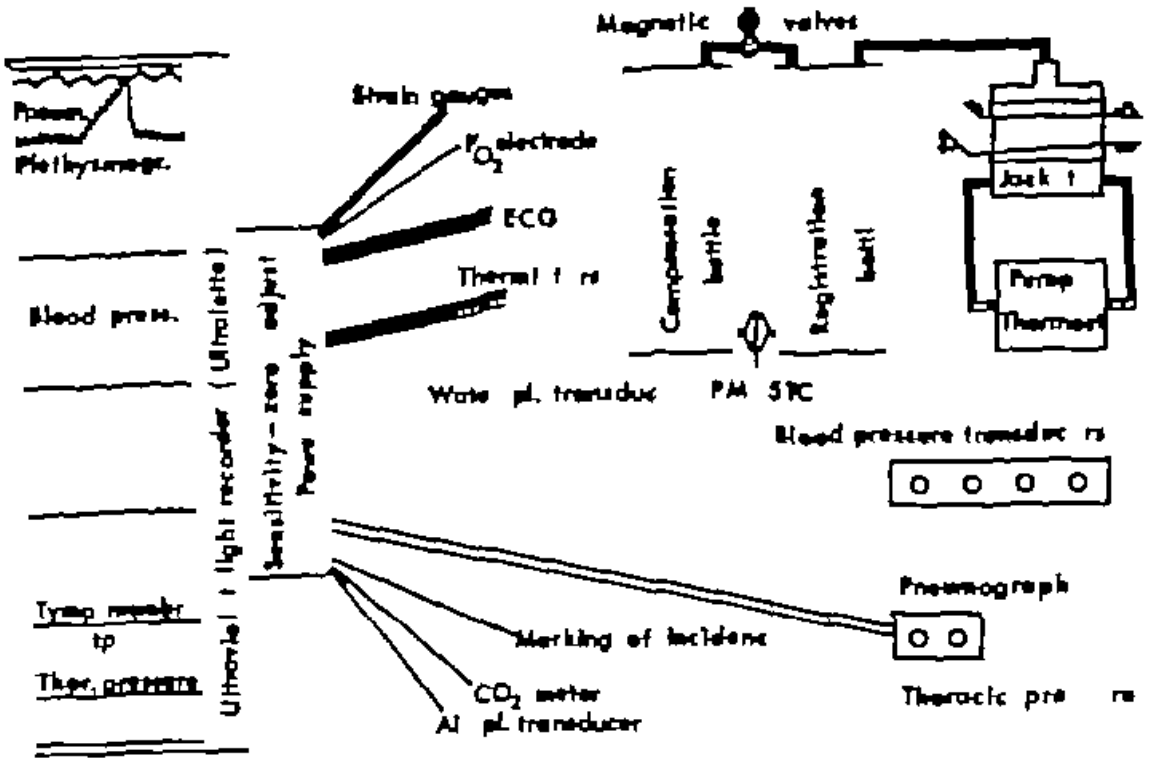

Fig 7 Block diagram of the main equipment used. Pressure equilibration between the bottles and the environment was performed with the magnetic valves.

4. *Wide bore tubes* The plethysmograph chamber communicates through a wide and rigid PVC tube (i.d., 8 mm e.d., 14 mm) with a 10 liter registration bottle (Fig 7). The wide bore tube allows a fast transmission of the response to the transducer membrane. The rate of ascent of a single cardiac oscillation recorded with this system was compared with the rate obtained with a perfectly rigid system, where the only elastic element was the membrane of a transducer (Statham, type BB) placed directly on the plexiglas plethysmograph. The PVC tube delayed the transmission only slightly and all the recordings of the duration of the ascending phase of a cardiac oscillation were less than one third of the lowest recordings of the "inclination time" obtained by Mune (1967) with a forefoot plethysmograph, in which narrow elastic rubber tubes were used

Measurement of volume The volume of the limb segment in the plethysmograph chamber was measured by filling the chamber up to a mark on the tube leading from the chamber, while the limb was still in the chamber The individual sleeve snugly fitted the segment of limb whose blood flow was to be measured. The water was led out and its volume was measured

accurately This volume was subtracted from the total water volume of the chamber measured several times without the extremity (the ends of the chamber were sealed with stiff rubber plates) A series of measurements in quick succession on the same arm, without change of position, gave the following values 535—535—525—530—533—538 ml, with a mean value of 533 ml. Thus the relative error of a single measurement of the volume was approximately ±1 to 2 % as compared with ±7 % when using the air plethysmograph (Dohn 1956).

The recording system The change of volume in a system consisting of a certain amount of gas molecules is measured with a transducer as the relative change in pressure, a principle which has been used for different purposes and for many years.

The differential form of the first law of thermodynamics can be applied to gases ($dQ=dU+PdV$) Here dU is the change in energy of the system, PdV is the energy exchange of the system in the form of work and dQ is the energy exchange in forms other than work (Fermi 1956). Slight compression or expansion implies only a small energy exchange in the form of work (PdV) and if the system is thermally insulated to prevent heat exchange with the surroundings ($dQ=0$) the internal energy of the gas will not change essentially according to the above equation. The compression or expansion of air molecules (air considered as an ideal gas) must thus be isothermal (*i.e.*, occurring at constant temperature) and reversible (*i.e.*, carried out at a hypothetically infinitesimally low rate) in order to satisfy Boyle-Mariotte's law of a hyperbolic relation between volume and pressure.

These requirements cannot, of course, be completely satisfied in practice, but the recording system illustrated in Fig 7 has proved to approach the ideal (Greenfield 1964) The two bottles and the transducer are enclosed in Rock Wool, in order to prevent thermal exchange with the surroundings ($dQ=0$) Excess water in the bottles increases the heat capacity of the system and thus further reduces the sensitivity to heat exchange with the environment In addition the bottles were filled with crumpled aluminum foil. This proved to have the advantageous effect of minimizing distortion of the calibration records observed. During recording the gas volume is reduced by 1—5 ml from 20,000 *i.e.* a 1/4 per mille pressure increase from the ambient pressure in the compensation bottle. The large size of the gas volume in the registration bottle makes the calibration practically independent of the volume of the limb segment and water in the plethysmograph chamber The use of the compensation bottle renders the system independent of fluctuations of barometric pressure, and largely

independent of fluctuations of temperature. Air temperature variations in the laboratory were minimal during application. The small pressure changes were measured with a Statham differential pressure transducer (PM 5TC pressure range ±7.8 mm Hg) connected to a sensitive mirror galvanometer recording on the U V recorder

The proximal occlusion cuff (6 cm wide) was inflated to pressures of 40 to 70 mm Hg, depending upon the individual (Munc 1967) Usually 50 to 60 mm Hg is optimal in normal subjects. The proximal cuff should be placed around the lowest part of the upper arm and as close as possible to the plethysmograph, but it is important that it is placed on the *upper* arm in order to close the veins as effectively as possible, as shown by Graf (1964 b)

The distal occlusion cuff (6 cm wide) was placed 2 cm distal to the lower border of the plethysmographs used in this study

The effect of variation of the pressure in the distal occlusion cuff was systematically studied with a water plethysmograph. The rate of relative volume increase by proximal, venous occlusion (60 mm Hg) was measured 1) without distal occlusion, 2) with continuous distal, arterial occlusion (270 mm Hg) for 10 to 20 minutes, 3) with intermittent, distal, venous occlusion (60 mm Hg) placed 2 seconds prior to inflation of the proximal cuff and kept until both cuffs were deflated (simultaneously). The results

Table 3 Different types of distal occlusion.

Procedure	Rate of relative volume increment FU	No. of observ
1) Without occlusion	7.6 ± 0.4	15
2) Arterial occlusion	4.9 ± 0.1	30
3) Intermittent, venous occlusion:	4.9 ± 0.2	0
3) Intermittent, venous occlusion	3 ± 0.06	15
4) Simultaneous distal and prox. occlusion.	3.1 ± 0.13	29

5) Constant distal venous occlusion (mean of 4 determinations the prox. occlusion period is indicated in sec, from the commencement of distal venous occlusion):

Sec	5—15	35—55	45—55	65—75	85—95	105—115
FU	2.5	2.9	3.6	3.9	4.1	3.9

The above figures are mean values in FU (*i.e.* ml blood per 100 ml forearm and min) ± SE. The order of the different procedures was changed in a random fashion. The figures of the upper and lower part of the Table are from two different subjects.

are given in the upper part of Table 3 In another subject procedure 3) was compared with procedures 4) 10 seconds of venous occlusion simultaneously by the proximal and the distal cuff (60 mm Hg), and 5) constant, distal venous occlusion (60 mm Hg) for 2 minutes. The results are given in the lower part of Table 3 In this study proximal venous occlusion was applied 3 times each minute, namely between 5 and 15 25 and 35 and 45 and 55 seconds of each minute, except in procedure 3), where the proximal cuff was inflated at the 7th 27th, and 47th second for 8 seconds Without wrist occlusion, the rate of the relative volume increment was high and was generally attributed to the increased rate of filling of the veins underneath the plethysmograph from the veins of the hand which normally have a large blood flow The agreement between the results obtained with procedures 2) and 3), and in the other subject, 3) and 4), indicates that the result does not vary with the type of occlusion. Thus, arterial wrist occlusion, introduced by Grant & Pearson (1938) and simultaneous application of distal and proximal venous pressure, recommended by Graf (1964 b), give corresponding values. We mostly used distal venous occlusion shortly before application of the proximal collecting pressure, as suggested by Professor Kruhoffer because it allows more precise determination of the initial slope (an artifact is avoided), and because procedure 2) may be unpleasant for the test subjects. Procedures 1) and 5) cannot, of course, be used for blood flow measurements, because the influence of the part distal to the segment plethysmograph is unknown and variable.

Pressure source Since compressed air from a central compressor system was available in the laboratory a simple inflatory–deflatory system was designed for securing venous-occlusion and venous-collecting pressure. All rubber tubes connected with the cuffs had an internal diameter of 9 mm allowing practically instantaneous inflation and deflation by the above system, consisting of a plastic bottle (15 liters) and a membrane manometer. The inflation and deflation was controlled by three magnetic valves timed to act automatically at an intermediate interval of 2 seconds

Calibration of the water plethysmograph The *recording system* was calibrated by injection of a known quantity of air with a well greased glass syringe into the system and measuring the galvanometric deflection.—In the daily routine work the *plethysmograph* was calibrated by injection of a known quantity of water into the water compartment (Fig 5) With the isothermic recording system described above, these procedures cause identical galvanometric deflections per ml volume reduction (*i.e.* no transmission loss—as mentioned previously). The deflection upon volume reduction corresponded to that upon volume increase, but occasionally slight hysteresis

was seen. The calibration was performed during breath-holding and with arterial occlusion by the proximal cuff.

If plethysmographs with thick sleeves are used, the equipment must, of course, be calibrated by injection of heparinized saline into the veins of the limb segment in the plethysmograph, (*i.e.*, 'limb calibration as recommended by Dahn 1964). We occasionally advanced a catheter from a hand vein into a vein located in the middle of the plethysmograph and in the axis of the limb and calibrated by injection of saline. *Limb calibration* is comparable to plethysmographic calibration in the water compartment, only if the sleeve fits well. During such calibrations the veins must be occluded at the upper and lower border of the plethysmograph during the injection.

With the above 3 procedures we found almost the same mean galvanometer deflection per unit of volume of air, of water and of heparinized saline (0.510—0.506—0.501 cm/ml, with 10 observations in each group)

Calculation of blood flow

During measurement of the flow the base line of the plethysmogram was essentially stable. Occasionally when base line drift was observed, no measurements were made until the cause, usually leakage, had been found and eliminated. The blood flow was defined as the tangent of the angle (v) between the base line and the initial slope during venous collection. The angle was measured with a protractor provided with a string (Dahn 1965). The blood flow was expressed in flow units (FU=ml blood/100 ml limb volume × min). The relevant constants (deflection on calibration, D cm/ml speed of recording paper S cm/min limb volume, V ml) were pooled to form a constant, C $100 \times S/D \times V$ as suggested by Dahn (1965), and $C \times \operatorname{tg} v$ gave the blood flow This method of calculation was used for air and water plethysmography

Air plethysmography

Dohn rubber plethysmographs and a transducer (Tybjerg Hansen 1949) with amplifier were kindly placed at our disposal by Dr. N A. Larsen, Department of Clinical Physiology Bispebjerg Hospital, Copenhagen. The Dohn plethysmogram was also recorded on the U V Recorder, with a suitable mirror galvanometer.

Recordings by the Dohn plethysmograph were compared with those by the water plethysmograph described above. Resting blood flow and flow at the end of 4 minutes arterial occlusion were recorded simultaneously

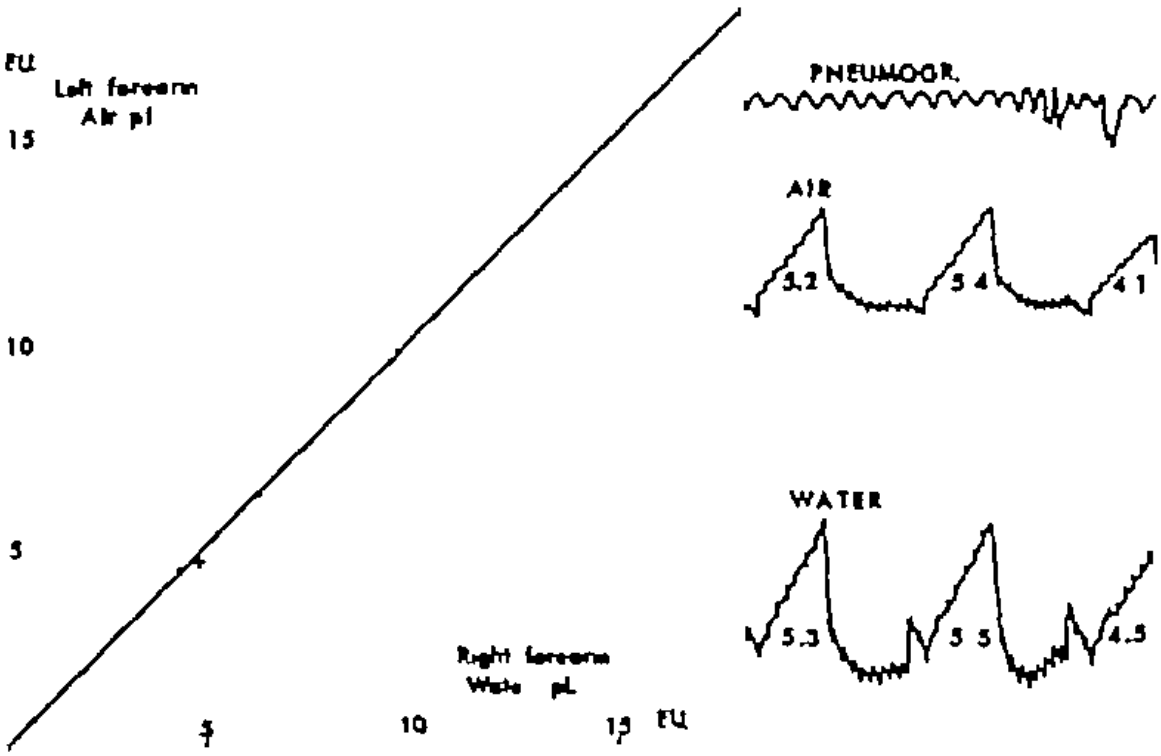

Fig 8 Comparison between air and water plethysmography The cross indicate the average (± SE) of the resting blood flow measured on 31 occasions. The points are paired individual figures. FU = ml blood/100 ml forearm × min.

on a normal subject with the water plethysmograph on the right forearm and the rubber plethysmograph on the left. A set of recordings is shown in Fig 8 The two methods gave essentially equal values at the same skin temperature, also when the mutual location of the two plethysmographs was changed to the opposite forearm. An agreement between two methods found in this way must be more difficult to attain, than by simultaneous measurements on the same arm, so the comparison between right forearm and left is considered fair. The low values (Fig 8) recorded with the Dohn plethysmograph, occurred simultaneously with an incidental temperature of 32 C underneath the Dohn plethysmograph, while the majority were measured at 33 to 34 C, as in the water plethysmograph.

In another normal subject the resting blood flow was recorded 30 times with the Dohn plethysmograph on the right arm, and thereafter 30 times on the left forearm. The mean value ±SE was found to be 3 6±0.04 and 3 7±0 03 FU respectively

Dohn (1916) found the error of a single measurement of the limb segment volume by the air displacement method to be ±7 %, and Graf (1964 b)

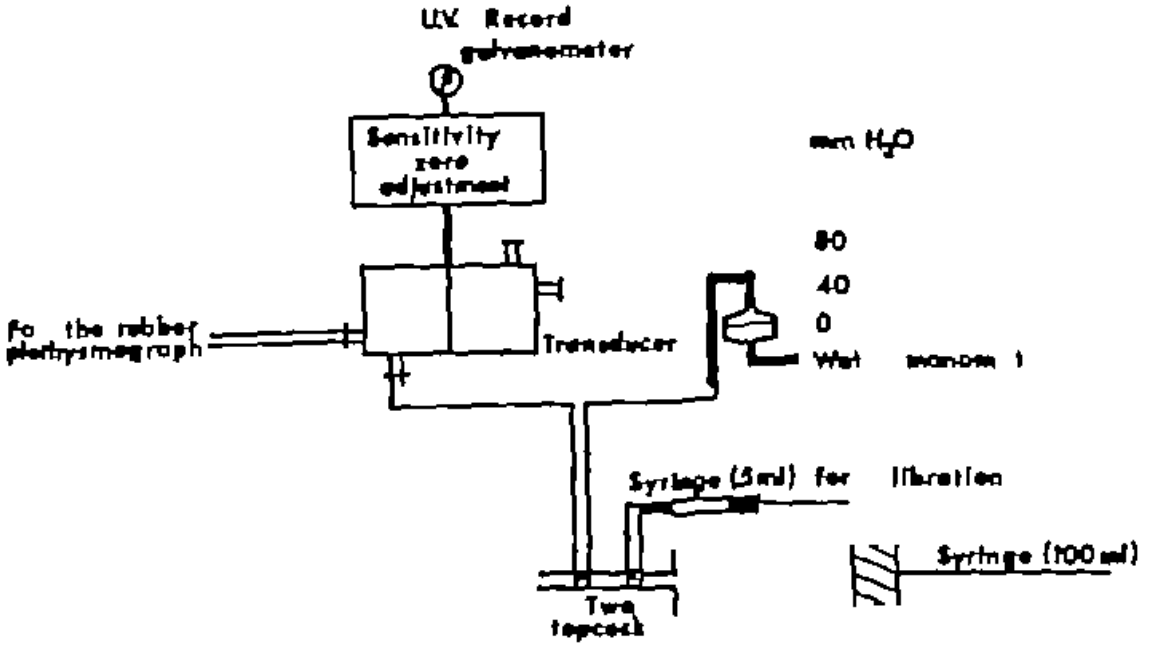

Fig. 9 Simplified design for use with Dohn's rubber plethysmographs. The pistons of syringes are kept carefully lubricated with grease.

and Munc (1967) gave roughly similar values. Since the elastic rubber plethysmograph can be applied to limbs of different thickness, Dohn's measurement of the volume by air displacement is not acceptable, regardless of the apparent accuracy attainable by repeated measurements on a single limb. Results from the air displacement method were not always in accordance with water displacement measurement and with calculation of volume, while the later two methods always agreed well mutually Therefore, these two methods were preferred.

Graf (1964 b) found the error of measurement of the air plethysmography recording device, including the plethysmographs by ± 3.2 % SD (from the pressure level (40 mm H_2O) in the cuff). Values for the apparent rate of arterial inflow of 0.5 to 40 ml/100 ml × min can be measured with sufficient accuracy by venous occlusion plethysmography (Graf 1964 b). A subdiastolic pressure in a proximal cuff produces a negligible decrease of the arterial inflow and thus does not naturally alter the variable to be measured in venous occlusion plethysmography (Graf & Rosell 1964 b).

If a suitable transducer recorder system is available, air plethysmography can be performed with the equipment shown in Fig 9 With simultaneous

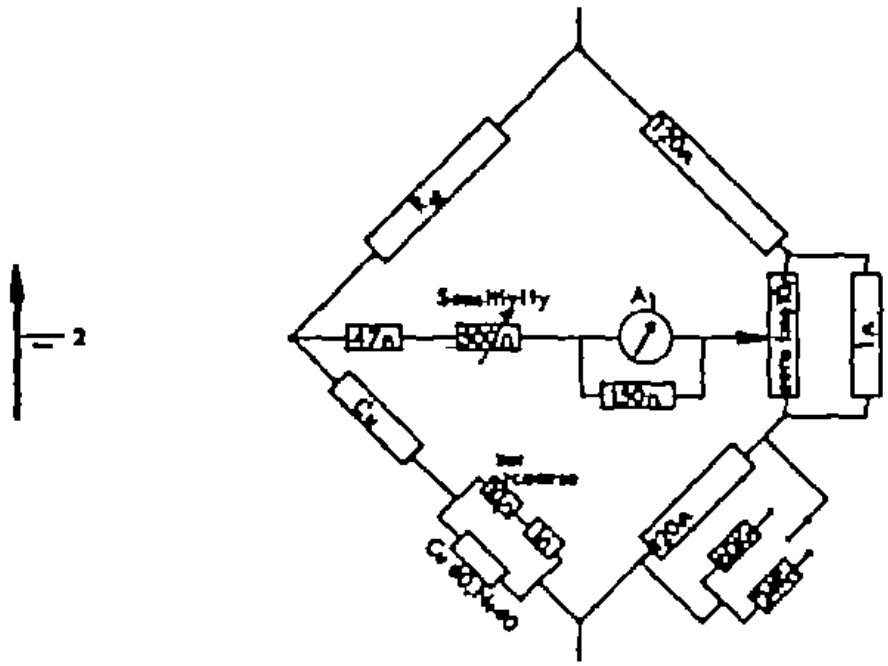

Fig 10 Diagram of the strain gauge supply and Wheatstone bridge circuit. Two separate bridges are used simultaneously The copper wire (Cu) has a resistance of $0.28 \times R_{st}$ and mounted on the strain gauge (R_{st}) The resistance (Cu 60, Ni 40) is—as indicated—of constantan and its size is $0.76 \times R_{st}$ The galvanometer type A_1 (ABEM), is used with a damping resistor of 150 ohms. The 120 ohms resistors are highly stabilized. The 1 % resistors for electrical calibration (60 and 24 Kohms) is of the metal film type, and corresponds to a resistance change of 0.2 and 0.5 ‰, respectively

recording of the temperature underneath the rubber plethysmograph, for comparison with blood flows obtained by others this method may seem convenient.

Strain gauge plethysmography

Whitney's (1953) power supply for the two Wheatstone bridges carried the sensitivity adjustment, common to the two channels at the input side of the circuit, with the consequence that the input voltage to one strain gauge would change, if the other was disconnected during the procedure. In the present study the power supply was highly stabilized with a variable output voltage (0 to 40 V) and a maximal current of 1 amp. The output voltage was fixed at 2 V In order to maintain an accuracy of 1 % on the electrical calibration (Horeman 1958), the 10 ohm zero-fine-potentiometer was shunted with a 1 ohm precision resistor Further modifications are shown in Fig 10

Blood flow was calculated from strain gauge curves in the following way The strain gauges were exact copies of the original gauges used by Whitney (1953), and provided from A. B Charteres, London School of Hygiene. Before the method was adopted for the experiments with breath-holding the strain gauge principle was systematically examined. Whitney mounted the gauge at a tension of 20—30 g We measured the galvanometer deflection by changing the resistance of the Wheatstone bridge circuit (Fig 10) with 0 5 % when the two strands of the gauge were loaded with 10, 20 30, 40 50 and 60 g The galvanometer deflection (*i.e* change in bridge output) was naturally found to be constant, with exactly the same deflection at 20 30, and 40 g An initial tension of 30 g was therefore used throughout.—In venous occlusion plethysmography the variable of interest is the relative change of limb volume (dV/V) per unit of time. Whitney's first assumption is that the entire change in volume of the limb is due to corresponding changes of the transverse sectional area of the limb, with no significant change in length (1953) Whitney also assumed that the transverse section was circular, and that the shape of the section remained unaltered during expansion or contraction. Therefore, if R is the radius of the circular section, it is obvious, if the absolute change in area (A) is small (dA) that the relative change in area (dA/A) will be $2R\ dR/R^2 = 2\,dR/R$, if $(dR)^2$ is small, and the relative change in circumference $2\,dR/2\,R = dR/R$. The relative change in the volume of the limb is therefore equal to twice the relative change in its circumference or girth (dG/G), the change in girth is assumed to be identical with the relative change of the gauge length (dl/l). The resistance of a conductor (r) equals Specific resistance × length/area, so that if the volume of the conductor is constant, dl/l will be half the relative change of the electric resistance, dr/r Hence, dV/V equals dr/r The strain gauge is connected in a Wheatstone bridge (Fig 10). A 0.5 % relative change of the resistance of one of the normal resistors (120 ohms) will cause a galvanometer deflection (d_e) of the same magnitude as a 0.5 / change in resistance of R_{st} (Fig 10). In this way the strain gauge can be calibrated electrically Thus the galvanometer deflection (d_e) corresponded to ½ ml/100 ml limb volume, and $2 \times d_e$ cm ordinate to 1 ml blood per 100 ml. The number of flow units was simply calculated with the equation $FU = S \times \operatorname{tg} \nu/(2 \times d_e)$ where S is the speed of the paper of the recorder in cm/min.

A strain gauge placed on a forearm with a girth of 28 cm showed a galvanometer deflection of 1 1 cm by reduction of the "gap" (Whitney 1953) with ½ mm (*i.e* a relative change in length of 0.178 %). According to this result a similar relative change in volume of 0 5 % should show

a galvanometer deflection of 1 54 cm. However an electrical calibration with a 0 5 % change in resistance gave a deflection of 2.35 cm. When the gauge was detached from the arm and placed horizontally between two fixed points where the length could be altered with an accuracy of ±0.01 mm, a change in length of exactly ½ mm showed a galvanometer deflection of 1 65 cm corresponding to 2.35 cm at a relative change in length of 0.25 % (*i.e.*, a change in resistance of 0.5 %). Thus correct physical calibration is in accordance with the electrical calibration, while the gap reduction on the limb, as suggested by Whitney yields much too low galvanometer deflections. Such a "calibration" should be avoided.

Blood flow was measured on a forearm with a water plethysmograph and with a strain gauge applied in the usual way (Whitney 1953), and close to the proximal border of the plethysmograph. A double loop of mercury in rubber, from one of Whitney's strain gauges, was fixed by rolling a piece of Scotch tape around the gauge at one site (1 cm wide) after which the gauge was placed underneath the sleeve of the water plethysmograph. With these three devices 31 resting blood flows were measured simultaneously and the two strain gauges were calibrated electrically The average value ±SE was 6.2±0 2 FU for the water plethysmograph and 5.2±0 2 FU for the double loop gauge beneath it, while the classical strain gauge close to the water plethysmograph only gave 4.1±0.2 FU although the temperature of the skin underneath it, was almost as high as in the water plethysmograph (33 6 C as compared to 34.1 C). Assuming —at this occasion—the water plethysmograph to measure approximately true blood flows, then the gauge surrounding the entire limb does not measure true values, and the gauge applied as suggested by Whitney with only 2/3 of the circumference in contact with the limb and 1/3 with the mounting plate, gives even lower values. Expansion of the limb covered by the mounting plate may not to its total extent increase the length of the mercury in rubber and hereby lead to fictitiously low results when the blood flow is measured with such a design.

Whitney (1953) found the 'blood flow' measured with strain gauges, to be 20 % larger (Fig. 11) than that indicated by simultaneous measurements with a water plethysmograph, a difference which may be due to his inadequate mechanical calibration and to the fact that his strain gauge was in contact with the limb only over 2/3 of the circumference. It is no consolation that these two pitfalls—under certain conditions—can eliminate each other and produce the same average value as the water plethysmograph. Horeman (1958) and Brakkee & Vendrik (1966) who introduced the electrical calibration, did not report on any comparison between the elec

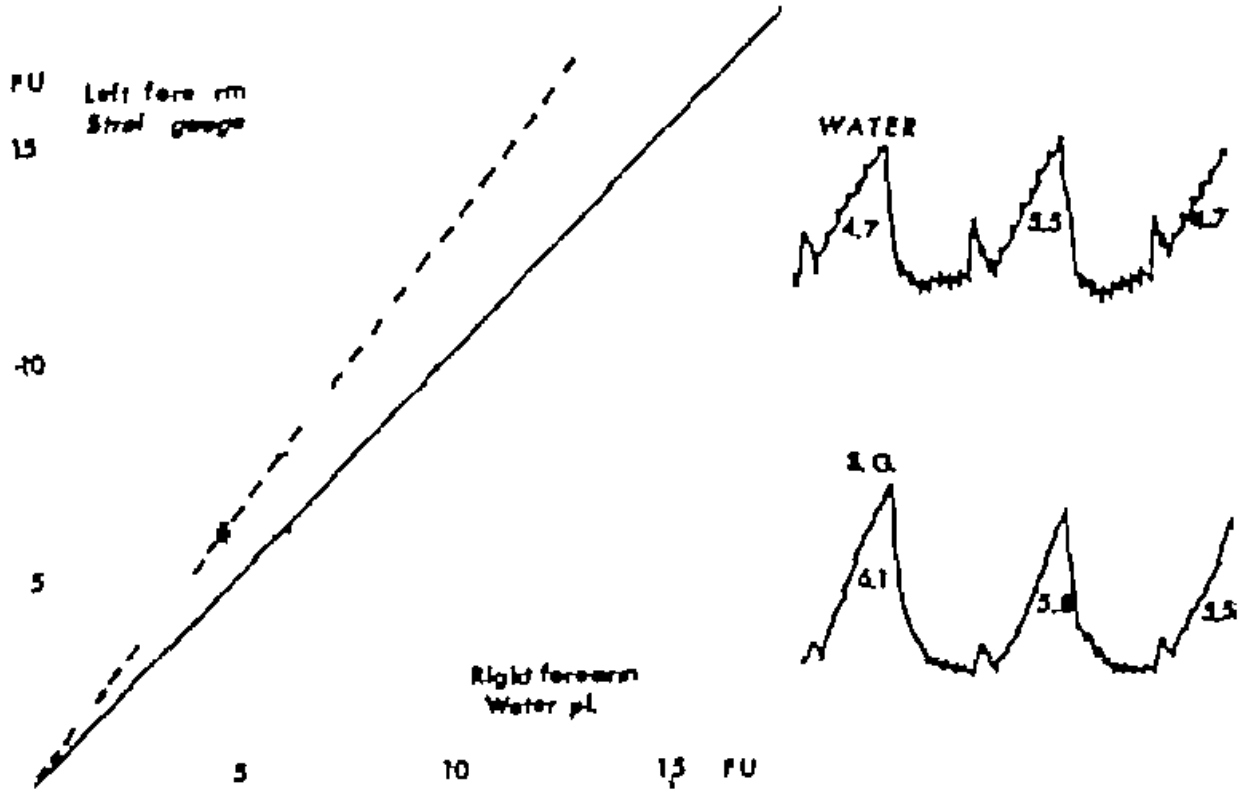

Fig. 11 Comparison between strain gauge and water plethysmography. The above strain gauge results are calculated on the basis of Whitney's original, mechanical "calibration" on the arm. *The cross is the average value (± SE) of 31 determinations.*

trical and the mechanical ('gap reduction) calibration, and seem to have preferred the electrical calibration and a gauge covering the whole circumference for practical reasons. As shown above even these improvements do not permit the strain gauge to measure true blood flows, as judged by the results from the water plethysmograph.

Although serious objections might have been raised against Whitney's method, it is emphasized that blood flow *variations* can be measured with reasonable accuracy with strain gauges, as shown in Table 12.

E. AUXILIARY EQUIPMENT

In classical physiological studies "body temperature" ('core temperature') in man is preferably measured per rectum. Recently Benzinger & Taylor (1963) suggested intracranial temperature (tympanic membrane and nasal cavity) as the measurement of choice. The tympanic membrane—like the anterior ethmoidal region, the anterior wall of the sphenoid sinus, and Rosenmueller's fossa—are supplied with blood from internal branches of

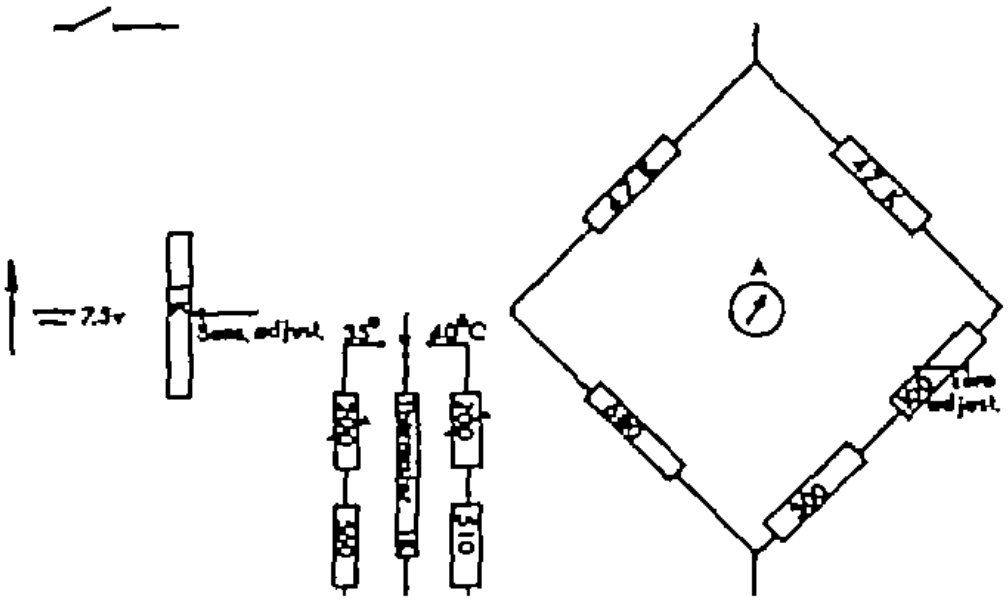

Fig. 12 Thermistor circuit. Philips thermistor type E 214 AE/P 1 K. The thermistor can be calibrated electrically at 35 and 40°C. The maximal sensitivity is 14 mm galvanometer deflection per degree (C). The galvanometer type A (ABEM) has an internal resistance of 110 ohms and is critically damped with 900 ohms. The sensitivity is 10 mm/A at a distance of 30 cm from the mirror. All fixed 1 % resistors are of the metal film type, and the resistance is given in ohms.

the carotid artery. Temperatures measured simultaneously at these sites showed similar relative changes during drastic changes of the external or digestive tract temperature, indicating that hypothalamic temperatures vary in the same way unless the local blood flow and generation of heat varied from one area to another (Benzinger & Taylor 1963). During corresponding drastic environmental changes, the (mutually identical) temperature changes in the cranium were greater and faster than those recorded in the rectum.

Benzinger & Taylor (1963) preferred thermocouples because their response is essentially linear over a wide temperature range (zero to 50 C). In the present study thermistors were used because they could be made equally linear in response over a sufficient large temperature range, and because they could be used directly with the mirror galvanometers available, without amplification. A simple electric calibration was found convenient (Fig. 12). Normal resistors equal to the thermistor resistance at 35 and 40 C were introduced into the bridge circuit instead of the thermistor

(Fig 12). The minithermistor was moulded in araldite and held against the eardrum by a plug of foam rubber The test subjects tried to place the thermistor at the eardrum, always with great care. A light touch of the eardrum elicits a pain sensation of short duration. A minithermistor of the same type was also placed on the skin. The temperatures were read to the nearest 0.1 C. In the course of the earlier experiments, the temperature of other thermistors placed in the rectum or on the skin, were read routinely

By definition a thermometer measures only the temperature of the thermometer. Thus, a so-called "absolute, true temperature" is, at best, a recorded figure with a careful description of the environment in which the bulb is located. The magnitude of some of the tympanic membrane temperatures (Fig 29—31) obtained, indicates that the test subject had not placed the thermistor *on* the eardrum but probably close to it, during these experiments.

Control of intracranial, body surface, and environmental temperature is important when alteration in successive blood flow measurements are to be attributed to other factors. Recording of the respiratory pattern, as a control of normal breathing is equally imperative to exclude flow changes of respiratory origin. In the present experiments the signals from a pneumograph or a pneumotachograph, were therefore always recorded on the U V recorder via a Statham transducer

PART II

PROCEDURES, RESULTS AND DISCUSSION

CHAPTER 5

Breath holding and decompression sickness

As mentioned in the introduction, serious accidents had occurred during training in the submarine-escape tank in Norway. Information obtained at personal interviews with the men and from their case reports (dizziness, eructation, fatigue, pains, pareses, and paralysis, *i.e.*, severe neurological phenomena, immediately relieved by recompression) suggested decompression sickness as the cause of these accidents, *i.e.*, an explanation incompatible with the general consensus of opinion at that time. To check the tenability of such an explanation I dived 60 times to depths of 15—18 meters and occasionally to the bottom of the tank. These dives were performed within a total period of 5 hours. The pattern of each dive ('bottom drop') was as follows: The mean rate of descent was 0.8 meter/second, which implies that the diver took 15 seconds to reach the bottom of the tank, where he remained (rested) prone until the urge to breathe became irresistible. This occurred within one to two minutes, and then he climbed, as quickly as possible, up a rope suspended from above the tank. The rate of ascent was about 1.5 m per second. The interval between consecutive dives varied from a few seconds to one or two minutes.

After three hours' diving symptoms began to appear. Increasing nausea, dizziness and eructation, and after the last dive, mild pain in the left hip. Later the pain became more intense and the right knee also became painful. The right leg and arm felt abnormally weak, and it was difficult to walk and even to stand. After about 2 hours there was severe chest pain that could not be relieved by expiration or by change in posture. The pain was accompanied by inspiratory distress and by a sensation of imminent fainting: paresthesia of the right hand and dullness of vision. After a further hour a colleague found me markedly pale and weak, as if I were about to faint. He examined me and confirmed the visual disturbances and paresis of the right arm. The symptoms and signs progressed and abdominal pain and anesthesia of the ulnar region of the right hand supervened. I was then placed in a recompression chamber. At 6 atm abs the dizziness and nausea disappeared immediately and 5 minutes later the pain and partial paresis regressed and after 25 min at 6 atm abs the paresthesia and anesthesia disappeared, leaving only a feeling of pins and needles in the right hand. I was therefore given treatment according to Table 5 of the U.S. Navy

treatment table (U S Navy Diving Manual 1963), which requires about 20 hours in the recompression chamber. The chest pain, accompanied by an intense feeling of fear of death, reappeared for a few minutes every time the pressure was reduced in the process of stage decompression. The treatment was successful except for persistent weakness of the right hand.

Similar symptoms and signs were experienced by three Norwegian escape-training tank instructors. Cross (1965) has reported a syndrome called taravana among the skin-diving pearl divers of the Tuamotu Archipelago in the South Pacific when severe it comprises loss of consciousness and paralysis of one or more limbs, and it is often fatal. The similarity between the diving patterns of the pearl divers and of subsequent symptoms of taravana and those in the Scandinavian cases described here suggest that the underlying mechanism was the same in both disorders. The response of taravana to recompression has not yet been investigated. The symptoms and signs described are consistent with the diagnosis of decompression sickness. The dramatic response to recompression can probably be explained only on the basis of bubbles in the central nervous system (for further discussion, see ref. *A B*)

Despite convincing evidence of bubbles in the nervous system and other tissues it was still debatable whether they were due entirely to increased tissue nitrogen tensions, as in ordinary decompression sickness, or whether molecules of other dissolved gases, particularly carbon dioxide, might have contributed to the bubble formation.

Since it is extremely difficult to measure mean tissue nitrogen tensions, even in animals the tissue nitrogen tensions were calculated from observed alveolar nitrogen percentages (ref. *B*). The calculation of the tissue nitrogen tensions during repeated breath-hold dives rests on some simple arguments advanced in the famous work on decompression sickness by Boycott, Damant & Haldane (1908) Calculations of nitrogen tissue tensions (here called P_tN_2, in the equations called Y) for hyperbaric exposures are time-consuming. More than 30,000 P_tN_2 calculations were necessary for a systematic examination of all variables. The calculations were made with the use of an electronic computer (GIER, programmed in ALGOL 60). The calculations are based on alveolar nitrogen fractions from samples obtained from divers at the bottom of the submarine-escape training tank. Fig 13 shows the increase in alveolar nitrogen percentage as a function of time (the time of descent plus the time at depth) Assuming that the increase of the F_AN_2 was linear the mean F_AN_2 was 0 83 for one minute breath-hold dives and 0.88 for the two-minute dives. To simplify the calculations it was assumed that the subject was exposed to the mean F_AN_2 values during the entire exposure

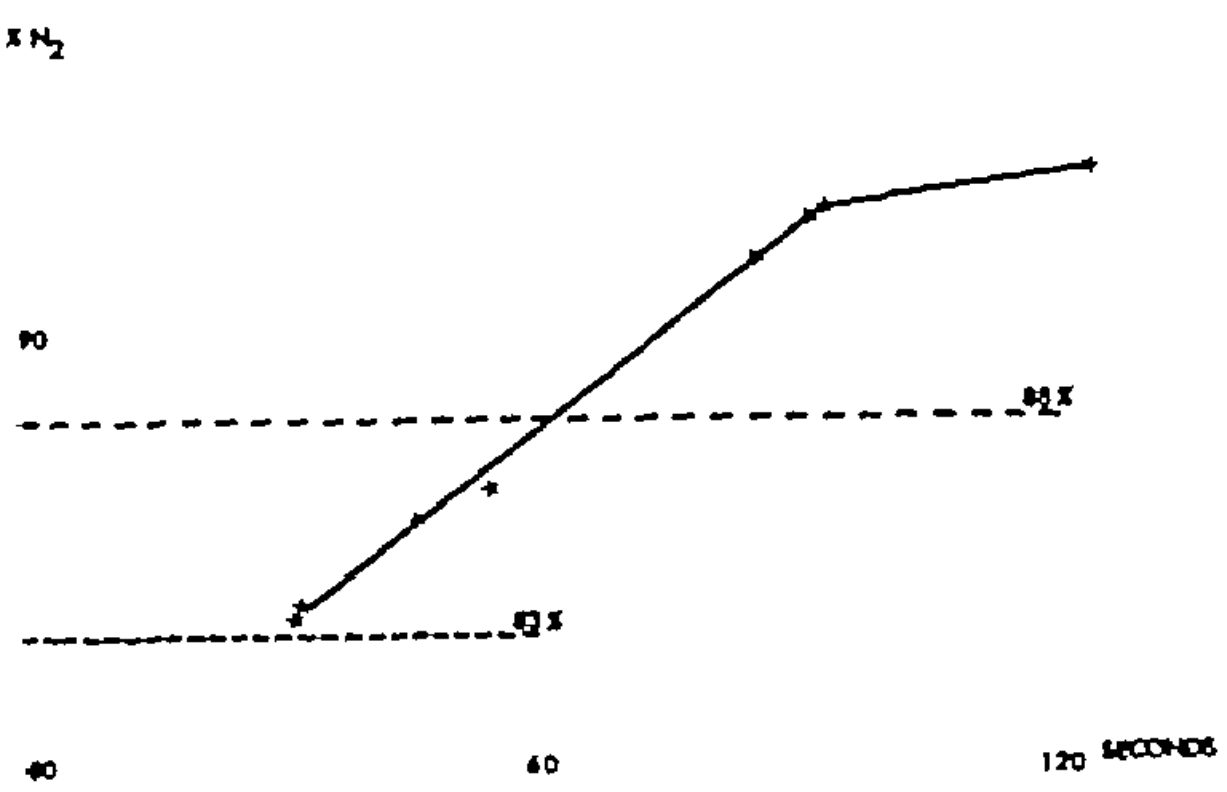

Fig. 13 N_2 percentages from alveolar samples obtained at the bottom of the submarine escape training tank. The abscissa is the period from the start of the dive to the time of sampling

time. The exposure time is defined here as the total time under water, and the surface interval as the time from the end of one dive to the beginning of the next.

The human body may be regarded as a complex of tissues, each 'tissue unit' absorbing or eliminating N_2 exponentially with and individual half time of saturation and desaturation. The half-time is the number of minutes necessary to produce P_tN_2 changes equal to half of the P_{N_2} difference initially existing between the arterial blood and the tissue. The nitrogen tensions before and after each of 48 dives were calculated on the basis of the body model consisting of an array of tissues with 5- 10- 20- 40- 80- and 120-minute half-times, as conventionally assumed in such calculations of N_2-exchange (Yarbrough 1937 Dwyer 1956 Workman 1965) The hypothetical P_tN_2 values obtained for an infinite number of dives—mathematical limit values (lim X_n and $\bar{X}_n$, see ref. *B*)—were also calculated. All P_tN_2 values were expressed in mm Hg and calculated with an accuracy of two decimals. When a P_{N_2} difference occurs between the arterial blood and a tissue, the rate of change in P_tN_2 will at any time be a constant fraction of the prevailing P_{N_2} difference. To describe the rate of the change in P_tN_2, the

treatment table (U S Navy Diving Manual 1963) which requires about 20 hours in the recompression chamber. The chest pain, accompanied by an intense feeling of fear of death, reappeared for a few minutes every time the pressure was reduced in the process of stage decompression. The treatment was successful except for persistent weakness of the right hand.

Similar symptoms and signs were experienced by three Norwegian escape-training tank instructors. Cross (1965) has reported a syndrome called taravana among the skin-diving pearl divers of the Tuamotu Archipelago in the South Pacific when severe it comprises loss of consciousness and paralysis of one or more limbs, and it is often fatal. The similarity between the diving patterns of the pearl divers and of subsequent symptoms of taravana and those in the Scandinavian cases described here suggest that the underlying mechanism was the same in both disorders. The response of taravana to recompression has not yet been investigated. The symptoms and signs described are consistent with the diagnosis of de compression sickness The dramatic response to recompression can probably be explained only on the basis of bubbles in the central nervous system (for further discussion, see ref. *A B*)

Despite convincing evidence of bubbles in the nervous system and other tissues it was still debatable whether they were due entirely to increased tissue nitrogen tensions as in ordinary decompression sickness, or whether molecules of other dissolved gases, particularly carbon dioxide, might have contributed to the bubble formation.

Since it is extremely difficult to measure mean tissue nitrogen tensions, even in animals, the tissue nitrogen tensions were calculated from observed alveolar nitrogen percentages (ref. *B*). The calculation of the tissue nitrogen tensions during repeated breath-hold dives rests on some simple arguments advanced in the famous work on decompression sickness by Boycott, Damant & Haldane (1908) Calculations of nitrogen tissue tensions (here called P_tN_2, in the equations called X) for hyperbaric exposures are time-consuming More than 30,000 P_tN_2 calculations were necessary for a systematic examination of all variables. The calculations were made with the use of an electronic computer (GIER, programmed in ALGOL 60) The calculations are based on alveolar nitrogen fractions from samples obtained from divers at the bottom of the submarine-escape training tank. Fig 13 shows the increase in alveolar nitrogen percentage as a function of time (the time of descent plus the time at depth). Assuming that the increase of the F_AN_2 was linear, the mean F_AN_2 was 0 83 for one minute breath-hold dives and 0.88 for the two-minute dives. To simplify the calculations it was assumed that the subject was exposed to the mean F_AN_2 values during the entire exposure

the equilibrium tension may be expressed as a percentage of the largest possible P_{N_2} increment. The largest P_{N_2} increment (mm Hg) possible in the tissues at F_{AN_2} values of 0.83 and 0.88 respectively depends upon the depth (expressed in m of fresh water pressure) of the dive $[[((depth/10 + 1)\ 760) - 47]\ F_{AN_2}] - 567$. This percentage is called the equilibrium saturation percentage of a tissue with a given half-time. In the calculations of the equilibrium tensions for tissues with different half-times, from a representative exposure, the coefficient of variation (SD 100/x) was found to be as small as 2 %. One may therefore talk about a mean equilibrium N_2 tension for the whole organism (P_{tN_2}).

The arithmetic mean (MESP) of the equilibrium saturation percentages of all tissues considered is calculated to express the degree of N_2 saturation obtainable for the organism as a whole. This is done in the following equation

$$MESP = \frac{[\Sigma(\lim Y_n + \lim X_n)/12 - 567]\ 100}{[[((depth/10 + 1)\ 760) - 47]\ F_{AN_2}] - 567}$$

Corresponding to the two P_{tN_2} arrays there are two mathematical limits for each of the six tissues of different half-times and $\Sigma(\lim X_n + \lim X_n)$ is the sum of these twelve limits. For further details see appendix (ref. *B*).

Critical N_2 tensions

On the basis of experiments with air-supplied diving a number of maximum permissible P_{tN_2} (max tens) levels have been specified for each half time tissue (Workman 1965). These are (critical) tensions above which decompression sickness is likely to occur. If the form of analysis described is correct, it should be possible to exceed the max tens, by repeated breath-

Table 4. Number of dives necessary to exceed the maximum allowable tissue N tension (max tens) in different half-time tissues.[1]

Tissue, half-time	5	0	20	40	80	120

Surface intervals are of 1 min duration, exposure times of min duration.
Indicated only if max tens is exceeded within the calculated 48 dives.

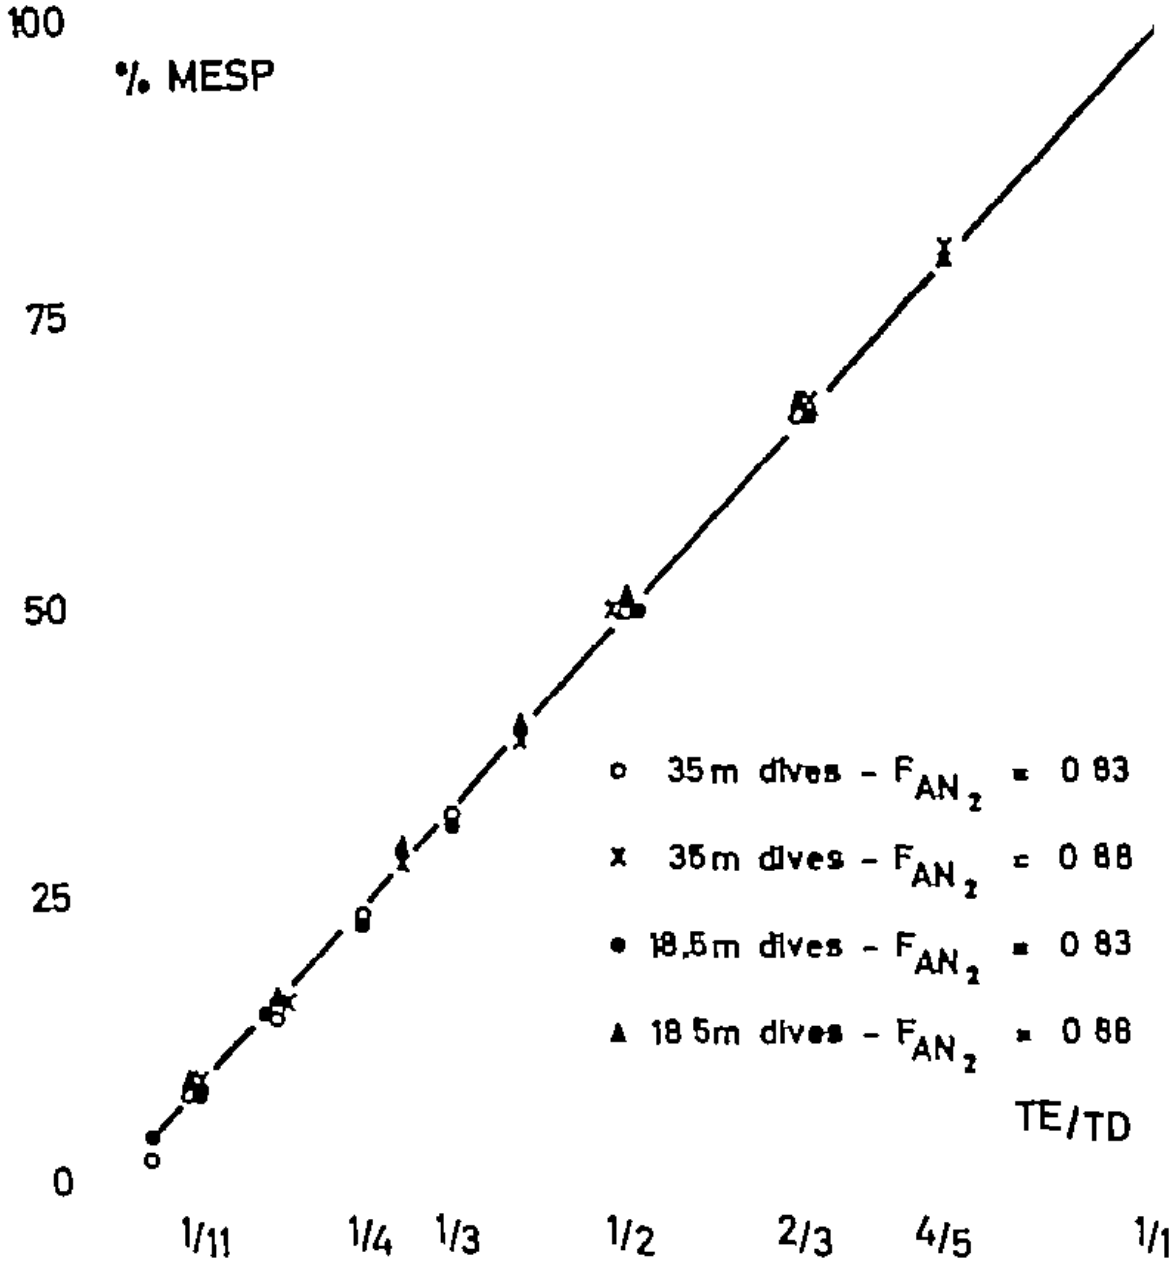

Fig. 15 Mean equilibrium saturation percentage (MESP) at different exposures. The ratio of total exposure time (the sum of all exposure times) to total time of diving series (the sum of all exposure times and all surface intervals) is the abscissa (TE/TD). The calculations are based on surface intervals of ½ 2, 5 10, and 20 minutes duration.

hold diving (Fig 14 and Table 4) and thereby explain the decompression sickness observed (ref. *A*), entirely on the basis of gradually increasing P_{IN_2} values during repetitive diving The observed serious neurological signs disappearing after decompression indicate that the P_{N_2} of the central nervous system is the decisive cause of this condition. This does not, of

course, rule out the possibility of other contributory factors such as the progressive CO_2 retention (ref. *C*) In addition the increased CO_2 tensions in the tissues might favour formation and growth of the bubbles by speeding up the delivery of CO_2 to the bubbles.

N_2 saturation degree

The total exposure time (TE) is defined here as the sum of all exposure times during series of dives. The total duration of a diving series (TD) is defined as the sum of all exposure times and surface intervals during repeated diving Analysis of the MESP equation after substitution of the expressions for $\lim \lambda_n$ and $\lim X_n$ (see appendix, ref *B*) showed that MESP is governed essentially by the ratio between TE and TD As apparent from Fig 15 the relation between MESP and the TE/TD ratio is essentially linear the variation of MESP with the F_{AN_2} and the diving depths is negligible.

When depth and duration of an air-supplied dive do not exceed certain limits, called no-decompression limits (Workman 1965) direct ascent to the surface without stage decompression is considered safe (Workman 1965) But the so-called no-decompression limits" refer to conventional, air-supplied diving and may not be valid for breath-hold diving because of essential differences such as the difference in rate of ascent. The conventional no-decompression limits may therefore not be safe when applied in actual diving A practical procedure for evaluating the risks accompanying a series of breath-hold dives is suggested below At the Mangareva Islands in the South Pacific the native divers use surface intervals of about 10 min. No cases of the decompression sickness-like taravana syndrome are known there, but cases have been known to occur on the neighboring islands (Cross 1965) where the divers use shorter surface intervals. These observations are explained by the low MESP during breath-hold dives with long surface intervals (*i.e.* corresponding to low TE/TD ratios with only a minimal risk of decompression sickness) Thus, surface intervals of 10 min seem to eliminate the risk of decompression sickness during repeated breath-hold diving with exposure times and depths acceptable for humans.

Practical application

The MESP can be determined from Fig 15 and an estimation of the TE/TD ratio in actual diving series. The actual mean equilibrium N_2 tension is calculated by inserting this MESP value, the diving depth and the F_{AN_2} (dependent upon the exposure time) in the MESP equation.

According to Haldane's old rule for air-supplied dives, stage decompression is not necessary as long as the ratio between total pressure at depth and the pressure decrease during ascent does not exceed 2/1 (Boycott et al. 1908). Instead of Haldane's ratio between the total pressure at depth and the pressure decrease during ascent, one may use the ratio between the N_2 partial tension for the whole organism (*i.e.*, P_tN_2, which is dependent upon P_AN_2, here assumed to be 0.85) and the pressure decrease by ascent (*i.e.* for a MESP of 100 % $2 \times 0.85 = 1.7$), yielding a new ratio of 1.7/1. Conventional standard air decompression tables now give a ratio lower than 2/1 in order to increase the safety margin for air-supplied dives. Decreasing the 1.7/1 ratio to a reasonable value for repeated dives, such as a 1.5/1 ratio, of course increases the safety margin still more. If the ratio actually determined between the mean equilibrium P_tN_2 and the pressure decrease (expressed in mm Hg) by decompression is below 1.5 such a small P_tN_2 reduction is not likely to provoke decompression sickness. Under these conditions the planned skin diving series may be considered safe—as far as N_2 is concerned. If the actual ratio is found to be equal to or higher than, 1.5/1 the planned diving series should be cancelled.

Conclusions

Repeated breath-hold diving with insufficient intervals at the surface between consecutive dives can cause decompression sickness, especially if simulated or compressed air-supplied dives have been performed on the same day. Long surface intervals are recommended when repeated breath-hold dives are performed to depths of 10 m or more. The severe neurological signs (paralysis, visual disturbances ect.) reported, emphasize the danger of a long series of repetitive breath hold dives to greath depth. It is therefore preferable in practice to use a calculation of the TE/TD ratio (Fig. 15) and a generous safety margin from Fig. 15 to avoid decompression sickness, instead of using more specific time limits (Lanphier 1965, ref. *A*). It appears that the symptoms and signs observed in breath-hold divers can be explained entirely by the gradual increase of the P_tN_2 during repeated diving, but synergistic mechanisms may still participate in the development of tissue bubbles.

CHAPTER 4

Carbon dioxide retention and hypoxia as a cause of loss of consciousness and drowning

Craig, Jr., (1961 a, b) studied swimmers who hyperventilated before they dived into an ordinary swimming pool, where they swam 50 m in the horizontal plane just underneath the water surface. He ascribed diving accidents under such circumstances to loss of consciousness due to hypoxia. By hyperventilation the underwater swimmer depletes the carbon dioxide (CO_2) stores of his body The partial pressure of CO_2 in the nervous tissue regulating the ventilation seems to be the main stimulus of respiration, the contribution by the low oxygen (O_2) partial pressures being relatively small. During underwater swimming the diver uses up O_2 and produces CO_2, but since the CO_2 is used for repletion of the partly emptied CO_2 stores, the drive for respiration and for surfacing does not become imperative, and the breath-hold dive may end in loss of consciousness and drowning In other words, after hyperventilation prior to underwater swimming, the integrated respiratory drive during underwater swimming, created by the falling O_2 tension and the rising—but still subnormal—CO_2 tension, may be on a level, where it is not an effective stimulus of respiration, at the same time as the O_2 tension of the cerebral cortex is low enough to cause blurring of the mind, rapidly proceeding to loss of consciousness.

These considerations may apply also to drowning after breath-hold diving to great depth, but the evidence available is too little to warrant any conclusions. Schaefer & Carey studied one diver in the submarine escape-training tank at New London (1962). Lanphier & Rahn (1963) and Hesser (1965) described gas exchange during simulated breath hold diving, but these observations have been obtained in pressure chambers without water and the breath-holds were either of a rather short duration or O_2 was breathed prior to the breath-hold, in order to obviate the possibility of unconsciousness. The many studies of Korean and Japanese divers, who mostly perform short dives during which dangerous O_2 and CO_2 tensions (P_{O_2} and P_{CO_2}) are rarely reached, also seem to have had another purpose than studying the risks of extreme breath-hold dives.

To elucidate factors responsible for loss of consciousness and drowning during breath-hold diving to extreme depth and of long duration, the O_2 uptake, CO_2 retention, and alveolar air composition (P_{AO_2} and P_{ACO_2}) were measured during and after a single or series of breath-hold dives in

water and compared with those made during similar breath-holds in air

The dives were performed in the above described submarine-escape training tank (Fig 1) by the so-called 'bottom drop technique, according to which the diver remains vertical and descends feet first. He wore a nose-clip and a pair of pressure compensated goggles (Royal Navy type) Before and between the dives the diver rested submersed up to the neck at the edge of the tank. Before the diving the diver hyperventilated by taking 2 breaths and after a third, a maximal inspiration, pushed himself downward with the arms from the border of the tank, and descended without further movement of the limbs. After the first 2—3 meter loss of buoyancy owing to compression of the lung gas resulted in his descent to the bottom with increasing speed. The mean rate of descent was 0.8 m/sec. After lying a varying time flat on the bottom of the tank, he pulled himself up on a rope fastened above the tank. He ascended at a mean rate of 1 5 m per sec. Five submarine-escape training tank instructors and the author participated in the experiment. The main experiments were undertaken by three of these.

The mean diving time—total time under water— is shown in Table 6. In the single-dive series the diving time reached 124 seconds Attempts to stay as long as possible under water were discouraged. None of the test subjects ever lost consciousness. For the sake of safety surface intervals, (*i.e.*, total time between two successive dives) were between one and two minutes. Subjectively sufficient restitution to permit a new dive was obtained after the first few respirations in all subjects.

Composition of alveolar air

Before diving The effect of repetitive diving is apparent from Table 5 where the mean pre-dive tensions (last) illustrates the degree of pre-dive hyperventilation (here defined as a ventilation producing a P_{ACO_2} below normal level) Most dives were performed after mild hyperventilation (Subject EE and OL). Dives after violent hyperventilation (Subject PP) were unpleasent, mostly because of dizziness during the descent.

At end of dive. Twenty-one samples (7 × 3) were obtained after repeated dives to 18 5 m. As already found by Lanphier & Rahn (1963) in 10 m simulated dives, average P_{ACO_2} values were not far from normal (Table 5). In the very first expiration after each dive the P_{AO_2} values were usually about 60 mm. Two breaths later they were near normal. Some of the P_{AO_2} values of PP were very low (minimum 30 mm), primarily because of the longer diving time. Simultaneously the P_{ACO_2} had again fallen to values below normal. When surfacing the diver was cyanotic and at the

Table 5 Mean alveolar air composition before and after seven repeated dives.

Subject	Sample	PO_2, mm Hg	PCO_2, mm Hg	R

border of unconsciousness (Craig 1961 b, Lanphier & Rahn 1963 Otis et al. 1946 b).

In evaluation of the relative contribution of hypoxia and hypercapnia to unconsciousness, it would be desirable to know the gas tensions in the central nervous system at the end of the dive. The partial pressures of the alveolar air at the time of sampling are not ideal measures of these tensions. While alveolar gas tensions fall rapidly during a fast ascent, due to the expansion of the lung gases accompanying the decompression, this de compression does not by itself affect the gas tensions in the tissues. Since the tissue gas tensions do not drop instantaneously to the tensions prevailing in the blood entering the tissue and since the passage of blood from the lungs to the tissues takes time changes in tissue tensions must be expected to lag behind the tensions of the alveolar air at the time of surfacing

Single breath hold dives. Fig 16 shows the composition of the alveolar air during the dive. The samples are obtained while the diver is at the bottom of the tank. Each diver made only one dive (provided only one sample)

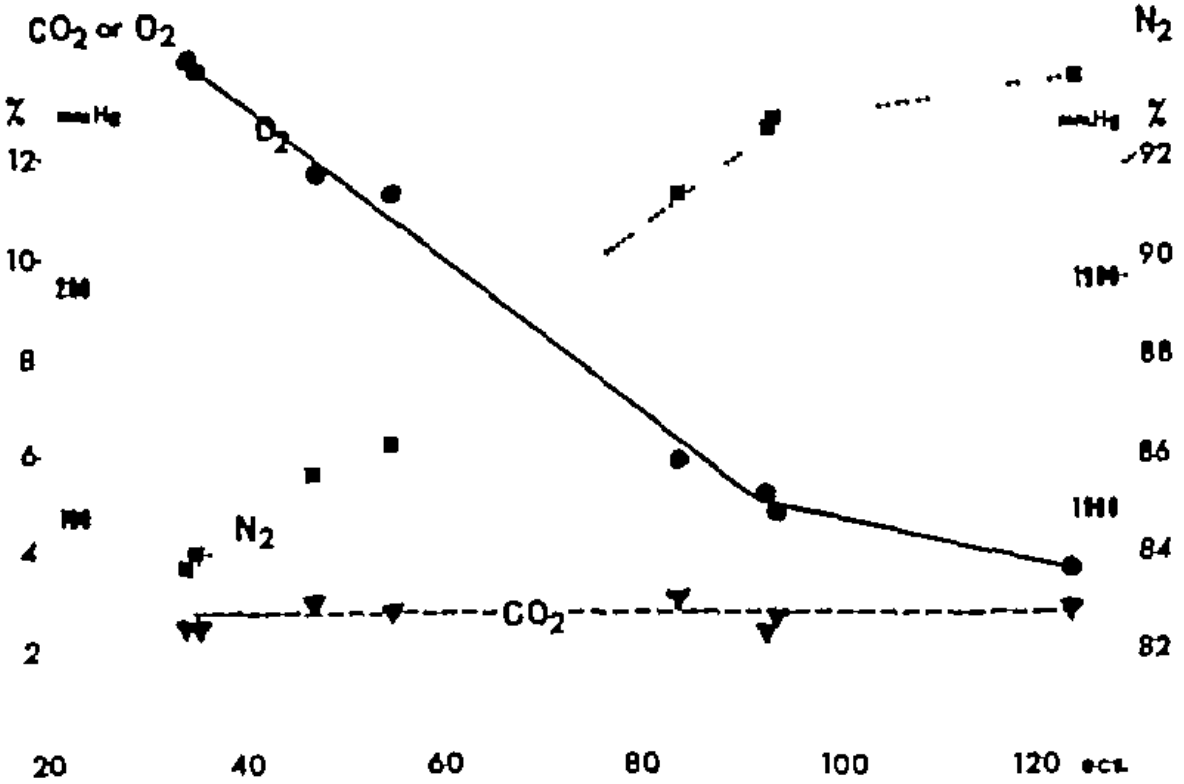

Fig. 16 Relation between diving time (abscissa) and oxygen, carbon dioxide, and nitrogen percentages in alveolar samples taken at 18.5 m of depth during single dives. The alveolar gas tensions at 2.85 atm abs are also shown. Each of 6 divers performed one dive per day and the points represent a total of 8 dives.

per day The carbon dioxide fraction is essentially constant—perhaps with a tendency toward a very small increase—and the alveolar oxygen fraction decreases steadily with diving time. Immediately after the descent to the bottom (2.8 atm abs) the P_ACO_2 is high, probably $2.8 \times 25 = 70$ mm Hg due to the compression of lung gas (P_ACO_2 at the beginning of the dive = 25 mm). Thus P_ACO_2, due to the descent to the bottom of the tank, exceeds the existing $P\bar{v}CO_2$, and CO_2 is transferred from the lungs to the blood. Hereby P_ACO_2 will fall toward the level shown in Fig 16 Initially during a breath-hold at high intrapulmonic pressure the cardiac output will be reduced by 20—40 % (Fig 24) so this CO_2 uptake from the lungs to the body is possibly blood flow limited in some subjects. The arterial CO_2 tension (P_aCO_2) is hereby increased to essentially the same value, and this stimulus probably in association with other stimuli elicited by the small lung volume at the bottom of the tank, makes the diver feel that he is already approaching his breaking point. This subjective sensation may be overcome—although not eliminated—by the will power of trained breath-

bold divers. After 35 seconds an alveolar CO_2 % of 2.7 is measured, which will correspond to a P_ACO_2 ($\simeq P_aCO_2$) of 57 mm at 18.5 m, and standard conditions. At the end of the dive is experienced an irresistible breaking point sensation owing to the decreased lung volume and the high P_aCO_2. This is not always followed by an adequate escape reaction. — It is interesting that when the diver is resting on the bottom of the tank, the P_AO_2 is very high, falling linearly from 380 mm, but still greater after a diving time of 90 seconds (Fig. 16) than when the diver rests at the surface (approximately 105 mm). Thanks to the high P_AO_2, blood passing through the pulmonary capillaries is reoxygenated completely during a dive of 90 seconds duration. However, when the subject rested at the bottom for more than 90 seconds, the P_AO_2 and P_aO_2 values were less than 100 mm. The low P_AO_2 and the Bohr effect (the greater the P_aCO_2 the lower the hemoglobin O_2 saturation) has then in fact caused a significant fall in O_2 saturation. The P_ACO_2 ($\simeq P_aCO_2$) now is still 57 mm and the P_aO_2 is 85 mm after 124 seconds, so that the blood cannot carry as much O_2 from the lungs to the tissues as before. Some divers have been reported to have lost consciousness at the bottom of the tank, possibly owing to the dangerous combination of a low P_AO_2 and a very high P_ACO_2. — During ascent the breaking point sensation disappears because of the increase in lung volume and the fall in P_ACO_2, even though the P_{O_2} will be decreasing considerably as the P_AO_2 falls. Since P_AO_2 may fall below the $P_{\bar{v}}O_2$ there is even a possibility of O_2 being transferred from the blood to the lungs during the last part of the ascent. Also during the ascent the decreasing P_AO_2 causes a fall in S_aO_2, reducing the rate at which O_2 is carried to the tissues from the lungs. Under these conditions part of the O_2 supplied to the tissues must be derived from the blood O_2 stores. However these O_2 stores are only 700 ml or less, which may easily be utilized by the muscles during 10 seconds of powerful ascent. If blood deprived of oxygen arrives at the cerebral cortex, the diver may lose consciousness just as he reaches the surface or before. Unconsciousness during ascent, but below the "buoyancy point" is a potentially fatal condition.

Net change of alveolar gases

The net transfer of gases from the lungs to the body during a "mean dive" (average of seven successive dives performed by one person) was calculated as the difference between the volume of O_2 or CO_2 in the lungs just after the final inspiration before a dive (V_I), and just before the first maximal expiration after the same dive (V_E) ΔVO_2 or $\Delta VCO_2 = (RV\ F_A + V_I\ F_I) - (RV + V_E)\ F'_A$ F_A and F'_A = fractions in end-expiratory

Table 6 Net changes of alveolar gases during a mean dive.

Test Subject	Diving time	ΔVO_2	ΔVCO_2	R
	sec			
EH	42 (40—45)	663	—260	0.39
OL	47 (44—50)	864	—268	0.31
PP	71 (41—80)	673	—164	0.24

sample from final expiration before the dive and in the first expiration after the dive, respectively Dead space volume was assumed to be negligible. The end-expiratory air was assumed to represent alveolar air concentrations in all parts of the lungs There was no loss of air from the lungs (no air bubbles were observed) during the dives because of the tight nose clips (Table 6) Assuming an alveolar exchange ratio (R) identical with a metabolic, respiratory quotient (RQ) of 0 8—1 0, the overall retention of CO_2 in a mean dive was 300—600 ml CO_2 (13 5—27 mM)

Between and after dives

In a separate experiment mixed expiratory air was collected in a Douglas bag during the first three surface intervals in a series of dives (120—119—123 sec) The first expiration after each dive was included. Calculations showed an oxygen uptake per minute surface interval of 590 ml, a CO_2 elimination of 430 ml, and thus an alveolar exchange ratio (R) of 0.73 disregarding a change in the composition of the lung air

The results obtained by fractional sampling of expired air after repeated dives are shown in Fig 17 Two minutes after the 7-dive series R exceeds 1 0 and after 6 minutes decreases toward normal levels. This pattern is less apparent after only four dives The Douglas bag-sampling technique is not adequate for a detailed analysis but, in general, the R alterations reflect both that the emptying of the CO_2 stores of the body occurs with a greater delay than the replacement of the O_2 stores, and that the excess CO_2 is relatively greater than the O_2 deficit. Assuming the metabolic, respiratory quotient (RQ) to be 0.8 during the 16-min collecting period

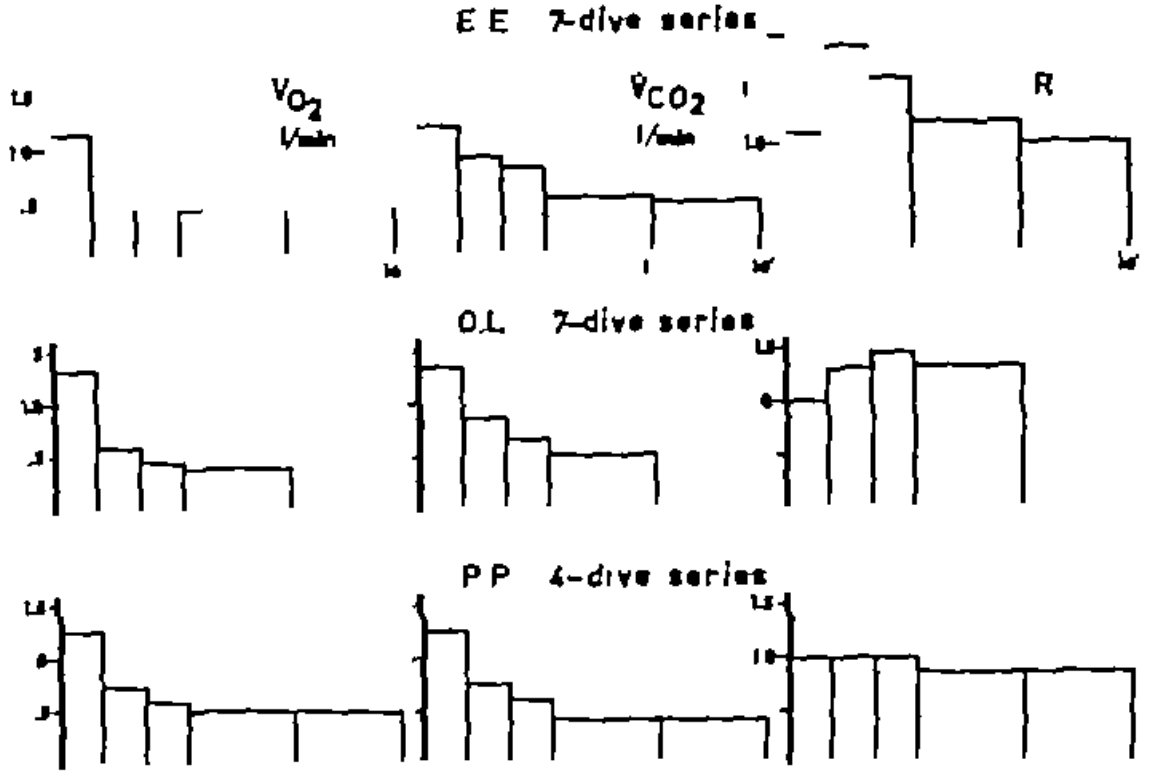

Fig 17 Oxygen uptake, carbon dioxide elimination (liters STPD/min), and alveolar exchange ratio ($R = \dot{V}_{CO_2}/\dot{V}_{O_2}$) after two seven-dive and one four-dive series. The abscissa is the first 16 minutes after the end of the diving series. During this time the subject was resting at the border of the tank in water up to the neck.

and the O_2 uptake for compensating the loss of O_2 from the O_2 stores to be 1 500 ml, subject EE eliminated about 5,000 ml excess CO_2 (223 mM) after 7 dives. Part of this CO_2 retention may help to overcome the respiratory alkalosis due to the pre-dive hyperventilation. However, in the final phase of the longest dives symptoms similar to CO_2 poisoning (headache, dizziness, respiratory distress, fear and a fuzzy state with water swallowing) were present. Although the divers had normal P_{ACO_2} values at the time of surfacing, the corresponding alveolar CO_2 tensions at the bottom of the tank immediately before ascent, must have been abnormally high (Fig 16).

Breath-holding above water

The alveolar air composition before and during prolonged breath-holding while resting above water at normal pressure, is seen in Fig 18 This is a P_{O_2} and P_{CO_2} diagram (Otis et al. 1946 b) Values within the broken lines

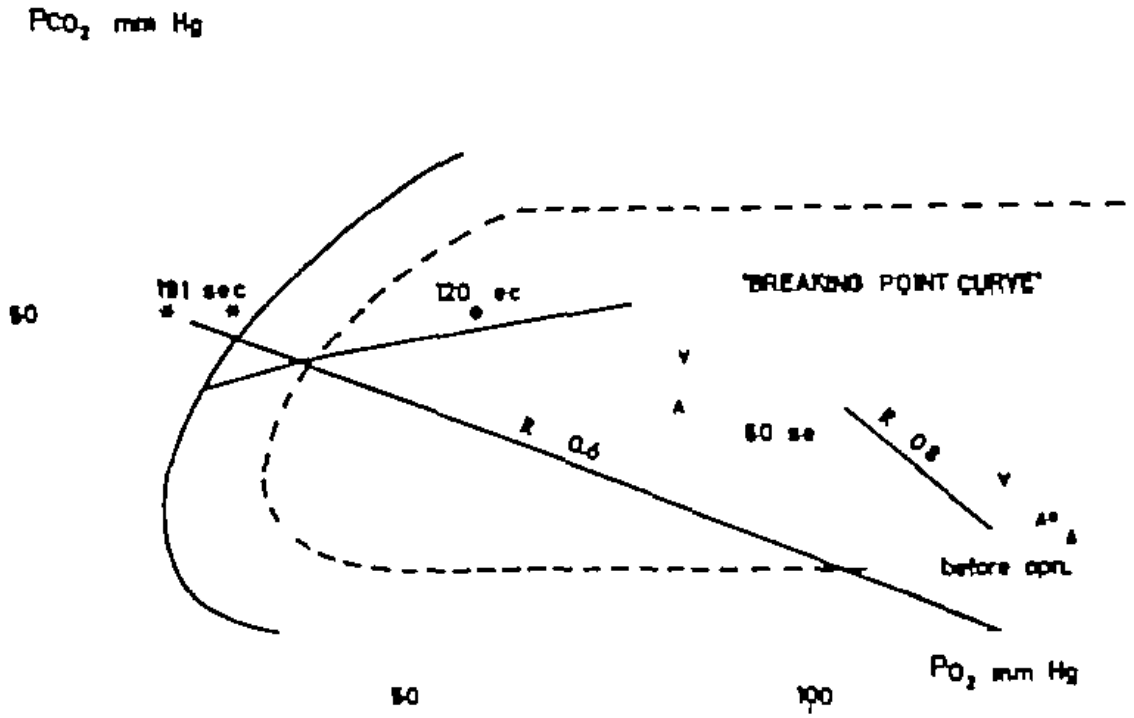

Fig 18 A Penn-Rahn diagram showing the alveolar air partial tensions before and after breath-holds of different duration (60—120—191 seconds). Ten subjects (with individual symbols) *resting supine* in air participated. All tensions are calculated from double determinations of alveolar fractions with a Scholander micro-analyzer

indicate unimpaired consciousness, between the broken and the continuous line impaired consciousness, and outside the continuous line, loss of consciousness (Otis et al. 1946 b). A conventional breaking point curve and two lines corresponding to two alveolar exchange ratios (R) are also shown. Also during breath-holding in air, the CO_2 delivery to the lungs is less than the O_2 uptake from the lungs. All 10 subjects (Fig 18) hyper ventilated with three, deep respirations before the breath-holding One of the subjects lost consciousness on two occasions, both times after 191 seconds breath-holding, lying supine in air. Turning the head and extending the neck in order to commence insufflation resuscitation immediately brought the subject back to consciousness, which commenced with expira tion of the air whereby the alveolar air sampling device was filled. The result of the Scholander analysis is shown at the asterisk to the left (Fig 18). After a resting period the subject insisted on repeating the experiment, and he lost consciousness at exactly the same breath-holding time (see the other asterisk) It seems as if the breaking point curve was past, resulting in a very low P_{AO_2}, while the P_{ACO_2} was not increased much more than

during most breath-holds. Thus, it is possible to lose consciousness by voluntary suppression of ventilation.

Comparison between breath-holding in air and in water

The most interesting difference between the composition of the alveolar air during breath-holding in air at normal atmospheric pressure and below water at a considerable increase in pressure, is that the F_{ACO_2} is low at the bottom of the tank after a 120 sec breath-hold dive (0.027—57 mm Hg), but high after 120 seconds of breath-holding above water level (0 07—49 mm, see Fig 18). During breath-holding the lungs can be compared with an aerotonometer. Immediately after the descent to the bottom of the tank, the P_{ACO_2} will be about 70 mm (see above) causing CO_2 to enter the blood from the lungs. However, after a short period at the bottom of the tank Fig 16 shows that P_{ACO_2} (and F_{ACO_2}) does not change essentially indicating that, in the period considered, hardly any CO_2 is given off to the lungs. This line of reasoning assumed that the decrease of the molar content of gas in the lungs during the dive is negligible. Thus, in the period considered in Fig 16 the difference between the P_{ACO_2} and the $P\bar{v}CO_2$ must be approximately zero, although immediately after descent the P_{ACO_2} will fall from 70 down toward 57 mm due to uptake of CO_2 into the venous blood. The arterial P_{CO_2} must also be essentially equal to that in the alveolar air. At our depth (18 5 m) and with no exercise during the dive, these three tensions are all about 57 mm Hg at standard conditions. The high arterial P_{CO_2} will limit the exit of CO_2 from the tissues, and the P_{CO_2} of the tissues will—although gradually increasing due to CO_2 production—necessarily be lower than 57 mm during a dive. Thus, the exit of CO_2 from the tissues seems tension limited (*i.e.*, inhibited by the high P_aCO_2) and to different degrees during breath-holding in water at increased pressure and above water at normal pressure, where the P_{ACO_2} will rise by cumulation of CO_2 in the lungs. This difference in P_{ACO_2} is not necessarily caused by the hydrostatic factor alone. A blood flow limitation (*i.e.*, a reduced blood flow inhibiting the transport of CO_2 from the cells to the lungs) may of course, also be a factor of importance. During breath-holding at high intrapulmonic pressure we have found the limb (calf and forearm) blood flow decreased by 50 to 100 %, with the subject resting supine in air (Chapter 7) An identical manœuvre performed as a breath-hold dive could hardly lead to an essentially greater fall in limb blood flow (Fig 29) Thus the difference between the overall retention of CO_2 in the tissues during a breath-hold dive, as compared to breath-holding in air may probably not be explainable

as due to the blood flow limitation but a part of the CO_2 retention occurring during both breath-hold diving and breath-holding in air may be caused by a reduction of the blood flow at high intrapulmonic pressure.

When swimmers and divers lose consciousness during breath-holding at sea level and in underwater swimming just beneath the surface, hypoxia may be the main cause (Craig 1961 a) However in repeated deep dives loss of consiousness with the risk of drowning may—in the light of the CO_2 retention discussed above—be caused by CO_2 narcosis (and acidosis) in *combination with the hypoxia.*

CHAPTER 5
Cardiac rhythm

Alterations of the cardiac rhythm during diving and during breath-holding have been demonstrated in many animals (Irving 1964) Among these the pronounced bradycardia of aquatic mammals (e.g duck and seal) has been the subject of intensive investigation (Elsasen 1960, Feigle & Folkow 1963 Murdaugh et al. 1961 Reite et al 1963 Scholander 1962) In aquatic animals important changes occur not only in heart rate, but also in the vascular resistance of organs and limbs, a change which reserves the reduced cardiac output and the limited O_2 stores for those organs most dependent on a continuous supply of oxygenated blood (Elsner & Scholander 1965) These phenomena are known as an "oxygen conserving reflex" or a "diving reflex" but the physiological mechanisms involved have not been fully explained. The problem has been studied systematically in ducks by H. T Andersen (1963) who found an intact trigeminal nerve essential for the development of bradycardia.

Occurrence of bradycardia during breath-hold diving has also been described in man (Craig 1963 Olsen et al. 1962 Hong et al. 1963 Sasamoto 1965 Hong et al 1967) It is assumed that the mechanism by which this bradycardia is brought about, is similar to the diving bradycardia" in animals (Irving 1964, Scholander 1962), though no supportive evidence has been produced. According to Elsner & Scholander (1965) the size of the "drving bradycardia in man is more marked if the breath is held with the face immersed in water than when the breath is held in air an observation suggesting involvment of one and the same type of reflex in the duck and man.

Olsen, Fanestil & Scholander (1962) found rather severe cardiac arrhythmia during breath-hold drving, and recently Wolf (1963) mentioned the possibility of the above suggested mechanism of "diving bradycardia" in man being similar to a mechanism of sudden, unexpected death by cardiac arrest. Lamb et al. (1958) found malignant, cardiac arrhythmia to occur in air pilots during breath-holding and also concluded that malignant arrhythmias might be responsible for cases of sudden, unexpected death.

Despite extensive zoo-physiological work on bradycardia the eliciting mechanism is still obscure (Scholander 1962, Irving 1964) Even in the duck, which has been studied most, the nature of the receptors involved is

unknown (Andersen 1966) It therefore seems unwarranted—though commonly done in the literature—to compare the bradycardia observed in humans during breath hold diving to the diving bradycardia in animals.

Experiments were carried out on 30 subjects to elucidate the nature of the bradycardia reported to occur in human subjects during breath-hold diving Preliminary studies showed that the response of the heart to breath-holding, varies with the intrapulmonic pressure and the ambient temperature. The pressure measured at the mouth was taken as the intrapulmonic pressure during breath-holding, an assumption which obviously require an open glottis to be correct. During these preliminary studies of 25 other subjects, electrocardiograms (paper speed 25—50 mm/sec) were obtained with information about the character of the cardiac arrhythmia found in a group of young normal subjects performing breath-holds in air and water. —Since previous investigators had believed both the "face immersion bradycardia" and the bradycardia described in totally submerged human breath-hold divers to be of similar origin as the diving bradycardia of animals (Elsner et al. 1965 Wolf 1965 Buck 1966 and Corriol et al. 1966), two experimental series were performed. In the first of these the heart rate was measured in the prone position during breath-holding with the face immersed in water at different temperatures. In the second the heart rate was measured during breath-holding, while the subject rested for 30 minutes in water up to the neck.

Procedure

The 30 subjects used were healthy volunteers aged 21 to 52 years. Seven of these were good swimmers (*i.e.*, they swam in a swimming pool or in the sea at least once a week all the year round) All breath-holds were performed after one deep inspiration (see below) and no previous hyperventilation was permitted. The breath-holding time, like the duration of the other manoeuvres, was always 60 seconds. After a single, deep inspiration—without previous overbreathing—they could hold their breath for 60 seconds without involuntary contraction of the diaphragm, as judged by the constant intrapulmonic pressure. Although the subjects claimed that they initiated the breath-hold after a maximal inspiration measurements indicated that 0 to 16 / of VC was still in reserve at the actual inspiratory levels achieved. The subject inspired from the functional residual capacity level (FRC) before each breath-hold. The inspired lung volume in each individual was reproduced with great constancy Thus it is likely that the subjects did not always achieve total lung capacity (TLC) prior to the

breath-hold, but for the sake of simplicity the initial lung volume (mean 90 % of VC, as judged from measurements from the RV level in breath-holds where only volume was measured) in the following is referred to as 'TLC'

The heart rate is here used as the total number of heart beats (all R—R distances) counted in 60 second periods. Even during quiet breathing counting of the number of heart beats for periods of less than 20 seconds showed an unacceptably poor reproducibility. A period of 60 seconds was therefore used. The response of the heart to a specific manoeuvre was expressed as the percentage change occurring during a 60 second manoeuvre, following a 60 second resting control period. Unless otherwise indicated, 30 observations were performed in each group of experiments on the 30 subjects. The mean percentage change ± the standard error (SE) is shown throughout, except in Fig. 20, where the standard deviation (SD) is indicated. In the present text apnoea is defined as a breath-hold without a marked increase of the intrapulmonic pressure. The subjects were instructed to arrest breathing with the respiratory muscles relaxed, but as judged from the intrapulmonic pressures (0 to 5 mm Hg) the subjects were often unable to relax their inspiratory muscles completely (Chapter 1). Breath-holding with a marked increase of the intrapulmonic pressure is called a 'Valsalva experiment or manoeuvre'. As mentioned above, two groups of experiments were performed.

I. Prone position (face immersion and controls)

The subject was placed as shown in Fig. 19 with the head supported by a sling covering the eyes. Before and during the experimental period a noise from a ventilator masked disturbing sounds. The nose was closed by a clip. During breath-holding the subject maintained an intrapulmonic pressure of zero to 5 mm Hg. The subject was studied under the following conditions: 1) apnoea plus face ventilation (see below), 2) apnoea plus face immersion, 3) face ventilation without apnoea, 4) face immersion without apnoea, 5) forearm immersion without apnoea, 6) mental stress.—An assistent started each of the manoeuvres by counting aloud the last 5 seconds down to the time zero.

II. Supine position (whole body immersion and controls)

Experiments were performed with the test subject in a bath with (or without) circulating thermostatically controlled water, in order to study the pulse changes during breath-hold diving. During the control periods —of 2 min duration—the subject rested in water up to the neck (Fig. 20).

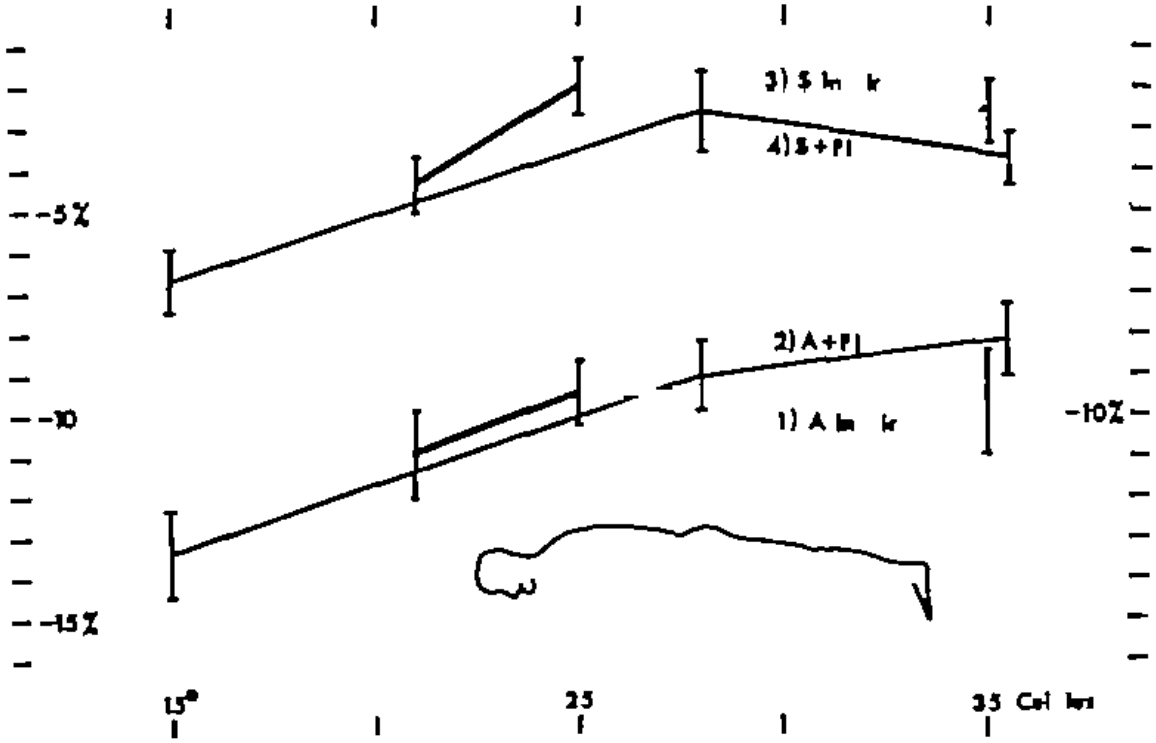

Fig. 19 The abscissa is the water or air temperature.
The ordinate is the percentage decrease of the resting, control heart rate at the different manoeuvres.) Apnoea in air (room air and face ventilation"),) Apnoea plus face immersion in water 3) Snorkel breathing in air 4) 'Snorkel' breathing plus face immersion in water —At each point is shown the mean value of 5 observations (from 30 subjects), except at apnoea in warm air (30 observations only) and in room air (97 observations). The vertical bars indicate the standard error of the mean (SE) The average resting (control) pulse is 75 beats/min.

The apnoea was performed by submersing the head in addition. The subjects spend a total of 30 min in the bath. Two series were made (A. and B) In A. the water temperature was kept constant (35 5 C) at an approximately neutral range" (Craig & Dvorak 1966) and the intrapulmonic pressure was varied from one breath-hold to the next. In B an "approximate neutral (*i.e.* zero to +5 mm Hg) intrapulmonic pressure was maintained during apnoea, and the water temperature was varied. Further details of the procedure are published (ref. *D*)

Results and Discussion

Studies on subjects in the prone position (face immersion)

At an intrapulmonic pressure of +5 mm Hg breath-holding in room air lowered the heart rate by 9 5 % (7 beats per minute, Fig 19). Essentially

the same response of the heart was found during apnoea with face ventilation in warm air (35 C) and during apnoea with face immersion in 28°C and 35°C water (Fig 19) These reactions may be explained as a response to the breath-holding *per se* Apnoea with the face immersed in cold water evidently adds further bradycardia to the apnoic bradycardia and ventilating the face with cold air (21 C) also seems to be additive (Fig 19). For technical reasons it was not possible to obtain the desired low air temperature of 15°C, but Fig 19 like Table 7 inevitably leaves the impression of the response of the heart rate being dependent on the ambient temperature, the temperature of the medium surrounding the face possibly being of particular importance. It thus seems possible to explain the bradycardia occurring as a response to the manoeuvres in the prone position as a combination of an apnoic bradycardia (see below) and a cold bradycardia

The 7 good swimmers showed a mean pulse response of −19 % (−15 beats/min) during apnoea with the face immersed in 15°C water and a −7 % response during apnoea in air. Their apnoic bradycardia then does not seem to deviate much from the average for the whole group (−9.5 %) In contrast with the claim by Corriol et al. (1966) who reported that the bradycardia due to apnoea (intrapulmonic pressure was not measured) has a greater size in trained swimmers the more pronounced cold bradycardia in our swimmers may simply be due to a smaller emotional-intellectual inhibition of the bradycardia, because swimmers are more used to cold water

The effect of local cooling of the face *per se* is apparent from results obtained in experiments where such cooling was produced by water or air in subjects continuing to breathe (Fig 19) in those cases (face immersion in water or 'face ventilation in air) the subjects were breathing through a respiration valve (von Döbeln type) with two rubber tubes of 30 cm in length (a two way snorkel without dead space) —Immersion of the forearm in 35°C water elicited a heart rate decrease of 2.4 % from the resting control pulse (average 75 beats/min ±2.2) while forearm immersion in 15°C water produced a 3 % decrease, when the usual counting down procedure was used. Identical figures were found when the immersion was performed without counting down aloud.—The subjects faced with an arithmetical problem all responded with considerable *tachycardia* to this—emotional—stress (+17 2±1.0 %)

During the above six manoeuvres the resting, control heart rate of the 30 subjects averages, as mentioned, 75 beats/min, with the subject at room temperature, dressed and prone. The 7 accomplished swimmers also had a mean resting heart rate of 75 but with a SE of ±5 9 beats/min. Thus

with a few exceptions the control pulse was below 80 beats/min. In each subject the control heart rate remained essentially the same during the 30 min procedure.

STUDIES ON SUBJECTS PLACED SUPINE IN A BATH (WHOLE BODY IMMERSION)

A. The recordings in the 6 subjects who kept their breath at different intrapulmonic pressures in a bath with (35 5 C water) or without water are shown in Fig 20 It is seen that the pulse response of the heart to apnoea is dependent upon the intrapulmonic pressure. Between −5 and +5 mm Hg, there is slight bradycardia and above +10 mm Hg the response becomes one of tachycardia, increasing almost linearly with the increase in intrapulmonic pressure. The relationship is present, whether the subject is in air or in water, though the slope of the curve was smaller for breath-holding in air than those for breath-holding in water The difference between the results obtained with water up to the neck and those obtained with total immersion of the head and body is very small and not significant.

B In the 100 procedures on 5 subjects resting supine in 35 C water up to the neck, apnoea suppressed the heart rate by 6 % (4 beats/min), compared with 14 % (10 beats/min) when the subjects were in 22°C water (Table 7). This difference is statistically highly significant ($p<0.001$) The difference is not correlated to changes in the respiratory pattern of the control periods or to the duration of the stay in water (Table 8) Thus also during whole body immersion the apnoic bradycardia can be augmented by exposure of the skin to cold water

Strangely enough breath-holding with only the face immersed produces a response of the pulse (14 %=10 beats/min) equal to that of apnoea with the subject up to the neck in cold water This might be explainable by the

Table 7 Heart rate response (percentage decrease of resting heart rate) upon apnoea lying supine in water

Water temperature	22.0°C	35 5°C
Water to the neck:	−14±1 5 %	−8±1.4 %
Total immersion:	−14± .0 %	−4±1 7 %
Sum:	−14±0.9 %	−6±1.0 %

All breath-holds were performed with an intrapulmonic pressure of zero to +5 mm Hg The results are mean values ±SE from five representative subjects. Five identical observations were performed on each subjects, yielding total number of 25 observations in each of the four groups (*i.e.* 5 observations at each temperature) The resting (control) heart rate is 71±0.7 beats/min in the warm and 75±0.8 beats/min in the cold water

Table 1 Respiration and heart rate response during apnoea.

	First	Last
Respiratory rate (breaths/min):	19.6±0.7	17.2±0.6
Respiratory depth (cm amplitude):	2.5±0.2	3.9±0.4
Heart rate response (% change):	−15.2±1.4	−14.3±1.1

The values are means of 25 observations in each group, and the SE is indicated. The first and the last half part of the immersion period (whole body immersion in 22°C water) is compared. The average resting (control) heart rate is 73 beats/min.

fact that in the case of the face the cold stimulus (15 C) was suddenly applied simultaneously with the beginning of apnoea, while in the body immersion experiments (in water of 22 C) the skin of the body had been exposed to cooling for a considerable time before the apnoea, *i.e.*, the skin (body) had had time to adapt itself to the lower temperature in the later case, but not in the former.

Previous reports often fail to include the information about the intrapulmonic pressure during breath holding and the water temperature. A detailed discussion of such reports is not considered pertinent, as these two variables, demonstrated in the present study to affect the heart rate during breath-holding, were either not measured or were not varied with the aim of studying their effect on the heart rate. A similar argument has eliminated an extensive number of reports from the discussion in Chapters 6 & 7

Cause of "apnoic bradycardia" and "diving bradycardia"

The bradycardia during apnoea at intrapulmonic pressures around zero and the relative tachycardia during breath-holding at high pressures (Fig 20) can be explained by the following mechanism. At intrapulmonic pressures of zero, the intrathoracic pressure (*i.e.*, the pressure in the pleural space minus the atmospheric pressure) is approximately −10 mm Hg at 90 % of VC ("TLC") (Otis et al. 1946a, Knowles et al. 1959, Mead & Millic Emili 1964) This intrathoracic pressure is somewhat lower than the pressure with the lungs in the mid-position, such as in the control period, and *by itself* adds a stimulus to the baroreceptors of the aortic arch. Furthermore, by facilitating the diastolic filling and the venous return to the right half of the heart it should, according to Starling's law (Starling 1918)

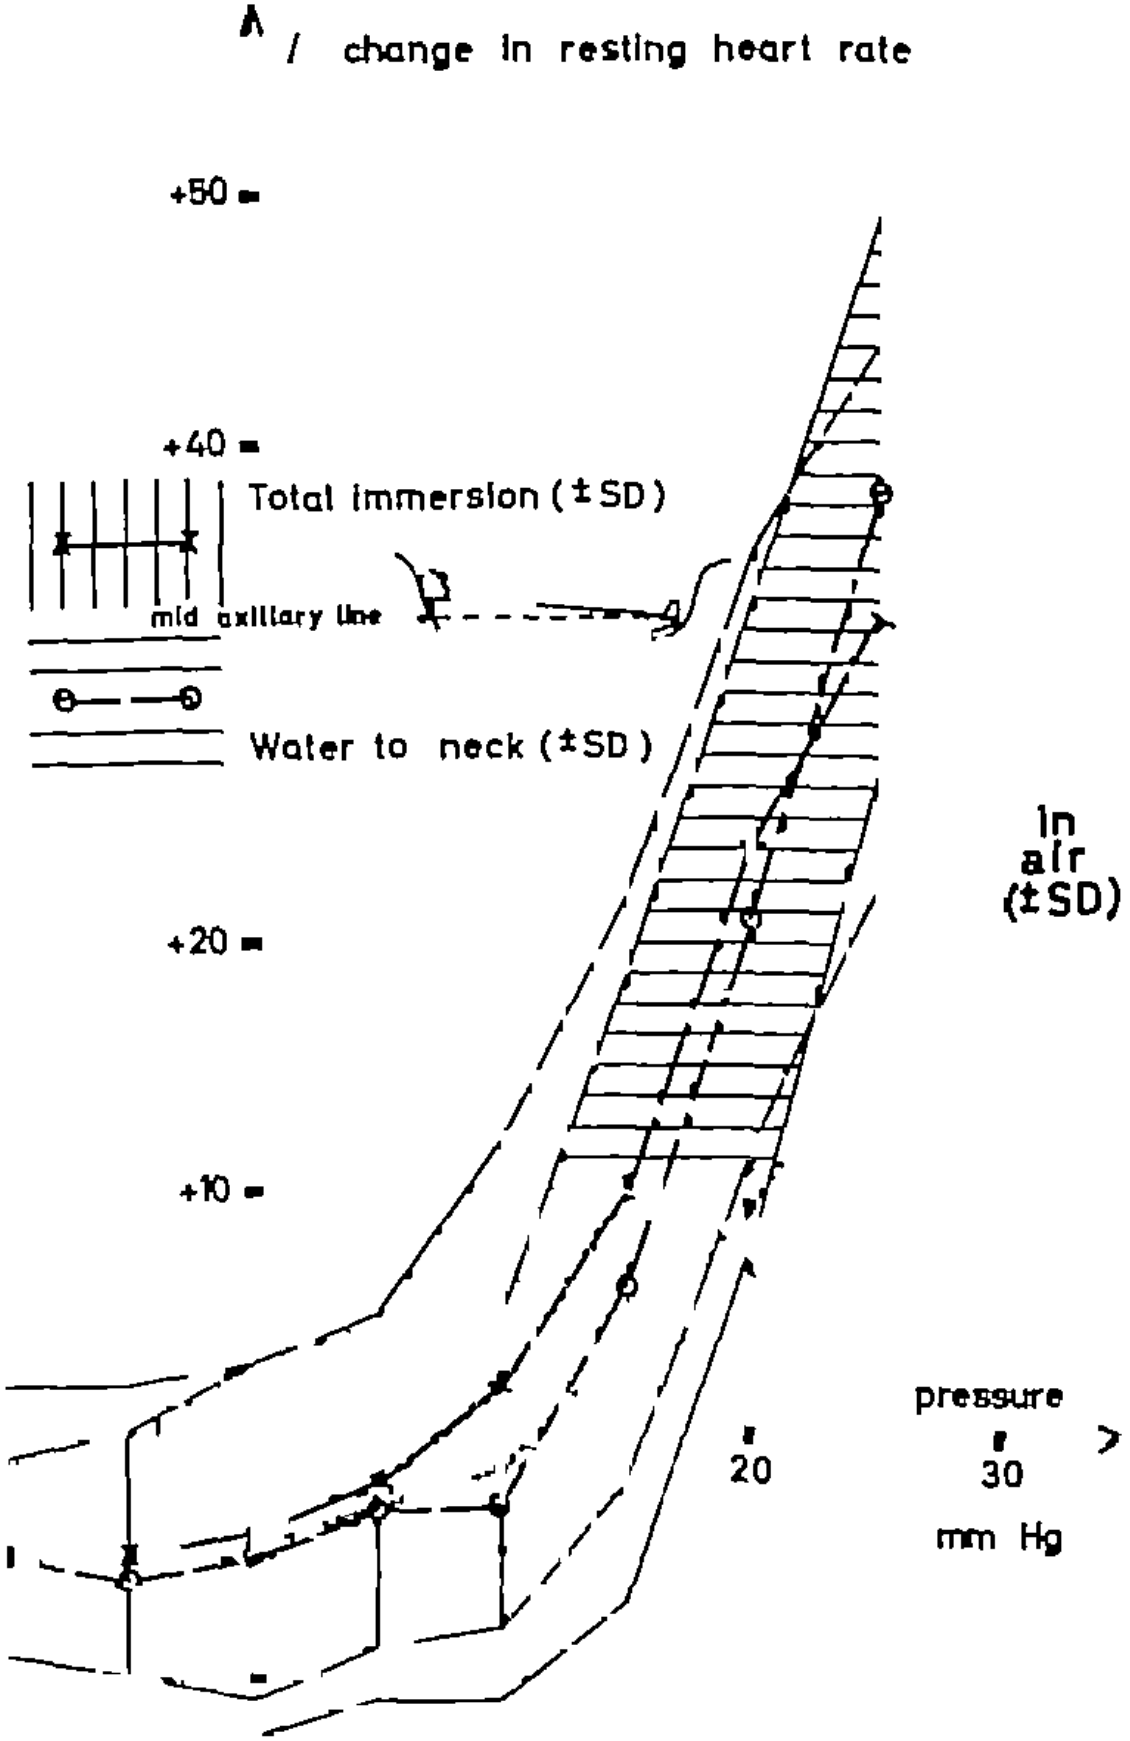

Fig 10 The mean heart rate response (±SD) to breath-holding varying with the intra-

increase the stroke volume, leading—with a short latency—to a rise in systemic arterial pressure. This would add a further stimulus to the baroreceptors (aortic and carotid), which might in turn explain the bradycardia actually observed during such breath-holds (Fig 20) At an intrapulmonic pressure of +8 to +12 mm Hg, no pulse response is to be expected, since the intrathoracic pressure is of the same—slightly negative value—as in the normal midposition in the control periods. It is in keeping with this argument that no alteration of the heart frequency was found in any of the 3 experimental series at breath-holds at an intrapulmonic pressure of +8 to +12 mm Hg (Fig 20) On the other hand, when a subject holds his breath at 'TLC' and with an intrapulmonic pressure of +20 to +30 mm Hg, the intrathoracic pressure will be positive (+10 to +20 mm). Thus, under such conditions the situation will be the reverse of that considered first, *i.e.*, there will be an immediate lowering of the stimulus to the aortic receptors followed by a lowering of the stimulus to the baroreceptors because of a fall in systemic arterial pressure due to impaired venous return to the heart and a fall in stroke volume. In fact, the tachycardia expected occurred under such conditions (Fig 20).—Measurements of blood pressure during breath-holding (14 subjects) in this laboratory showed mean pressures of +1 to +5 mm Hg in intrathoracic veins, and an increase of the mean arterial blood pressure (direct) of 30 % from the resting control values, when breath-holding was performed at 'TLC' with an intrapulmonic pressure of zero Breath holding at 'TLC' and an intrapulmonic pressure of +20 to +30 mm was accompanyed by an initial fall of 35 to 47 % of both the pulse pressure and the resting mean arterial blood pressure. There is adequate stimulation of the high pressure baroreceptors to explain the changes observed in heart rate (Chapter 7).

Judging from the present results, the bradycardia described in the literature as occurring in humans during breath-hold diving can be interpreted as consisting of two independent components an apnoic bradycardia varying in severity with the intrapulmonic pressure (Fig 20) the other, a cold bradycardia varying in severity with the temperature of the water. The cold bradycardia demonstrated in man in the present investigation is different from the temperature-*independent* (Andersen 1963)

pulmonic pressure. The water temperature was 35 5 to 36°C, and the room temperature was 25°C. The curves are the mean values of twelve observations in six subjects. The mean resting, control heart rate is 7 beats per min.

"diving bradycardia" described in ducks In the light of these considerations Irving's generalisation (1939)—a *diving bradycardia reflex* common to animals and man—appears unfounded. Raper et al. (1967) found no evidence of oxygen conserving reflexes in man during breath-holding in air at an initial lung volume of FRC, and at an airway pressure which they assumed to be zero Already Mutdaugh et al. (1961) suggested that the bradycardia reported in some vertebrates may reflect nonspecific effects, rather than a "true diving adaptation"

Cardiac arrhythmia and other ECG abnormalities

Five persons out of 25 studied electrocardiographically (Elema Schomander mingographs) in a previous project, showed definite rhythm disturbances during breath-holding (atrial premature contraction, partial sino-auricular block without symptoms) Seven subjects out of 25 showed no sign of cardiac arrhythmia, and the remaining 18 showed occasional sinus arrhythmia during the deep respirations before and after the breath-holds. The sinus arrhythmia occurred in the subjects both in the air and in water and was seen both before and after the breath-holds. *During* the breath-holds several ECG wave alterations were seen Low voltage, isoelectric P_{III}—Q_{III}—T_I Q_I and Q_{II} of 5 mm, prolonged QRS and RS-T depression. *After* the breath-holds the ECG assumed its original appearance, apart from some deep (3—5 mm) Q_I and Q_{II} in a few subjects.

Sudden death

Olsen et al. (1962) found premature ventricular beats to be more common than premature atrial beats in pearl divers. Premature beats of ventricular origin are often more malignant (*i.e.* often associated with a severe decrease in the functional capacity of the heart) than those of atrial origin (Cecil & Loeb 1959) Lamb et al. (1958) also reported serious arrhythmia following breath-holding These findings suggest that breath hold diving carries substantial risks. Lamb et al (1958) and Wolf (1965) felt that cardiac arrhythmia during breath holding, especially the "diving bradycardia" might become severe enough to arrest cardiac activity and cause sudden death. But no severe arrhythmia could be demonstrated in more than 2,000 dives performed by the present 25 young subjects The sinus arrhythmia in 18 of the 25 subjects, the occasional premature beats of atrial origin in 3 and the ventricular beat observed in one, is of no importance (Cecil & Loeb 1959). The ECG wave alterations described reflect only the respiratory effort of the manoeuvres. The increased intrathoracic ("intratruncal")

pressure during the Valsalva manœuvre (*i.e.*, during breath-hold diving micturition, defecation, strenous lifting etc.) is normally not dangerous in man, but the effect of the stress on the circulation may be quite different in patients with severe myocardial damage (Wolf 1965) Judging from the observations made in the present young normal subjects accidents during breath holding and skin diving are probably due to loss of consciousness caused by hypoxia and hypercapnia (Chapter 4) rather than to cardiac arrhythmia.

CHAPTER 6
Cardiac output

The changes in blood pressure and heart rate during and after a Valsalva manoeuvre have been studied by among others, Hamilton et al. (1936) Dornhorst et al. (1952) Candel & Ehrlich (1953), and Sharpey-Schafer (1955) but the effect of such manoeuvres on the cardiac output ($\dot{Q}$) in normal man has received only little attention. Otis et al. (1946 c) found a decrease in stroke volume during a Valsalva manoeuvre in 2 subjects examined with a ballistocardiograph.

The changes in heart rate during breath-holding (Chapter 5) made it reasonable to measure the cardiac output and the blood pressure, in order to study further the mechanism of the observed variations.

The method is described in Chapter 2 and the procedure has been published (ref. *E*). The experiments were performed in association with Dr. H. Wetterqvist in Lund 1965

Results

Out of the 8 subjects examined, 4 (group A) made Valsalva manoeuvres after three deep inspirations ("TLC") with intrapulmonic pressures of about 20—30 mm Hg, thereby increasing the mean central venous pressure to 12—18 mm Hg (Fig 21 and 23) During the first few seconds of the manoeuvre a moderate rise in the arterial pressure was observed (Fig 21), but it was quickly followed by a fall of the mean arterial blood pressure to some 75 % of the control level. The pressure in the brachial artery is assumed to be representative of the arterial systemic pressure.—The other 4 subjects (group B) held their breath after three deep inspirations (also "TLC") with intrapulmonic pressures about 0 to 10 mm Hg Such breath-holds did not influence the mean central venous pressure (control values 1 to 5 mm Hg). The manoeuvre started with a 15 % fall of the arterial mean pressure (Fig 22) All mean pressures were recorded with an electronic integrator. A detailed description of the pressure curves has been published (ref. *E*).

In the subjects in group A who performed Valsalva manoeuvres, a fall of cardiac output was observed, while in those of group B this variable was found to be higher during breath-holding (Table 11) than the control

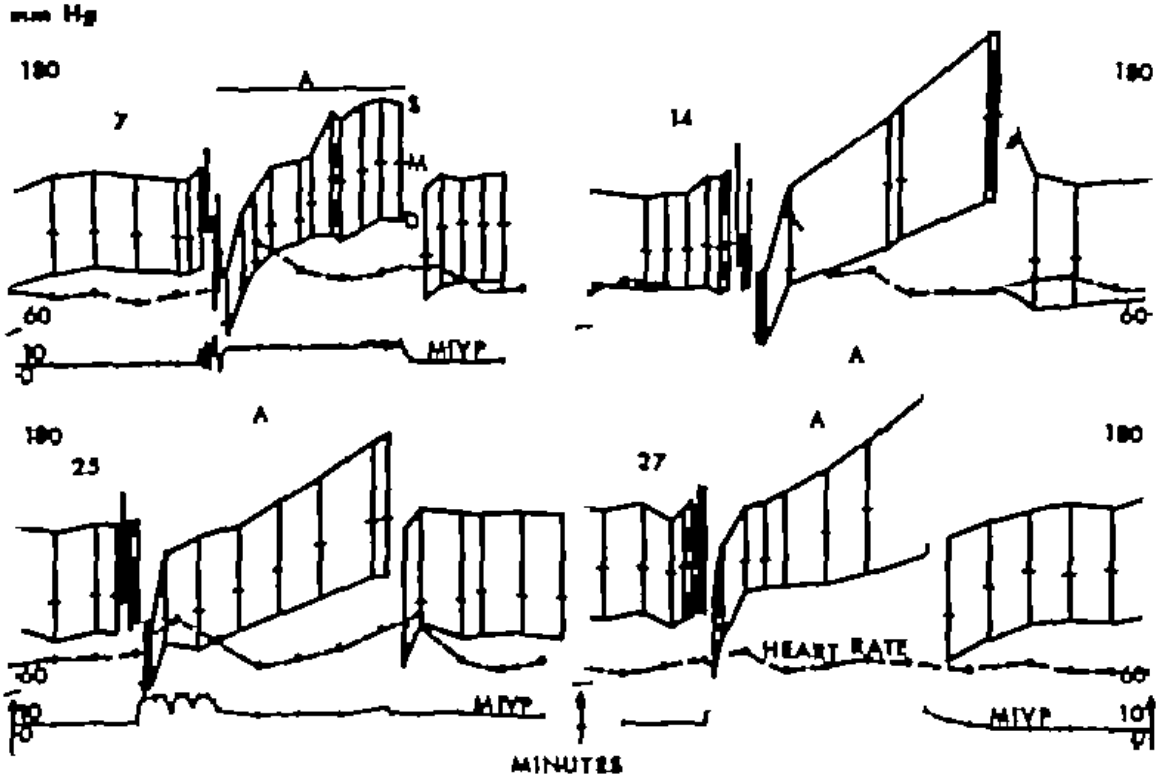

Fig. 21 Systolic (S), diastolic (D) and mean (M) brachial artery pressure, heart rate (broken curves), and mean intrathoracic (central) venous pressure (MIVP) of the group A subjects performing Valsalva manœuvres (A). Ordinate: mm Hg and beats/min. Pressure oscillations from the three inspirations before the manœuvre and from involuntary contractions of the diaphragm in the last part of the manœuvre, are interposed on the venous curve of subject 7. Central venous mean pressure of subject 14 was not recorded in this experiment, but it was usually about +2 mm during rest and rose to about +12 mm Hg.

level (Table 11). A decrease of $\dot{Q}$ at the commencement of the Valsalva experiment corresponded to a decrease in stroke volume in group A (Fig. 24, Table 11). Apnoea (group B) produced only a slight alteration of the stroke volume (Table 11). The stroke volumes of Table 11 are—for the sake of simplicity—converted to percentage changes from the control values (Fig. 24). Group A consists of subjects with relatively high resting cardiac indices (liter blood/min $\times$ m^2 body surface area), while group B consists of subjects with somewhat lower indices (Table 9).

Analysis of the arterial blood gas tensions, pH and base excess showed the oxygen partial tension and the pH decreased, while the carbon dioxide partial tension increased, the change varying with the duration of breath-holding (Table 10). The base excess showed no consistent changes during the breath-holds.

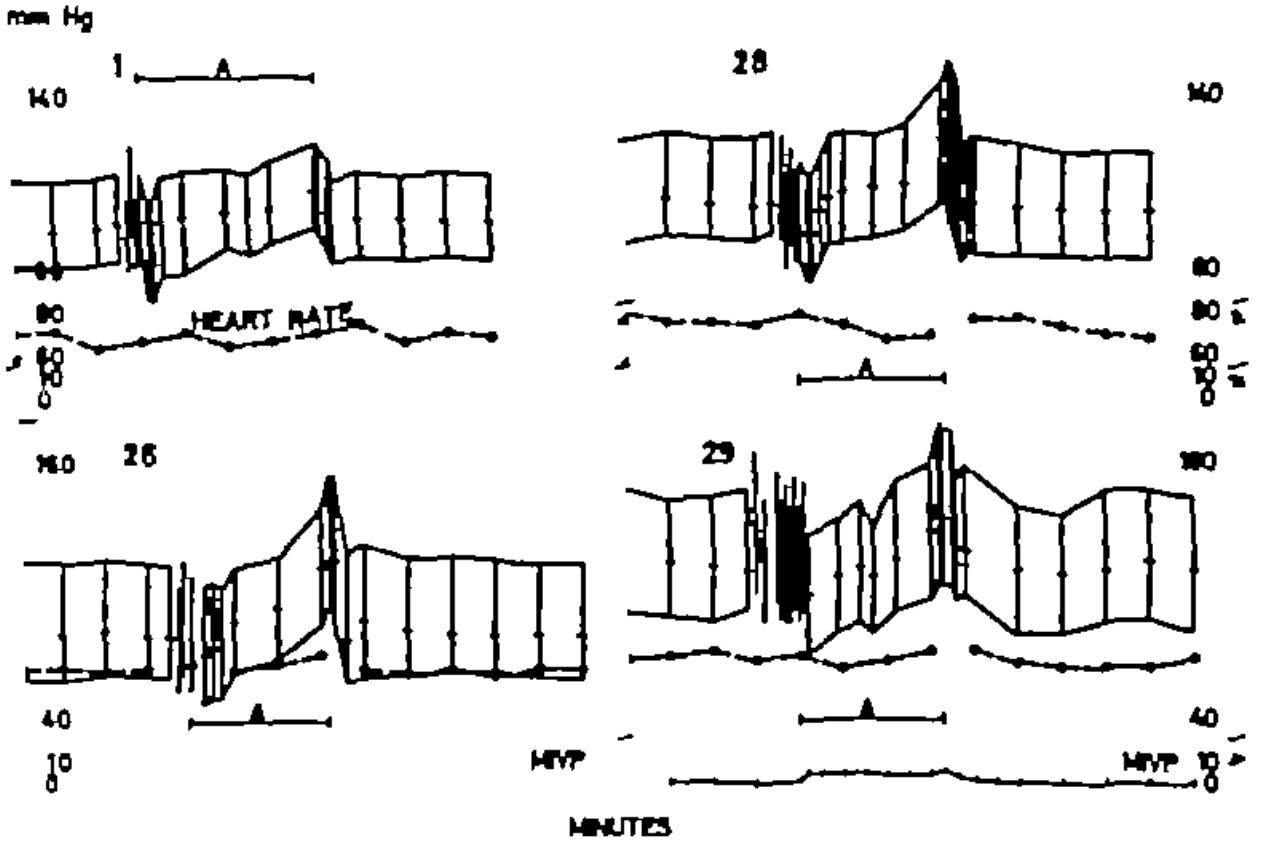

Fig 22. Results from apnoea (group B) with the same variables as in Fig. 2 The venous pressure of subject 1 did not vary with the alterations in intrathoracic pressure with deep inspirations, and was assumed to be peripheral venous pressure (catheter advanced 5 cm).

Discussion

The variables measured in this and the following Chapter should preferably be measured simultaneously The $\dot{Q}$ ought to be measured during the first 30 seconds of the breath-hold in an attempt to get the greatest variation per unit of time, and preferably at different levels of intrapulmonic pressure and lung volume during breath-holding A beat to beat registration of stroke volume would be even more useful, instead of the present indicator dilution technique. If the present method is used in a period, where $\dot{Q}$ is steady and where recirculation is avoided, it can—at best—measure $\dot{Q}$ rather inaccurately When $\dot{Q}$ is thought determined repeatedly during a Valsalva manoeuvre it is reasonable to assume that none of these provisions are fulfilled. However, the indicator dilution technique was available in Lund as a routine method, and it was assumed acceptable for the purpose, which was a rough estimate of relative changes in $\dot{Q}$ As it will be shown in Chapter 7 a simultaneous measurement of blood pressure and limb blood flow has later been performed.

During breath-holding at high intrapulmonic pressures (+ 20 mm Hg or more) the vessels running to the right atrium will be considerably compressed, with diminuition of the venous return, and according to

Table 10 Blood-gas and acid-base values.

Subject	Breath-hold sec[1]	P_aO_2 mm Hg	P_aCO_2 mm Hg	pH	Base excess meq/l blood

	$\dot{Q}$	4.9	5.1	4.6	6.5	7.5				5.7	6.7

During the breath-hold, $\dot{Q}$ was measured approximately 40—70 seconds (early)—and in group A also 120—15 seconds (late)—after the commencement. Each subject was studied during —5 breath-holds.

Starling's law it is reasonable to expect a decrease of the stroke volume of the right half of the heart (Table 11 see also Chapter 5) Bolt et al. (1955) believed that the normal flow equality in output from the left ($\dot{Q}_L$) and the right ($\dot{Q}_R$) half of the heart, is preserved during a Valsalva manoeuvre. However, Cudkowicz and O'Neill (1965) have measured $\dot{Q}$ in patients, with a single injection of Coomassie Blue into the superior vena cava, and

simultaneous withdrawal from the pulmonary artery representing $\dot{Q}_R$ and the femoral artery representing $\dot{Q}_L$, during short voluntary apnoea with open glottis, and lung volumes about TLC, FRC and RV they found a rather great difference between $\dot{Q}_L$ and $\dot{Q}_R$ and postulate a temporary disequilibrium during breath holding at TLC. At the RV level both $\dot{Q}_R$ and $\dot{Q}_L$ decreased ($\dot{Q}_L$ most). A corresponding decrease was recently found in a study of the $\dot{Q}$ measured with the pressure-gradient technique during short Valsalva manoeuvres at an intrapulmonic pressure of +40 mm Hg (Greenfield et al. 1967) no information of the lung volume was reported. A 50 % decrease of the $\dot{Q}$ was found at the end of the manoeuvre. The pressure-gradient technique measures simply the difference in lateral pressure above the aortic valve and 4 cm from this point via a double-lumen catheter introduced percutaneously into the femoral artery and advanced to the aortic location. By a modified Poisseuille equation the aortic blood flow is calculated from the pressure difference per unit of length and an angiographic estimate of aortic radius. During periods where the mean arterial pressure and the aortic radius does not vary appreciably this method may well provide acceptable results for stroke volume of the left ventricle. However during a Valsalva manoeuvre both these values decreases considerably so even relative variations must be considered with reservation, also as far as this method is concerned. Nevertheless, all of the above mentioned methods—including the present (Fig 24, group A)—indicated a decrease in stroke volume during a Valsalva manoeuvre, as already predicted in the preceding Chapter, so the results seem acceptable in principle. —The first few seconds of a Valsalva manoeuvre are accompanied by a rise of the arterial pressure owing to the increase in the intrathoracic pressure (Sharpey-Schafer 1965). A few beats later this increase begins to disappear. Both the mean arterial blood pressure and the pulse pressure are reduced (Fig 21). The considerable fall in these pressures must be accompanied by a fall in impulse frequency from the baroreceptors in the carotid sinuses and from those in the aortic arch, where the increase in external pressure further decreases the transmural arterial pressure. Thus, the "negative stimulus" of a Valsalva manoeuvre to the sino-aortic baroreceptors must be extraordinary strong The carotid sinuses are generally regarded as being very sensitive in vagotomized cats a maximal "amplification factor" of 15 mm systemic pressure change per mm pressure change in the carotid sinuses, has been described (Scher & Young 1963). The medullary vasomotor and cardiac control centers respond with an arteriolar and possibly a venous constriction (Wallis et al. 1963) which will be considered in the next Chapter.

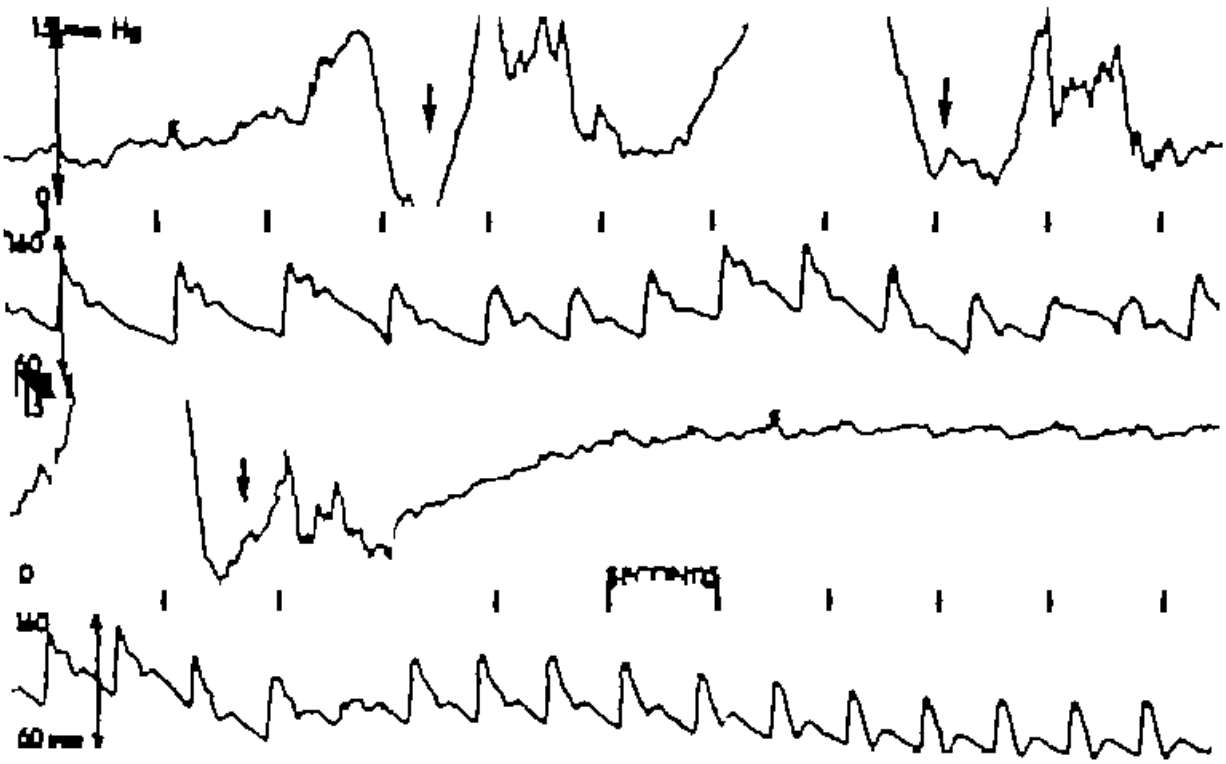

Fig 23 Blood pressure records from an intrathoracic vein and the brachial artery of subject 7 Arrows indicate the three, deep inspirations before the Valsalva manœuvre. The venous pressure follows the alterations of the intrathoracic pressure, which shows that the tip of the catheter is in the thorax. The ordinate is mm Hg, the abscissa is time in seconds, and the vertical line indicate the onset of the Valsalva manœuvre.

The subjects of group B performed the breath-hold with intrapulmonic pressures (*i.e.* apnoea) corresponding to an intrathoracic pressure at 'TLC' of −10 to −2 mm Hg and a mean central venous pressure of +1 to +5 mm (Fig 22). Apnoea was only accompanied by minor changes in arterial blood pressure (Fig 22), and cardiac stroke volume (Fig 24, group B) The small fall in the arterial blood pressure may be due to the preceding CO_2 elimination by the three deep respirations.

The venous return to the right heart is dependent upon a reasonable difference between the peripheral and central venous pressure (or rather right ventricular diastolic pressure). Because of the distensibility of the veins, a high intrapulmonic pressure maintained during prolonged breath-holding, would be able to deprive the heart for blood, regardless of the arterial response. However, as it will be shown later, a venoconstriction, possibly generalized, will protect the normal organism during such a condition.

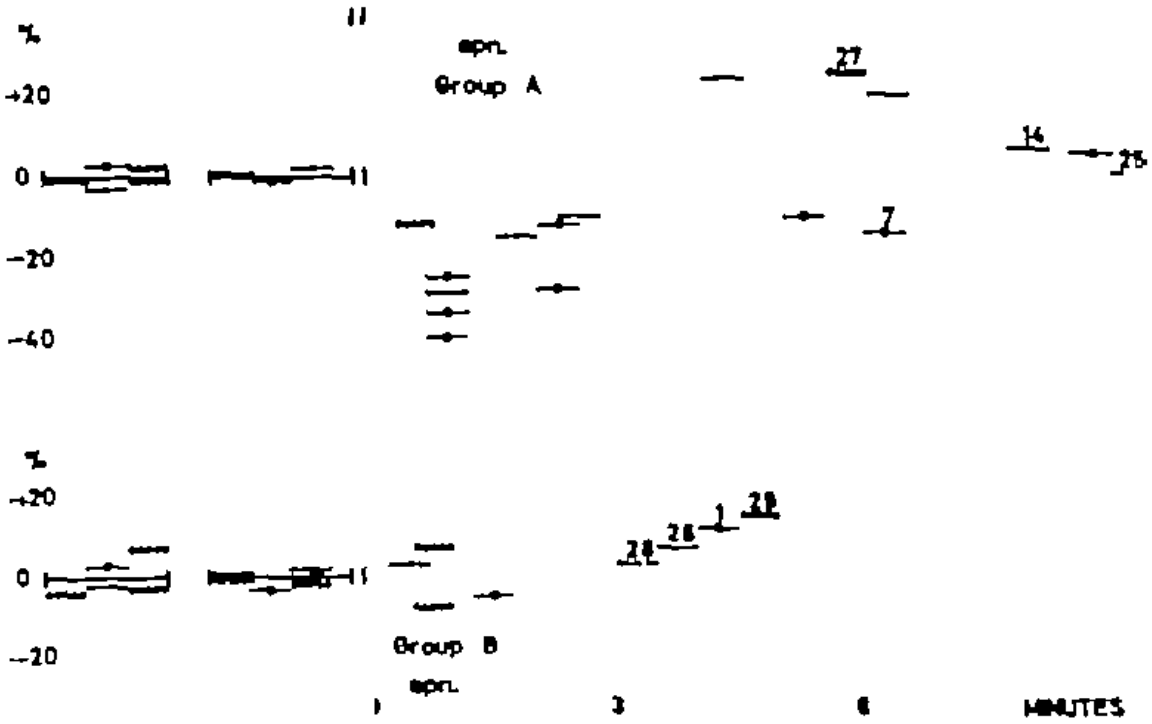

Fig 24. The percentage change in control stroke volume by breath-holding (ordinate). The time is the bachea. Before the breath-holds, the variation around the individual mean value in control stroke volumes is shown. The horizontal bars cover the periods in which the heart rate and Q̇ were determined. The figures to the right indicate the different subjects. Positive indicates higher negative lower values, than the control stroke volume.

The high P_aCO_2 (and possibly the low P_aO_2) found at the end of the prolonged breath-holds (Table 10) stimulated peripheral (and possibly central) chemoreceptors, and may be the cause of the arterial hypertension (Fig 21) —with a relative blood flow increase (Fig 25 27)– late in the breath-hold. In addition the adreno-medullary secretion may be involved possible via the sino-aortic receptors (Heymans & Neil 1958)

In conclusion the presented Q̇ determinations –although absolute values must be considered with reservation—confirmed the predictions of a small stroke volume during Valsalva manœuvres and an almost unaltered (or slightly increased) stroke volume during apnoea

CHAPTER 7
Blood pressure and limb blood flow

Although the *cardiac* function during breath-holding may seem explained in principle through Chapters 5 & 6 our knowledge of the circulatory changes occurring during apnoea and the Valsalva manoeuvre is still incomplete.

Sharpey Schafer (1955 1965) measured limb blood flow in association with the Valsalva manoeuvre, but the measurements were confined to the periods before and after rather short periods of a Valsalva experiment. Elsner & Scholander (1965) have performed some plethysmographic measurements (strain gauge) during immersion of the face in water, but the character of the breath-hold and the size of the blood flow is not clearly stated. Also Brick (1966) studied the forearm blood flow in relation to face immersion, but neither the intrapulmonic nor the intrathoracic pressure was measured during the breath holds.

It appears that no systematic investigation has been made of the human limb blood flow during breath-holding with Valsalva experiment or during breath-holding without a marked increase of the intrapulmonic pressure.

Material and procedures

A PRELIMINARY EXPERIMENTS

The first series of experiments were performed in Lund, Sweden, in collaboration with Dr I. Dahn. The subjects (three volunteers) lay supine with either both calves, or with one calf and one forearm or hand in the plethysmograph filled with water (34°C). The venous occlusion plethysmographs designed by Dahn were used (Dahn 1964, 1965). Two types of experiments were carried out

PROLONGED BREATH HOLDING. The procedure was started with a 4 minute period with intermittent registration of the control blood flow. The nose was closed with a foam rubber nose clip. The prolonged breath-holdings were performed after 3 deep inspirations. After the third, during which the subject filled his lungs, he held his breath at increased intrapulmonic pressure (Valsalva manoeuvre). With a little practice the test subjects

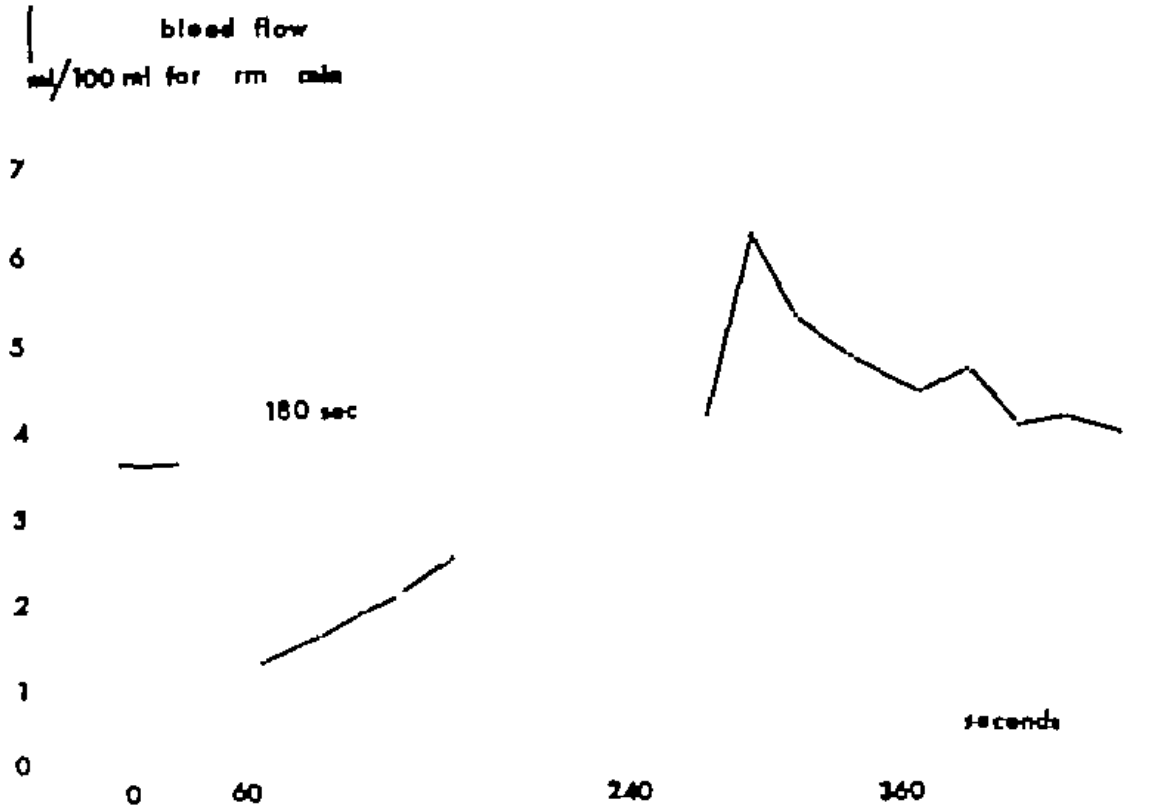

Fig 25 The blood flow in the right forearm measured before, during and after a breath-hold (Valsalva experiment at "TLC") of three minutes duration. The ordinate is ml blood/100 ml forearm × min and the abscissa is the time. Each point indicates the middle of a plethysmographic occlusion period.

increased their breath-holding time to 215 seconds. The flow of blood through the limb was measured both before, during and after each breath-holding (Fig 25 26 and 27)

PROLONGED BREATH HOLDING DURING SYMPATHETIC BLOCK. The same procedure was used here, but left stellate ganglionic block was performed beforehand, by insertion of a needle between the common carotic artery and the thyroid cartilage, and deposition of 10 ml Lidocaine hydrochloride (1 %) in the retropharyngeal space. A few minutes after the injection the solution reached the lower cervical and the upper thoracic ganglia, and a typical Horner syndrome developed. In the period from 10 to 45 minutes after the injection, plethysmographic recordings were made of the left hand or forearm (and both calves) during Valsalva manoeuvres.

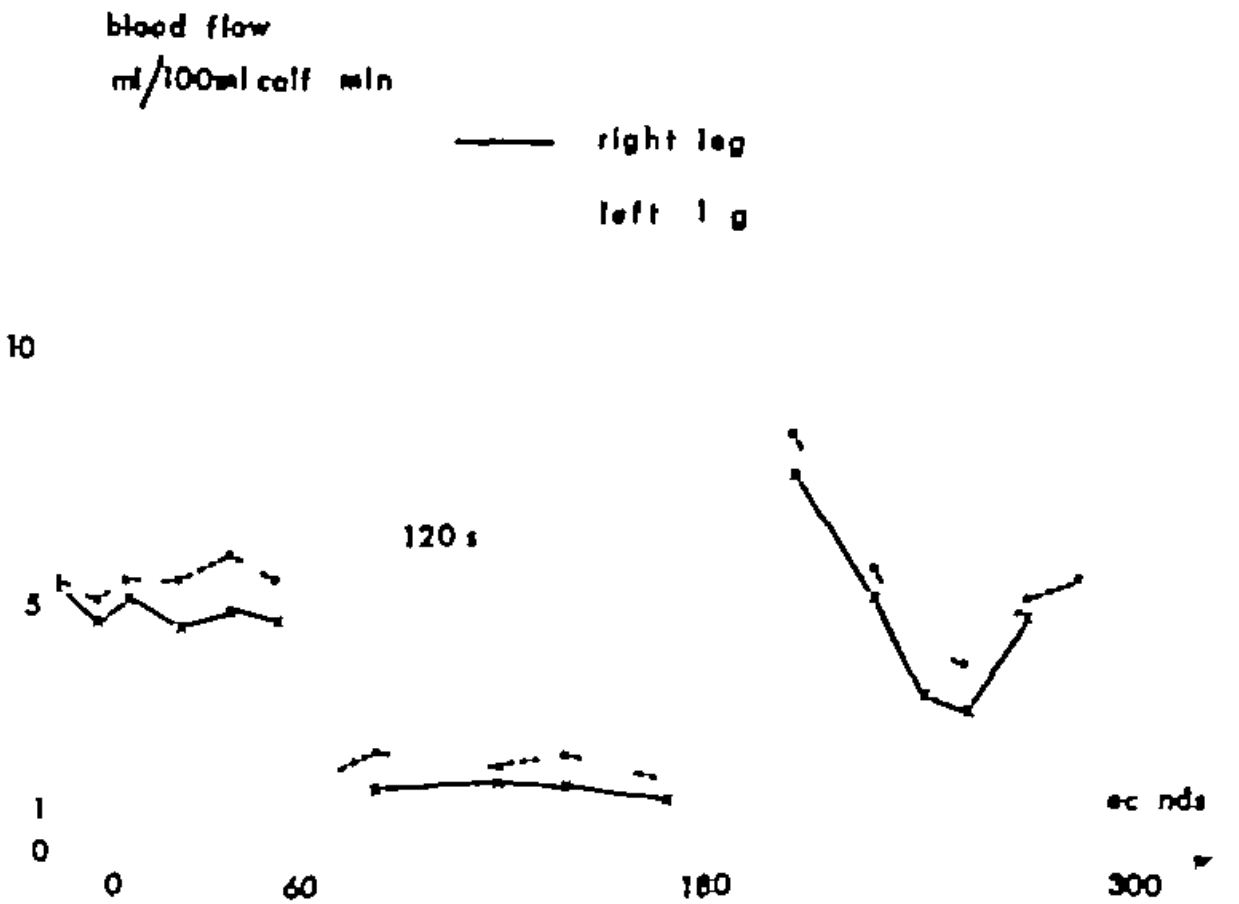

Fig. 16 Calf blood flow measured before, during and after 120 sec Valsalva experiment ('TLC')

B SUPPLEMENTARY EXPERIMENTS

The investigations performed in Lund (in 1965) were followed up by studies carried out in Copenhagen on 27 volunteers, well trained in the procedure. The observations were made in association with the development of the methods set forth in Chapter 2. Some of the results of these personal studies bearing on the limb blood flow and blood pressure during breath-holding, are given and commented below. All the subjects rested supine during the experiment (Chapter 2).

1 CONTROL EXPERIMENTS. In three subjects the venous pressure was measured via a catheter (Bardic Deseret Intracat model 1614), the tip of which was placed in a vein in the middle of the forearm segment enclosed in a Dohn (air) or a water plethysmograph. The other forearm was placed in a water or air plethysmograph, and its blood flow was measured three times each min as a control. In an attempt to avoid the usual increase in peripheral venous pressure during a Valsalva manoeuvre (Fig. 29) the veins

of the forearm were drained for blood in 30—60 seconds prior to the venous occlusion period by passive elevation of the forearm (30 cm above the horizontal level) of course, no pressure was applied to the cuffs of this arm during the elevation. Four seconds after the commencement of the Valsalva manoeuvre the arm was lowered into the horizontal position, and on the 5 sec, 60 mm Hg pressure was applied to the distal cuffs of both arms. The proximal cuffs were automatically inflated 2 seconds after the distal ones. Each person performed 9 Valsalva experiments of 1 minute duration and with 3 minute intervals. During each Valsalva manoeuvre the blood flow was measured only once in the previously elevated arm, either between the 7—15., the 27—35., or the 47—55 second. The subjects performed the same kind of Valsalva manoeuvre each time after a deep inspiration ("TLC") through a pneumotachograph (which was then closed by an assistant), the subject created an intrapulmonic pressure of 30 mm Hg —In the second phase of the control experiment a narrow cuff (6 cm) was placed around the right arm at the axilla. The cuff was inflated to 30 mm Hg for 60 seconds in order to simulate the increase in peripheral venous pressure of the limb caused by a Valsalva experiment (Fig 29) Of course, the subject relaxed and breathed normally during this simulated "Valsalva manoeuvre"

2. Standard experiments with water plethysmographic measurement of the blood flow through a forearm were carried out in 27 volunteers Each test subject held his breath at different intrapulmonic pressures, either after a deep inspiration ("TLC") or after a normal expiration (FRC) The breath-holdings lasted 60 ("TLC") or 35 (FRC) seconds, respectively During breath-holding the subject kept the intrapulmonic pressure constant at one of the following values 0, 10 20 30, or 40 mm Hg

3 Comparison The flow of blood was measured before, during and after Valsalva manoeuvres ("TLC" at 30 mm Hg). The left calf was placed in a Dohn plethysmograph and the right forearm in a water plethysmograph (34 C) The left forearm was surrounded by a double loop of mercury in-rubber, fixed—at one point—with 1 cm wide Scotch tape. One of Whitney's strain gauges was used for the loop but his mounting plate and calibration method was excluded for reasons given in Chapter 2. The experiment was performed several times with intervals in which control blood flow was measured (Table 12)

4. Blood flow and pressure. In 14 of the subjects the flow of blood through a forearm was measured with a water or a Dohn plethysmograph, while the arterial blood pressure, as well as the central and peripheral

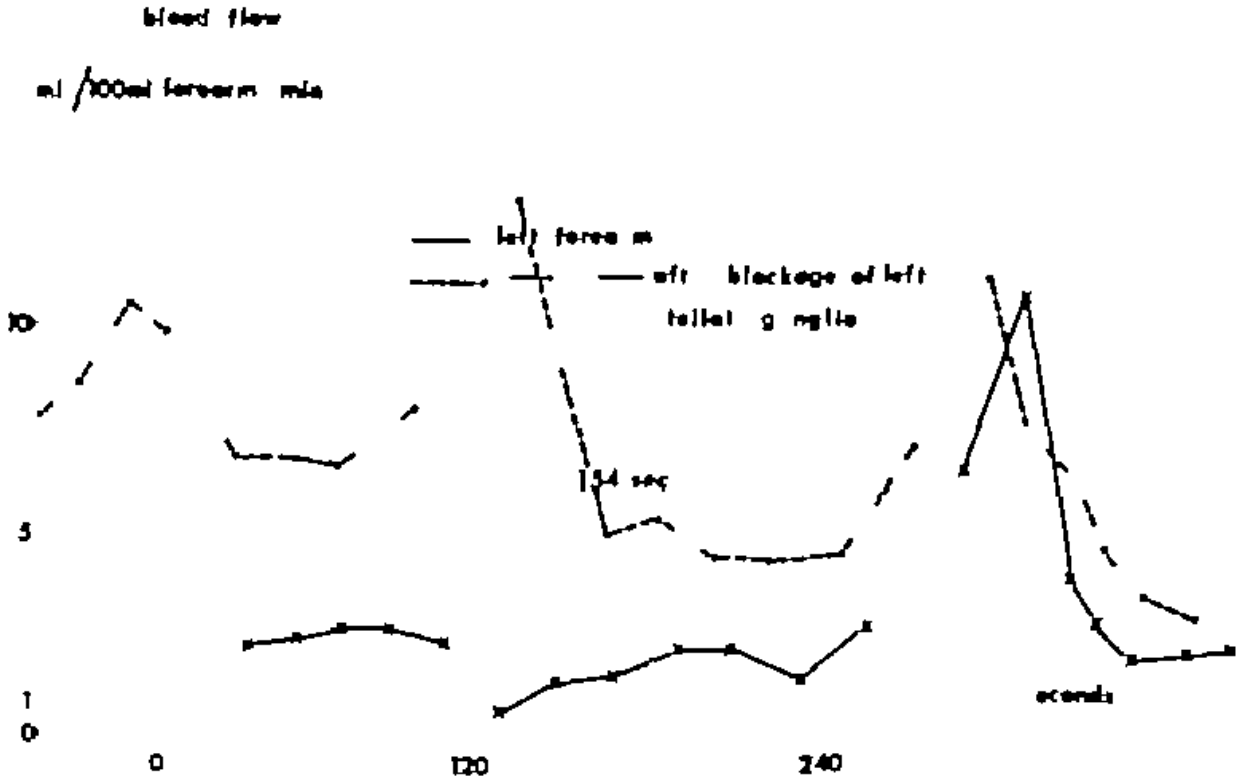

Fig. 27 Forearm blood flow altered by a Valsalva manoeuvre ('TLC') performed both before and after sympathetic blockage.

venous pressures, were measured via catheters introduced percutaneously in the vessels of the other arm. Separated by intervals of three minutes of *normal* breathing, the subject held his breath at *different* intrapulmonic pressures and lung volumes, as described above.

5 Muscle and skin vessels. Hand and finger blood flow has not been the topic of interest, for reasons that will become obvious for anybody who tries to measure this variable. However, the right hand blood flow of one subject was measured. The distal exit of the chamber of the water plethysmograph was closed. The subject was wearing a glove of thin rubber fixed with latex glue to one of the stiff rubber plates (Fig 6) which was used to close the proximal hole of the chamber. The plethysmograph chamber was kept at a temperature of 37°C. The flow of blood through the hand was measured for three minutes as a control (9 determinations). The subject then performed a Valsalva experiment of 60 seconds duration ('TLC' at an intrapulmonic pressure of 30 mm Hg) during which the blood flow was measured. Then the temperature of the plethysmograph chamber was lowered in steps of 1—3 C, and at each step the above experiment was repeated the lowest temperature tested was 10 C. The control blood flows decreased from 12.3 at the 37°C to 2 2 FU at 10°C.

6 Venoconstriction In three subjects the right forearm was placed in a water plethysmograph, and the venous pressure was measured in a vein in the middle of the segment. The right forearm segment volume and the venous pressure was recorded. A blood pressure cuff (12 cm wide) was placed around the upper right arm and inflated to 190 mm Hg for 3 minutes. After one min of this period had elapsed, the subject held his breath ('TLC' 30 'TLC' 0 FRC 30 FRC 0) Simultaneously as a check the flow of blood through the left forearm was measured intermittently with a Dohn plethysmograph.

Results and comments

The modified water plethysmograph was found to be more reliable than the air and the strain gauge plethysmographs, probably due to the fixed, local temperature and to the tailor made sleeves. The Dohn (air displacement) plethysmograph was hardly acceptable, since the volume of the limb segment was difficult to obtain with a reasonable accuracy The strain gauge method, even in the modified form covering practically the whole circumference and with correct calibration, was only applied for measurements expressed in percentage change.

1 *Does* the plethysmographic method fail to measure essentially true blood flows during a Valsalva manoeuvre? Since the peripheral venous pressure increases to a magnitude of 20—25 mm Hg, it would be reasonable to assume that the distended veins would create a back-pressure interfering with the arterial inflow (ignoring—for a moment—the distensibility of the capillary bed) In the first control experiment described above, the Valsalva manoeuvre—as usual—produced a fall in the flow of blood through both forearms approaching zero. In a forearm which has not been drained of blood prior to the flow measurement the Valsalva manoeuvre and the proximal venous occlusion elicit an increase in peripheral venous pressure of approximately 20 mm Hg However, in the previously elevated (drained) forearm the venous pressure, assumed to be representative of that of the veins of the segment in general, only increases to approximately 10 mm Hg Consequently the blood flow reduction is not a function of the increase in venous pressure. On the other hand, no drastic blood flow reduction was observed in the experiments where the peripheral venous pressure was raised with a cuff at the axilla during normal respiration. Thus, the plethysmographic method seems to yield the same results, regardless of the size of the venous back pressure (10—20 mm Hg). It seems reasonable to assume that the flow of blood measured during a Valsalva experiment approximates the 'true value.

2. *The results of the preliminary experiments made in Sweden showed* that the Valsalva manœuvre was accompanied by a certain reduction of the flow of blood through the forearm (Fig 25) and calf (Fig 26) The results of the standard experiments *indicated* that the marked drop in the limb blood flow was only seen in the initial phase of a breath-hold at *increased* intrapulmonic pressure. Breath-holding after a deep inspiration ('TLC') and at an intrapulmonic pressure of zero to 10 mm Hg reduced the limb blood flow only slightly from the control level, while at 20 mm Hg a considerable drop in blood flow was seen, and at 30 to 40 mm Hg the reduction of the flow of blood through the limb was so drastic that the flow even approached zero. Breath-holding after a normal expiration (FRC) hardly reduced the limb blood flow at intrapulmonic pressures of 0 to 10 mm Hg, but at 20 to 30 mm the flow of blood was reduced to almost zero in 6 cases. Curiously enough—at that time—21 of the 27 subjects did not show this dramatic blood flow reduction at FRC with an intrapulmonic pressure of 20 to 30 mm Hg

Simultaneously measured intrapulmonic and central venous pressures showed a linear relationship during Valsalva manœuvres with the glottis open. Owing to the risk that some subjects, contrary to the instructions, closed the glottis and produced the intended intrapulmonic pressure with the upper part of their airways the central venous pressure was measured during standard experiments. Such false Valsalva manœuvres were not accompanied by a marked fall in limb blood flow and the central venous pressure did not rise much, although the mouth pressure was 30 to 40 mm Hg Consequently the details of the many standard experiments are without much value, except for the overall picture given above, and conclusions will be based on other experiments (4.)

3 *The results* of the experiment where the blood flow changes were measured simultaneously with 3 different plethysmographs are given in Table 12. The Valsalva experiment evoked a marked reduction of limb blood flow and the relative reductions were of a similar magnitude in the forearm and the calf (Table 12)

4. *Simultaneous* recording of arterial and venous blood pressure and limb blood flow gave the following results. Breath-holding at 'TLC' and intrapulmonic pressures of 20 to 40 mm Hg produced a marked fall in arterial blood pressure and limb blood flow along with an increase in the venous pressures (Fig 29). Breath-holding at 'TLC' and intrapulmonic pressures of 0 to 10 mm Hg only changed the blood flow and pressures to a small extent, and since the main point of interest was the marked blood flow reduction these experiments are only considered as controls.—The short

Table 12 Percentage reduction of the blood flow by breath-holding after a deep inspiration ("TLC") and with an intrapulmonic pressure of +30 mm Hg.

	FU	% change
Water pleth., right forearm	8.1/1.9	77
Strain gauge left forearm:	(5.6/1.5)	73
Dohn pleth., left calf:	3.8/1.0	74

FU denotes flow units (*i.e.* ml blood/100 ml limb × min) The figure above the oblique line indicate the control blood flow and below the line is shown the blood flow measured during the initial part of the Valsalva experiment. The blood flow is the average of 10 flow observations in one subject.

FRC breath-holds at high intrapulmonic pressure produced a more or less pronounced decrease in the arterial pulse pressure. However, in most cases the systolic pressure increased (Fig 30), and these subjects showed no marked reduction in the flow of blood through the limbs (Fig 30) On the other hand, in three cases both the systolic arterial pressure and the pulse pressure dropped during breath-holding at FRC and high intra pulmonic pressure, and in all of these a marked fall in limb blood flow followed (Fig 31) In Fig 30 the increase in peripheral venous pressure is delayed as compared to the rise in the cases with marked flow reduction (Fig 31)

Catheterisation of all together 64 blood vessels (brachial artery (14), superior vena cava (22) peripheral vein (28)) was never attended by any complications

5 *In the hand* surrounded with water at different temperatures the Valsalva manoeuvre, at each temperature level produced a definite reduction of the blood flow down to about 0.5 ml/100 ml hand × min. Of course, a plethysmograph used on intact limbs can never reveal with certainty whether skin or muscle blood vessels are involved in the blood flow reduction. However, the hand when cooled down to low temperatures showed a blood flow reduction during Valsalva manoeuvres, to the same absolute value as at higher temperatures. This suggested involvement of the muscle blood vessels, since the cutaneous vessels should be essentially closed beforehand at such low temperatures.

6 *In order to* demonstrate an increase in venous tone it is necessary to show an appreciable pressure rise in veins unable to change their volume. The segment volume of the arm (560 ml) whose circulation was arrested

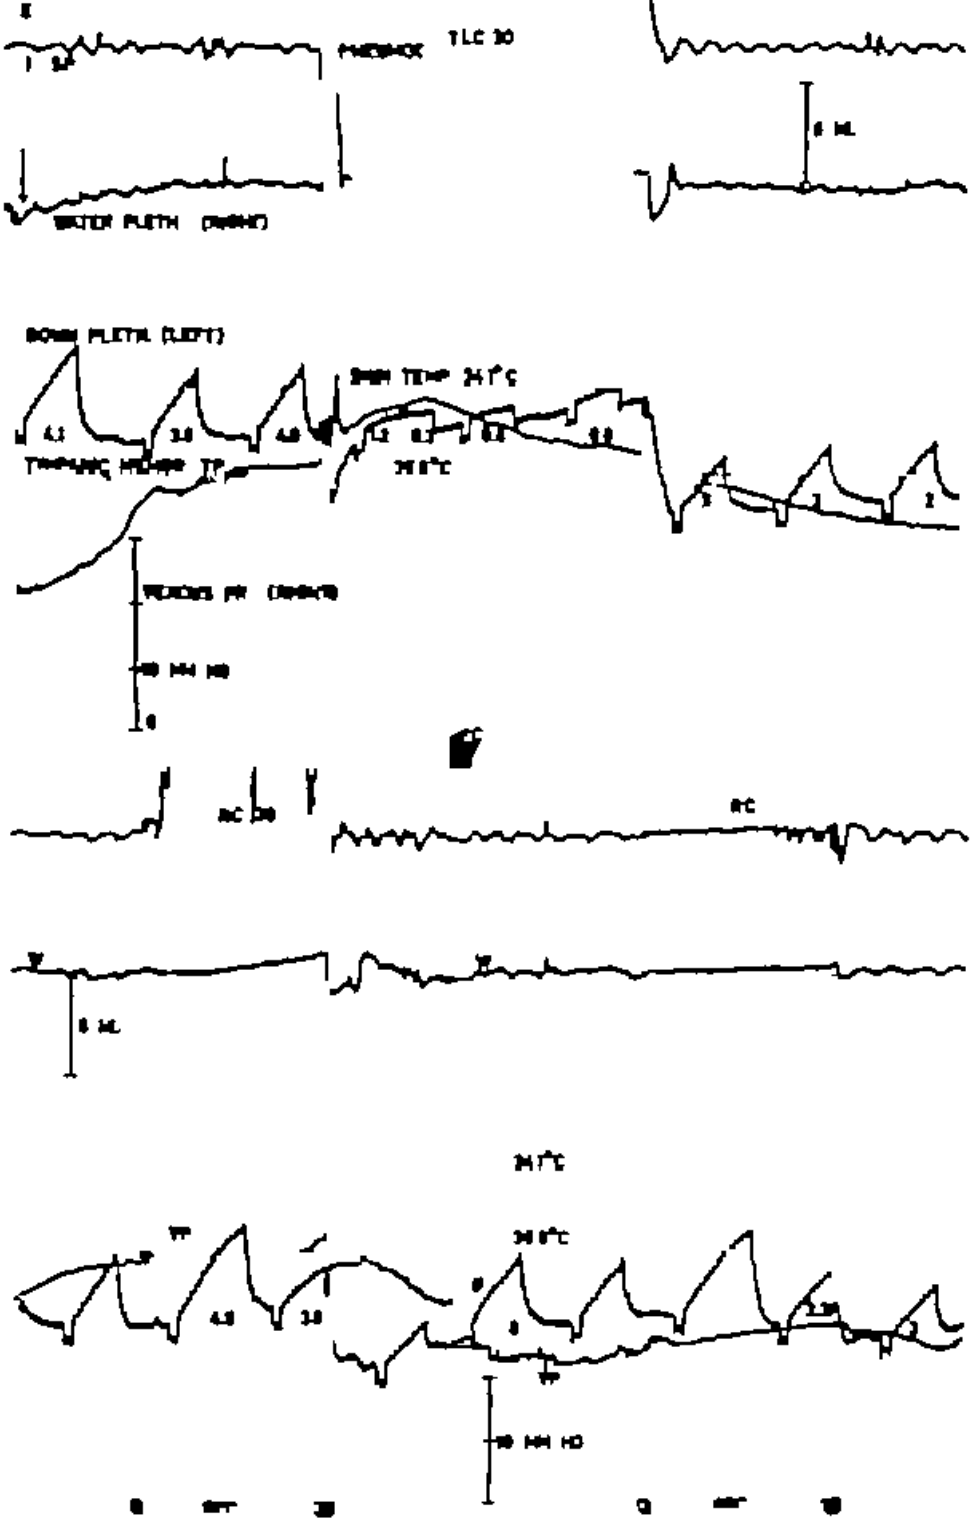

Fig. 18 Left forearm blood flow (Dohn plethysm. D) in FU V rietions in the right forearm segment olume measured with water plethysmograph (W), and in the venous pressure (VP) of the segmental veins, were recorded during arterial occlusion (90 mm Hg) of the right arm. Several secoods after the application of the arterial occlusion (A), the VP reached certain level whereafter the subject performed a breath-hold ("TLC" o, "TLC" 30, FRC o FRC 30 mm Hg). In the control phase VP was 1 mm Hg, to which must be added water column equal to 5 mm Hg The VP level reached before the breath-hold, varied between 20 and 40 mm Hg, dependent upon the content of blood of the veins when the arterial occlusion was applied (A). Pneumotachogram (P) and temperatures are recorded as control.

did not vary essentially with time (Fig 28) so input or output of blood through the vessels in the humerus or any other source is excluded. Only breath-holds ('TLC' 30) at high intrapulmonic pressure elicited a marked rise in venous pressure (11 mm Hg) without essential change of the volume of the segment. Immediately after circulatory arrest the blood volume of the limb will be distributed to the different categories of vessels according to their elastic and active tension. After this equilibration the passive tension of the vein wall will probably be constant, and a marked increase in venous pressure presumably due to an increase in active tension of the venous wall, *i.e.*, venoconstriction.

Although it was not proved with simultaneous volume an pressure measurements, previous experiments (Page et al. 1955—and later other authors) on isolated venous segments *in situ* made it likely that the Valsalva manœuvre provoked venoconstriction in human limbs. The above increase in peripheral venous pressure of 10 mm Hg is difficult to explain on any other basis than venoconstriction.

Cause of the limb blood flow reduction

From a theoretical point of view the fall in the flow of blood through the limbs during the Valsalva manœuvre must be due to a fall in the arteriovenous pressure difference (*i.e.*, perfusion pressure) a passive or active increase in the resistance of the small vessels of the limbs, or a combination of these.

Reduced perfusion pressure According to the Poiseuille equation, the flow is identical with perfusion pressure divided by resistance. The mean pressure of the brachial artery drops from about 100 mm Hg in the control period to approximately 75 mm during the initial part of a Valsalva manœuvre (Fig 29) while the peripheral venous pressure rises from 5 to 20 mm Hg Thus the arteriovenous pressure difference has fallen less than 50 % while the simultaneous percentage drop observed in limb blood flow was always greater and often approached 100. Therefore, the conclusion must be drawn that only part of the observed fall in blood flow can be accounted for by the reduction in perfusion pressure *alone*

Passive increase in resistance However, the fall in arterial pressure and rise in venous pressure leading to a reduction in perfusion pressure may have produced a change in the dimensions of the resistance vessels of the limb and thus reduced the flow of blood. In rigid straight tubes, as used by Poiseuille, the resistance is constant and—if the coefficient of viscosity and the length of the tube do not vary—inversely proportional to the fourth

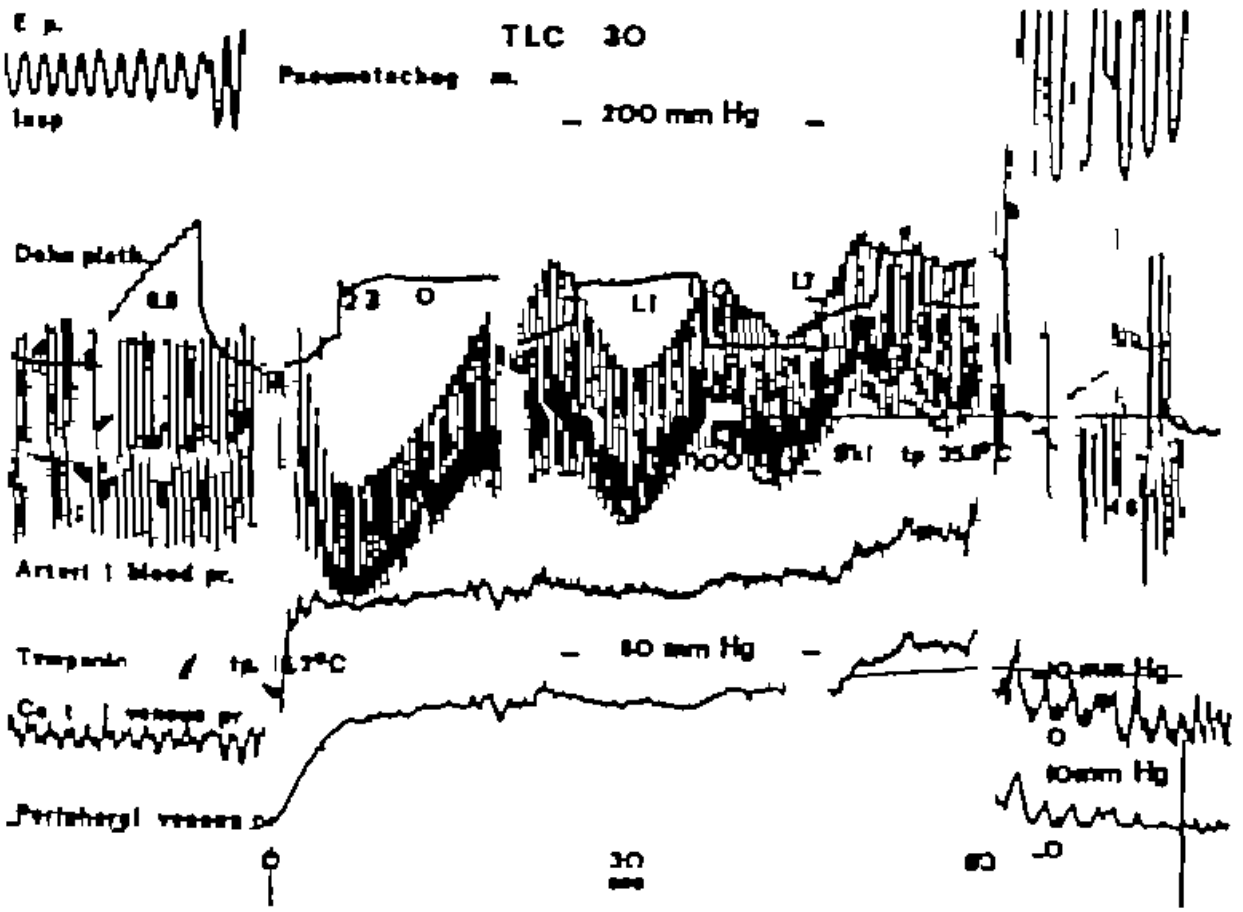

Fig. 29 Simultaneous recording of blood pressure and blood flow The breath-hold was performed after a deep inspiration and at an intrapulmonic pressure of 50 mm Hg On the ordinate 0 to 10 mm Hg are venous pressures, while 5 100, 150, and 200 mm Hg are arterial pressures. The blood flow values are given along the plethysmogram. The temperatures are practically constant. Eighty similar experiments confirmed the covariation between blood flow and arterial pressure shown above.

power of the radius. Since blood vessels are distensible, their radius depends upon their transmural pressure (*i.e.*, the difference between the intravascular pressure and the tissue pressure) The resistance vessels are here defined as those producing the major part of the resistance it is to be expected that the intravascular pressure of these vessels should, on an average, be close to the mean of the arterial and the venous pressures. It is also likely that the tissue pressure of relaxed limbs is about zero and remains so during a Valsalva manœuvre. Thus—in the control period as well as during the Valsalva manœuvre—the transmural pressure of the resistance vessels should, on an average, be close to half the sum of the arterial and venous pressures. In the control period the transmural pressure will be approximat ely (100 + 5)/2 mm Hg, while during the Valsalva experiment, at the time where the flow approaches zero, it will be (75 + 20)/2 mm Hg (Fig 29)

Thus, according to this reasoning, the Valsalva manœuvre should only lead to a reduction in the transmural pressure of the resistance vessels of a few mm Hg Even considering the fourth power relation between resistance and radius mentioned above, it can hardly be expected that such a moderate reduction in transmural pressure could lead to a decrease in the radius of the resistance vessels responsible for a major increase (toward infinity) in their resistance.

Active increase in resistance Since even the combined effect of the 2 factors just mentioned, cannot alone explain the observed fall in flow to nearly zero one seems compelled to assume that contraction of smooth muscle in the wall of the resistance vessels is also an important contribution to these falls in blood flow Such a contraction, or vasoconstriction, is probably brought about reflexly since vasoconstriction was not found during Valsalva manœuvres in limbs with sympathetic block (Fig 27) Part of the limb blood flow reduction can therefore most likely be explained by a reflex vasoconstriction with a sympathetic efferent path to the resistance vessels

The initial marked fall in the flow of blood during a Valsalva manœuvre was followed by a slow rise (Fig 25) This may in part be accounted for by a gradual increase in arterial blood pressure (Fig 21) but some relaxation of the resistance vessels possibly evolved by local hypoxia may also be involved, especially during some of the prolonged breath-holds. However in most cases the blood flow was reduced also in the later part of the manœuvres (Fig 26 29) suggesting a *marked* vasoconstriction, especially since the arterial blood pressure had reached normal levels (Fig 29).

The afferent path of the reflex arc

An essential part of the limb blood flow reduction during a Valsalva experiment, is due to a reflex vasoconstriction of the resistance vessels with a sympathetic efferent path, so it seems worth while to search for receptors related to the afferent side of the reflex arc.

Since the venoconstriction shown above is seen only during the same types of breath-holds as is the marked constriction of the resistance vessels, the trigger mechanism is assumed to be the same for both phenomena.

First the above results will be compared with results obtained by others, in an attempt to solve the receptor problem. Sharpey Schafer (1965) recorded limb blood flow immediately *after* short breath-holds with unknown lung volume and sometimes unknown intrapulmonic pressure (in certain cases the intra-œsophageal pressure was approximately 40 mm

Hg), and found a blood flow reduction, which—because of the short duration of the breath-hold—may have certain characteristics in common with that observed *during* a Valsalva experiment here. Sharpey-Schafer (1965) assumed the existence of a reflex constriction of both arteries and veins reducing the blood flow and concentrated his interest upon the "paradoxical role of vasoconstriction" in the period *after* the Valsalva manoeuvre. The marked degree of peripheral vasoconstriction with a limb blood flow approaching zero during the initial phase of the Valsalva manoeuvre, was not recognized. The important effect of a fall in perfusion pressure, and of a fall in transmural pressure of the resistance vessels, was not considered. However, Sharpey Schafer's (1965) interpretation is in accordance with the essential part of the explanation given above (*i.e.*, active increase in resistance).

Recently Brick (1966) reported a mean decrease in the flow of blood through the human forearm of 25 % on immersion of the face in water with the subject prone. The intrapulmonic pressure was not measured.—We repeated Brick's experiment and found the forearm blood flow to decrease by 68 % (mean) during 60 sec breath-holding with the subject prone ('TLC' and an intrapulmonic pressure of 20 mm Hg). The same blood flow decrease was found during similar breath-holds with the face immersed in water at 15 and 28° C. Thus, the blood flow reduction, which Brick attributed to face immersion, seems to be elicited simply by breath-holding at increased intrapulmonic pressure, and his suggestion is not a fair solution to the receptor problem.

Other possibilities must be considered.—*Receptors* might be situated in the thoracic wall, pulmonary tissue (stretch receptors) or in other compartments of the respiratory system. Assuming an adequate stimulus of such receptors to be an increase in receptor length per unit of time, it is clear that pulmonary stretch receptors can be excluded as a possible explanation, since the marked blood flow reduction is also seen during breath-holds at FRC (Fig. 31), namely where both pulse pressure and the arterial systolic pressure fell. The basis for these exceptions may be a relatively insufficient blood volume (Nordenfelt 1964). The limb blood flow drops with the arterial blood pressure, regardless of the lung volume during the Valsalva experiment (Fig. 30, 31).—*Receptors* might be located in the venous system, in the right half of the heart, or in the pulmonary circulation. Especially the 'low pressure baroreceptor reflex to skeletal muscle vessels of man' (Barcroft 1963), is a highly attractive explanation of the vasoconstriction. The evidence for the low pressure receptors is the increase in forearm blood flow by raising the legs of recumbent subjects or by negative pressure

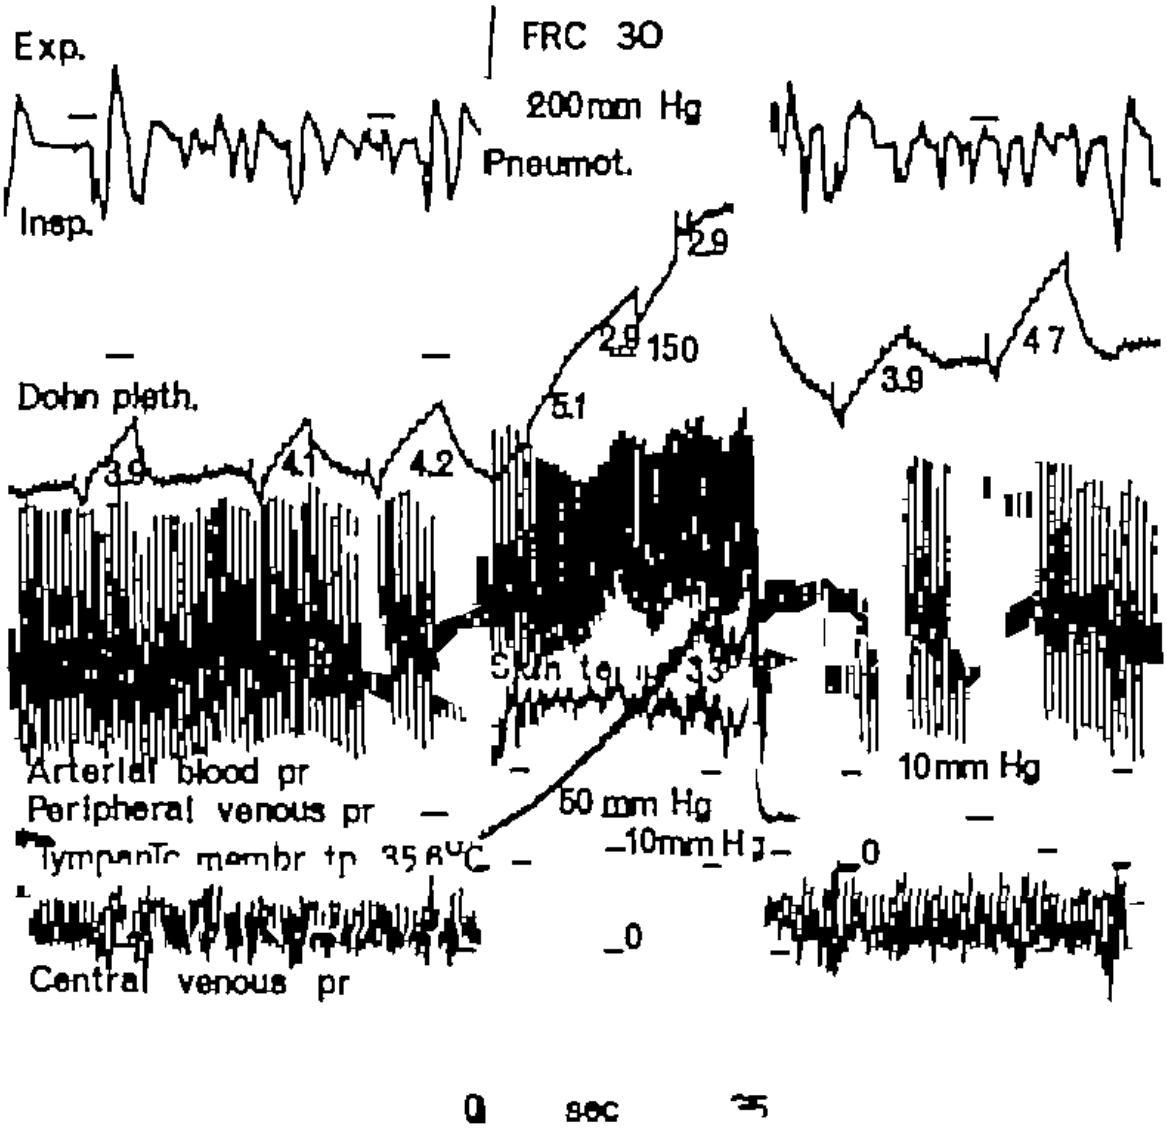

Fig 30 Record of a 55 sec breath-hold after normal expiration (FRC) and at an intrapulmonic pressure of 30 mm Hg. Variables as in Fig 29. Twelve similar records (FRC, pressure of 20 to 30 mm Hg) and eight control experiments (FRC, pressure of zero to 1 mm Hg) are available.

breathing. The effect of these experiments on the arterial blood pressure is not considered of importance in such argumentation. Other reflexes are considered in the monograph by Heymans & Neil (1958). Unfortunately most of the evidence of their existence and function is indirect, as shown in the above example.—*Receptors* might also be located in the left half of the heart and the systemic arteries. Receptors other than sino-aortic have been postulated (Heymans & Neil 1958) but most of the evidence

put forward is indirect and the functional role of such receptors is neither clear nor proved. The baroreceptors believed to exist in the myocardium of the left ventricle may be an exception. In contrast, the receptors found in the carotid sinuses and in the wall of the aortic arch have a proved functional importance (Heymans & Neil 1958) but even their function is not yet properly understood. Adequate stimulus of these receptors is not only the mean transmural pressure of the vessels, but also the size of the pulse pressure, and the rate at which it changes. The dramatic fall in arterial blood pressure due to a Valsalva manoeuvre, is a strong "negative" stimulus to the sino-aortic baroreceptors (possibly the receptors cease to fire) The reaction to such a condition is in healthy persons—after a certain delay—a vasoconstriction of both arterioles and veins. The profound vasoconstriction was demonstrated above and the problem seems explained by well-known physiological concepts, without assuming the existence" of "receptors of unknown origin" or other hardly informative hypotheses as is commonly done in the literature.

In some cases breath-holding at FRC and high intrapulmonic pressure did not lead to a marked fall in limb blood flow These cases differed from those represented in Fig 31 because the systolic and the mean arterial pressure *rose* although the pulse pressure fell (Fig 30), in contrast to the cases represented in Fig 31 In these cases the negative stimulus to the baroreceptors may not have been present, indicating sufficient venous return, probably mainly from the abdominal blood deposits (Nordenfelt 1964) Moreover the high arterial mean pressure and relatively low peripheral venous pressure counteracts the fall in perfusion pressure and in transmural pressure of the resistance vessels.

Although a major part of the reduction of the flow of blood through the limbs seems explainable by the classical high pressure baroreceptor reflex, this does not necessarily exclude influence of other parts of the nervous system. Afferent impulses from many sources including the central nervous system itself, may influence the activity of the circulatory control centers. Besides the output from these centers to the heart, the arterial, and the venous systems may not always follow the same relative pattern from one situation to the next.

Since the flow of blood through the limbs approaches zero during breath-holding at high intrapulmonic pressure, a greater blood flow reduction could not be expected during the same manoeuvre performed in water (regardless of its temperature) During breath-hold dives to depths of some meters, the pressure difference across the lungs and chest wall will most likely be small and not lead to marked changes in limb blood

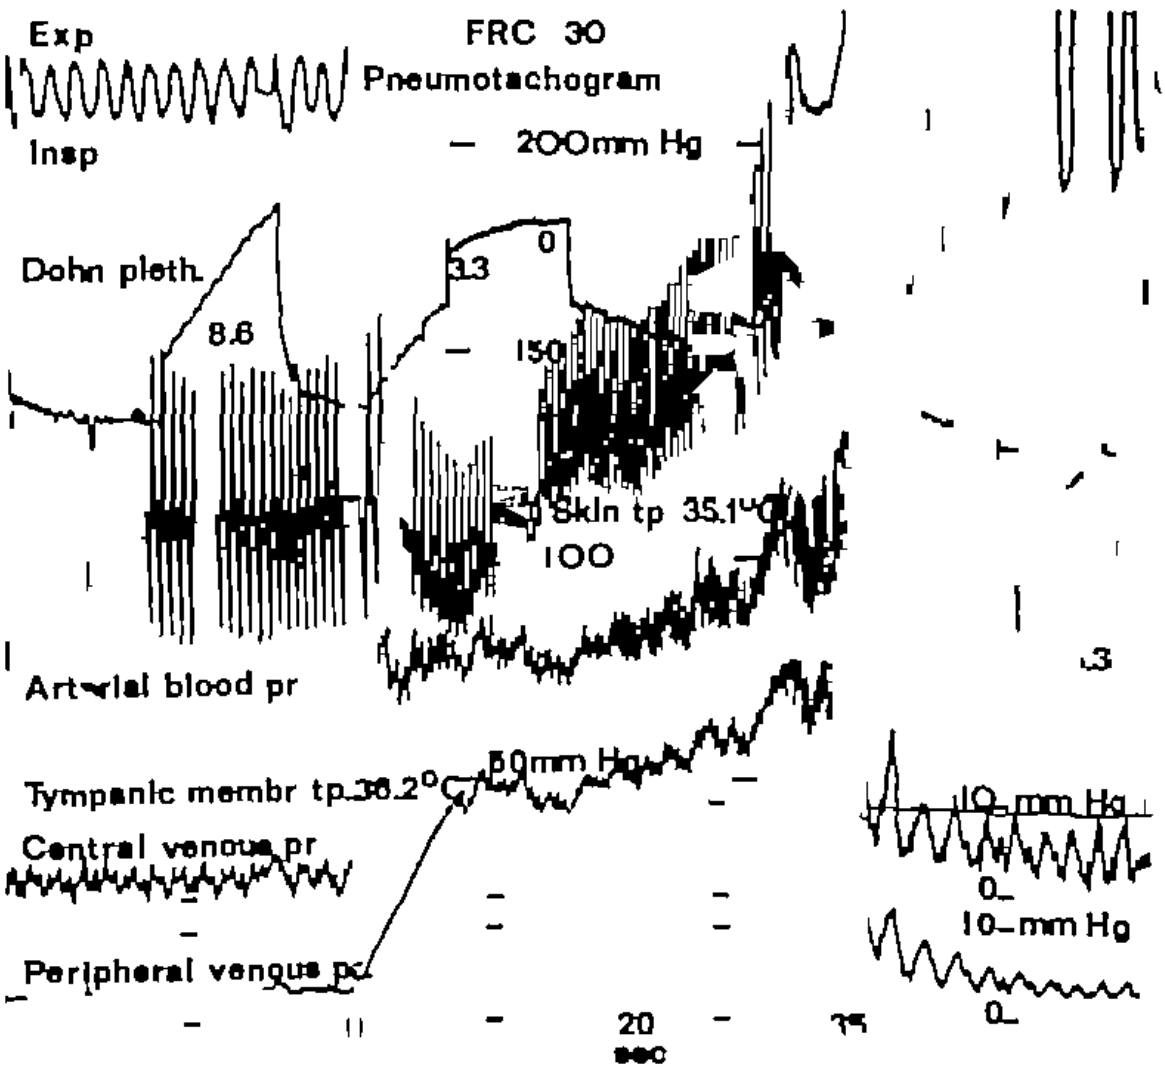

Fig. 31. As Fig. 30, but with faster speed of the recorder. A 35 sec breath-hold is performed after normal expiration and at an intrapulmonic pressure of 3 mm Hg. Three similar records (FRC, pressures of 20 to 3 mm Hg) and two control experiments (FRC, pressure of zero and mm Hg are available).

flow except where the subject performs a Valsalva manoeuvre. During deep dives toward the limit of human performance, the intrapulmonic pressure will probably be negative, and the blood content of the thoracic vessels will increase. This rather special condition is possibly accompanied by a small relative increase in limb blood flow. In general the cardiovascular changes are not likely to potentiate essentially the serious consequences of gas accumulation during breath-hold diving in otherwise healthy subjects. —The Valsalva experiment and unconsciousness have been analyzed by Nordenfelt (1964).

In the above argumentation it was mentioned that the function of the high pressure baroreceptors is not completely understood at present and that even more information is needed as far as other receptors are concerned. For persons interested in circulation and neurophysiology these problems should be highly attractive, especially when sufficient knowledge from animal experiments is provided to justify a study in man.

Summary and conclusions

Serious accidents in a submarine escape training tank prompted an investigation of the basis of the:
loss of consciousness and drowning
changes in cardiac rhythm and
alterations in limb blood flow cardiac output and blood pressure occurring in association with breath-holding (in air and in water).

Experiments were carried out on 129 persons some of whom participated in 2 or more projects.

In these experiments determinations were made of the
composition of alveolar and expiratory air with a modified Scholander micro-analyzer and electrodes
air volumes with gas meters, pneumotachographs and spirometers
intrapulmonic pressures with water manometers
ECG with conventional device and with equipment modified for use under water
direct blood pressures with percutaneous technique and strain gauge transducers
cardiac output (mean stroke volume) with the indicator dilution technique
tympanic membrane and skin temperatures with thermistors, and
limb blood flow with water air and strain gauge-plethysmographs.

All variables were registered simultaneously with selected mirror galvanometers and recorded on a UV recorder. Only ECG registration made it necessary to use an amplifier between the detector and the recorder.

The following observations of interest were made:
In 4 divers who got a severe neurological disease after repeated breath-hold diving, treatment with recompression produced immediate and total relief
after repetitive dives to depths of 20—30 m of 1—2 min duration and with surface intervals less than 10 minutes, the predicted N_2 tissue tensions exceeded the maximum permissible tensions of conventional air supplied diving

on two occasions a test subject lost consciousness by suppressing the ventilation voluntarily for 190 seconds each time

carbon dioxide retention occurred during repeated breath-hold diving

the alteration in heart rate observed in humans during breath holding varied with the intrapulmonic pressure ('apnoic bradycardia and tachy cardia during Valsalva manoeuvres) and the environmental temperature ('cold bradycardia')

breath-holding with an intrapulmonic pressure of 20—40 mm Hg (Valsalva manoeuvre) produced a drastic reduction of limb blood flow (approaching zero) if the arterial blood pressure fell essentially this reduction could be partially prevented by sympathetic block.

These findings appear to warrant the following conclusions

Avoidance of decompression sickness requires surface intervals of at least 10 minutes between consecutive, deep breath-hold dives

decompression sickness calls for immediate recompression treatment, especially because of serious neurological signs

psychological factors (will power feeling of competition) may be of decisive importance in breath-hold diving accidents

loss of consciousness with the risk of drowning may be caused by CO_2 narcosis in combination with the well-known hypoxia during ascent from deep breath-hold dives

apnoic bradycardia is elicited from the sino-aortic baro-receptors and the cold bradycardia is caused by cold stimulation of the skin

the reduction in limb blood flow by breath-holding at increased intra pulmonic pressure is caused by the fall in perfusion pressure and by a sino-aortic baroreceptor reflex with a sympathetic efferent path to the arterioles

Despite the complexity of the circulatory regulation in general, it seems as if no hypothetical mechanisms are necessary in the interpretation of the cardiovascular changes observed during breath holding since these changes are presumably explainable alone on the basis of classical physiological mechanisms, whose existence is generally accepted.

Resume og konklusioner

Alvorlige ulykker i en tank til optræning af U-bådsmandskab i fri udslusning startede en undersøgelse af grundlaget for

Bevidstløshed og drukning

forandringer af hjerterytmen, og

ændringer af perfusionshastigheden i extremiteterne, hjertets minut volumen og blodtrykket, optrædende i forbindelse med vejrholdning (i luft og i vand)

Der udførtes forsøg med ialt 129 personer af hvilke nogle deltog i 2 eller flere projekter.

I disse forsøg undersøgtes

Sammensætningen af alveole og exspirations-luft med en modificeret udgave af Scholanders mikro-analysator og med elektroder,

luftvolumina med gas-ure, spirometre og pneumotachografer,

intrapulmonalt tryk med vandmanometre,

EKG med konventionelt udstyr samt med udstyr modificeret til under vandsbrug,

direkte blodtryk med perkutan teknik og 'strain gauge" transducere,

hjertets minutvolumen (middel-slagvolumen) med indikatorfortyndingsteknikken,

trommehinde- og hud-temperaturer med termistorer, og

perfusionshastigheden i extremiteterne med vand luft og "strain gauge" plethysmografer

Alle variable blev registreret simultant med udvalgte spejlgalvanometre og opskrevet med en UV-skriver (ultraviolet følsomt papir) Kun ved EKG registrering var en forstærker nødvendig imellem detektor og skriver

Følgende observationer synes af interesse

Fire dykkere med en alvorlig neurologisk sygdom efter gentagne dyk under vejrholdning, blev behandlet med rekompression som medførte øjeblikkelig og total helbredelse,

efter en serie dyk til dybder på 20—30 m af 1—2 minutters varighed og med mindre end 10 minutters overflade-intervaller overskred beregnede vævstensioner af kvælstof de maximalt tilladelige tensioner ved konventionel trykluftdykning,

ved 2 lejligheder holdt samme forsøgsperson vejret i 190 sekunder indtil han besvimede,

efter gentagne dyk under vejrholdning fandtes en betydelig kuldioxyd-ophobning

hjertefrekvens under vejrholdning varierede med det intrapulmonale tryk ('apnoe-bradycardi' og tachycardi under Valsalva manovrer) og den omgivende temperatur ('kulde bradycardi')

vejrholdning med et intrapulmonalt tryk på 20—40 mm Hg (Valsalva manovre) fremkaldte en drastisk reduktion af perfusionshastig heden i extremiterne (nærmende sig total ophør), dersom det arterielle blodtryk faldt væsentligt denne reduktion kunne delvis forhindres ved blokade af de sympatiske efferente tråde.

Disse fund synes at berettige til følgende konklusioner

For at undgå dekompressionssygdom må man benytte overflade intervaller på mindst 10 minutter mellem dybe dyk under vejrholdning,

de alvorlige neurologiske fund understreger betydningen af at denne form for dekompressionssygdom straks behandles med rekompression,

psykologiske faktorer (viljestyrke, konkurrenceforemmelse) kan være afgørende ved drukneulykker

beruselsestilstand med risiko for drukning kan forårsages af kuldioxyd-narkose kombineret med den velkendte iltmangel under opstigning fra dybe dyk,

'apnoe-bradycardi' udløses fra de sino-aortiske baro-receptorer og 'kulde bradycardien' af kuldestimulation af huden,

faldet i perfusionshastigheden i extremiteterne ved Valsalva's manovre forårsages af faldet i drivende tryk (perfusionstryk) og af en reflektorisk vasokonstriktion udløst fra de sinoaortiske baroreceptorer med en sympatisk efferent bane til arteriolerne.

Kredsløbsregulationens kompleksitet må erkendes i almindelighed, men hypotetiske mekanismer synes ikke nødvendige i fortolkningen af de cardiovaskulære ændringer der er iagttaget under vejrholdning Disse ændringer lader sig tilfredsstillende forklare alene på grundlag af klassiske fysiologiske mekanismer hvis eksistens der er almindelig enighed om.

Symbols

The symbols used here conform essentially to those published in Federation Proceedings 1950: 9 602–605

V	Air volume
$\dot{V}_A$	Alveolar ventilation per min (the expired alveolar ventilation)
V_D	Dead space
P_B	Barometric pressure
F	Fractional content of gas in the dry phase
f	Respiratory frequency per min
p	Pulse frequency per min
R	The alveolar exchange quotient, *i.e.*, VCO_2/VO_2 (the exchange between the atmosphere and the air in the respiratory system, or the exchange across the total alveolar membrane).
RQ	The metabolic exchange quotient (ratio) across the total surface of the cellular membranes.
I	Inspired air
E	Expired air
A	Alveolar air
	Arterial blood
v	Mixed venous blood
	Capillary blood
t	Tissue
P_{IO_2}	The fractional content of O_2 in the dry phase of the inspired air
$\dot{Q}$	Flow or volume rate of blood
$\dot{Q}_c$	Volume rate in the capillaries
S_vO_2	Saturation of hemoglobin with O_2 in mixed venous blood
P_{CO_2}	The partial tension of CO_2 in arterial blood
P_tN_2	The mean partial tension of N_2 in a (homogeneous) tissue compartment
RV	The lung volume after maximal expiration, *i.e.*, the residual volume
TV	Tidal volume, *i.e.*, the volume of air expired per breath
IRV	Inspiratory reserve volume
ERV	Expiratory reserve volume
VC	Vital capacity *i.e.*, the maximal volume expirable after maximal inspiration
FRC	The lung volume after normal expiration, *i.e.* the functional residual capacity =RV+ERV
TLC	The lung volume after maximal inspiration (total lung capacity = RV+ ERV+TV+IRV)
STPD	Standard Temperature and pressure, dry (0°C, 760 mm Hg)
BTPS	Body temperature and pressure, saturated with water vapour (37°C, P_B)
ATPS	Ambient Temperature and pressure, saturated with water vapour ($t°$ P_B)
t°C	The ambient (room) temperature in degrees Celsius

$\dot{V}O_2$	Alveolar O_2 exchange per min
VCO_2	Alveolar CO_2 exchange per min
atm abs	Atmospheres absolute pressure
min	Minute
sec	Second
mM	mill Molar
PE	Polyethylene terephtalate
PVC	Polyvinyl chloride
FU	Flow units (*i.e.*, ml blood/100 ml limb segment × min)

As indicated above a bar over a symbol denotes a mean value while a dot over a symbol indicates a time derivation (in general per min).

Capitals in suffixes symbolize a gas in an air phase, while small letters in suffixes indicate a gas dissolved in a liquid phase.

Generally accepted abbreviations in physics and chemistry are used (mm, μl, O_2, N_2, CO_2, v for Voltage, etc)

INTRODUCTION

The final step in the formation of blood clots in vitro as well as of thrombi in the circulation consists of the thrombin mediated conversion of fibrinogen to fibrin. The dissolution of clots or thrombi occurs through the action of fibrinolytic enzymes, giving rise to fibrin degradation products. Therefore estimation of the elimination rate of tagged fibrinogen seems to be valuable in the study of clinical disorders or experimental states, in which abnormal metabolism of fibrinogen can be expected. Such disturbances may involve the conversion to fibrin the fibrinolytic breakdown or the synthesis of fibrinogen. Obviously several mechanisms can occur simultaneously

Part of the present investigation has been devoted to clinical studies on the fibrinogen turnover in man. Normal subjects as well as patients with different coagulation disorders have been studied.

The greater part of the work has been experimental studies in dogs, in which the coagulation system has been activated by intravenous infusion of different procoagulants—thrombin, thromboplastin and a procoagulant isolated from human postpartum serum. Special interest has been devoted to the secondary changes, following the initial stage of intravascular coagulation A fibrinolytic "response to the coagulation trauma has been found and analysed with respect to quantity and quality of the appearing split products and the influence thereupon of fibrinolysis inhibitors.

In parallel with the experimental studies the incorporation of ^{131}I isotope into dog fibrinopeptides has been studied.

Review of the results of other investigations

In the last decades several studies have been made on the turnover of fibrinogen in human subjects. Such investigations have comprised *normal subjects* (Christensen 1958 Hammond and Verel 1959 Adelson et al 1961 Blombäck et al 1961 McFarlane et al. 1964 Amris and Amris 1964 Hart 1964 Takeda 1966) investigated by means of ^{131}I or ^{125}I labelled fibrinogen. Some earlier studies were made with the use of transfusion of plasma fibrinogen, labelled in vivo by means of ^{35}S-amino acids, from yeast or yeast hydrolysate (Madden and Gould 1952 Volwiler et al 1955 Gerdes and Maurer 1957) The authors using iodine-labelled fibrinogen have reported a half-life time for the protein of around 4 days (2.3—5 1) whereas in the studies made with radioactive amino acids a longer half life time (6.7 days) was found. Reutilization of radioactive amino acids from the catabolism of labelled body proteins seems to introduce an appreciable error in studies using fibrinogen labelled by the latter method.

Concerning states of *congenital coagulation defects* several different disorders have been studied. Gitlin and Borges (1953) followed the elimination of administered fibrinogen in ? cases of congenital afibrinogenemia. They determined the plasma fibrinogen concentration by an immunochemical method and found the half life time to be around 4 days. Rausen et al. (1961) using ^{131}I fibrinogen found in one case of congenital afibrinogenemia a half-life 3 0 days, and in 6 cases of hemophilia A, it varied between 2.8 and 3 6 days. Later Hart (1964) also with ^{131}I fibrinogen, investigated 10 patients with different types of hemorrhagic diathesis and found the half life times for those to be 3 6—4.5 days. These times were all within the normal range found by this author Among the patients of Hart were one case of each of von Willebrand's disease, prothrombin deficiency hemophilia A, hemophilia B and factor X-deficiency Takeda and Chen (1967) with the use of ^{125}I labelled fibrinogen, and also measuring the radioactivity with a whole body counter found the half-life for 10 patients with hemophilia A to be 2.34 ± 0.17 days, which is shorter than the time obtained by this author in normal subjects (mean 3 4)

Also patients with acquired or induced forms of coagulation disturbances have been investigated. Thus Hart, in the studies mentioned, followed the elimination of I fibrinogen in cases of platelet deficiency and Glanzmann's disease in which states the half life time also was found to be within normal limits The same author also studied the influence of anticoagulants as coumarin and heparin, which were found not to evoke any significant effects upon the fibrinogen survival. The influence of fibrinolysis inhibitor (epsilon aminocaproic acid, EACA) has been studied by Hart (1964) who found a prolongation of the fibrinogen survival in a normal subject and the same in a patient with factor X-deficiency Amris and Amris (1964) in one case of liver cirrhosis under treatment with EACA also found a prolongation

of the initial survival time to about the double. After induced fibrinolysis by means of streptokinase Hart found a distinct fall in labelled and unlabelled fibrinogen.

A further group although very heterogeneous, is represented by the *so-called "hypercoagulable states"* To these have been conferred several conditions, in which clinical experience has shown an increased incidence of thrombosis and where also hypercoagulability as judged by the findings of conventional coagulation investigations, has been more or less clearly demonstrated. In patients with polycythemia vera Christensen (1958) Blombäck et al. (1964) as well as Hart (1964) have found cases with a distinct shortening of the half life for fibrinogen. In patients with cancer Christensen (1958) and Hart (1964) also found a diminished half-life, especially in metastatic carcinoma With reference to the hypothesis of Duguid on the thrombogenic pathogenesis of atherosclerosis, studies in patients with coronary heart disease and/or hyperlipemia have been performed. Christensen (1958) in 3 patients, like later Blombäck and Carlson (1963) in a larger series, found no evidence of a changed half-life time Hart, on the contrary demonstrated shortened times in patients with arterial vascular disease In cases of liver cirrhosis, Christensen in one of two patients noticed a slight shortening. Blombäck et al (1964) Amris and Amris (1964) as well as Tytgat et al. (1968) found that an accelerated fibrinogen elimination can occur in this disorder In patients with burns, Davies et al. (1966) found half life times decreased to 1.3—2.1 days as against 4.5 days in their normals. In 2 of 6 patients with cerebral malaria Devakul et al (1966) observed a very rapid elimination of fibrinogen radioactivity

In disorders with increased plasma fibrinogen values as rheumatoid arthritis and nephrosis the half life times of ^{131}I labelled fibrinogen were within normal limits (Takeda 1967 Takeda and Chen 1967) In both states, besides the high plasma fibrinogen level, they found increased amounts of interstitial fibrinogen, transcapillary transfer rate and catabolic rate of the protein which changes were secondary to an increased synthesis of fibrinogen.

Present investigation

Labelling of fibrinogen

Human fibrinogen, prepared according to Blombäck and Blombäck (1956) was labelled with the jet iodination technique essentially as described by McFarlane (1956) The coagulability of the fibrinogen after labelling was around 92 per cent. Less than 0 4 per cent of the radioactivity was found in the supernatant after precipitation of the protein with trichloroacetic acid (TCA) The specific radioactivity (μC/mg) of fibrin, obtained by clotting the labelled fibrinogen with thrombin, was on the average 93 per cent of that in the labelled protein before clotting The yield of ^{131}I-isotope in the labelled protein was on the average 15 per cent of the isotope added. The mean label was 2.0 atoms of iodine per mole of fibrinogen.

McFarlane (1963) studying the turnover of ^{131}I labelled rabbit fibrinogen concluded that in this protein not more than 0.5 atoms of iodine can be incorporated into the fibrinogen molecule if denaturation is to be avoided. He defined denaturation as a rapid initial catabolism of injected labelled protein. In the present study on human fibrinogen the label was between 0.8 and 2.7 atoms per mole of protein. As no significant difference with regard to the extrapolated values for the plasma pool of fibrinogen was found it seems as if no denaturation had occurred. Also the fact that the specific radioactivity of fibrin was only a few per cent lower than that of fibrinogen suggests that only an insignificant degree of denaturation had taken place during iodination. Discussing our results with respect to those obtained by McFarlane we suggested that in rabbit fibrinogen the fibrinopeptide part, containing a tyrosine-O-sulphate residue, might be labelled (I A) In that case the iodination might have given rise to a molecular species liable to rapid excretion. Later Regoeczi and Walton (1967) however found no evidence that the fibrinopeptide part of rabbit fibrinogen is labelled with ^{125}I Therefore, other explanations must be sought.

Plasma half-life of I fibrinogen in normals and in different disorders

Normal subjects In our study the mean values of T for normal men and women were 4 7 and 4 4 days, respectively No significant difference in half life was found between the sexes, nor could any influence of age be observed. The values are in good correspondence with the majority of those obtained in other investigations. In some studies performed with the use of fibrinogen labelled with the monochloride method of McFarlane (1958) the latter author (1964) and Takeda (1966) obtained half life times in normal subjects of 3 1 and 3 4 days, respectively However Amris and Amris (1964) also with this method obtained a mean value of 4 3 days. According to Takeda (1966) long half lives as obtained by Hammond and Verel (1959) of 5 1 days, suggests the presence of labelled globulins. It has been found for rabbit fibrinogen (Atencio et al. 1965) that altered ^{131}I fibrinogen does not show a changed half life. Recently Tytgat et al. (1968) also using ^{131}I fibrinogen obtained with the monochloride method, found a half-life in normals of 5 0 days.

The average extrapolation value for the plasma pools in our study was 66 per cent, which is lower than those obtained by Amris and Amris (75—90) and by Takeda (84) This might indicate overiodination of our batches. As mentioned above, however there was in this respect no significant difference between batches labelled with 0 8 to 2.7 atoms of iodine per mole of fibrinogen.

Coagulation factor deficiency states. In most studies on the fibrinogen turnover in cases of congenital coagulation defects a normal half-life has been found (Gitlin and Borges 1953 Adelson et al. 1961 Rausen et al. 1961 Hart 1964) Also this study showed no significant differences from the normal values. This suggests that the rapid turnover rate of fibrinogen, as compared to other plasma proteins, can only be accounted for to a small degree by consumption through intravascular fibrin formation. This finding seems to speak against an often proposed theory of a

continuous coagulation and fibrinolysis taking place within the blood stream. On this background the results obtained by Takeda and Chen (1967) studying the metabolism of iodinated fibrinogen in patients with hemophilia A, seem difficult to explain. They found a half life time for ^{125}I fibrinogen of 2 3 days as against 3 4 days in their normals. The catabolic and synthetic rates of fibrinogen were found to be markedly increased whereas the plasma fibrinogen concentration, intravascular and interstitial fibrinogen, and the transcapillary transfer rate of fibrinogen were not significantly different. Takeda and Chen suggested for the hemophilia A patients an increased rate of breakdown of fibrinogen with or without previous fibrin formation. However it should be remarked that the fibrinogen used for labelling by these authors was obtained by precipitation of plasma with ammonium sulphate This might imply that the protein was not sufficiently pure for use in metabolic studies, although the clottability was reported to be 95 per cent or more. Furthermore the radioactivity of plasma but not that of the fibrinogen fraction was assayed. For the reasons mentioned the validity of the results obtained by Takeda and Chen must be put into question.

Polycythemia vera In 3 out of 6 patients with this disorder significantly increased turnover rates of fibrinogen were demonstrated. Although in all patients studied the marrow findings indicated an intense platelet production, only those with normal platelet counts in the peripheral blood showed short half lives. This may be explained by an increased peripheral destruction of platelets, leading to thromboplastic activity which can initiate a hypercoagulable state The latter again could explain a rapid consumption of fibrinogen. Christensen (1958) also found a shortened half life in one case. Increased fibrinolysis has been reported to occur in polycythemia vera (Björkman et al 1956) but could not be found in the present study Even if with the use of sensitive methods an increased fibrinolytic activity can be demonstrated this is not contradictory to an occurrence of intravascular coagulation. Increasing evidence has been obtained for a close connection also in clinical disorders between these two expressions of abnormal coagulation (Merskey et al. 1964 and others)

Liver disorders In 4 patients with liver cirrhosis (and in one with fatty liver) an increased turnover rate of fibrinogen was found. This could not easily be ascribed to increased fibrinolytic or fibrinogenolytic activity as no consistent increase in plasma fibrinolytic activity could be demonstrated From the results obtained on the turnover of other proteins in liver cirrhosis (Volwiler et al. 1955 Wilkinson and Mendenhall 1963) our findings can not either be explained as depending on a generalized increase in protein catabolism. A hypothesis of increased consumption of coagulation factors by intravascular coagulation has been strengthened by clinical and laboratory observations in liver cirrhosis (Bergström et al. 1960 Zetterqvist and von Francken 1963—I B Johansson 1964) Recently Tytgat et al. (1968) have demonstrated the occurrence of intravascular coagulation in liver cirrhosis. These authors in 25 patients with liver cirrhosis of varying severity found an average half

life time for ^{131}I fibrinogen of 3 1 days as against 5 0 days in their normals. Furthermore, they found that in nearly all the patients, the half-life time was fully normalized during heparin treatment. Simultaneously there was a continuous increase in the plasma fibrinogen concentration. As a possible mechanism for intravascular coagulation in this disorder they suggested that a functional insufficiency of the hepatocytes and disturbances in the portal circulation could lead to a decreased neutralization of activated coagulation factors or of thromboplastic activity in the reticuloendothelial system of the liver This is in line with their finding of a shortened fibrinogen half life in two patients with essential portal hypertension splenomegaly and extensive collateral circulation but with normal function and structure of the liver This, in turn, fits well with the good clinical effect of heparin upon bleeding in a corresponding case (Zetterqvist and von Francken 1963 I B) In this connection, Fletcher et al. (1964) have suggested that their finding of an abnormal fibrinolytic response after nicotinic acid can be due to impaired clearance of plasminogen activator by the liver Thus, it might be that both coagulation active components and fibrinolytic activators are not sufficiently cleared in liver parenchymal injury An important contribution in this field was the observation by Spaet et al. (1961) that in dogs blockade of the reticuloendothelial system resulted in failure to clear thromboplastin and thrombin injected into mesenterial veins.

Epidermolysis bullosa. Two patients were studied because of previous findings of a shortening of the whole blood clotting time and of a resistance to intravenously administered heparin in this disorder (Bauman and Krause 1954 Fuchs 1952) No shortening of the fibrinogen half life was, however observed.

Summary

The half life time of ^{131}I fibrinogen in humans was studied with a labelled protein of high clottability There were no indications of denaturation of the fibrinogen by the labelling procedure.

In normal male and female subjects the half-life time was found to be 4 7 and 4 4 days, respectively which is in accordance with the results obtained in earlier investigations. Patients with different forms of coagulation factor deficiency states showed half life times within the normal range. This is in line with previous findings. However in recent studies Takeda has found a shortening of the half-life in patients with haemophilia A. In polycythemia vera the turnover rate in some cases was abnormally rapid. As this was in patients with relatively normal platelet counts in the peripheral blood, it was supposed that here a consumption of platelets occurred. This as well as the faster elimination of fibrinogen might indicate a state of intravascular coagulation. In some patients with liver cirrhosis a shortening of the half life time was found. As no consistent fibrinolysis could be demonstrated, it was supposed that also in this disorder a mechanism of intravascular coagulation could occur Strong support for this has been obtained through later studies by Tytgat. Finally in 2 patients with epidermolysis bullosa normal half life times for the labelled fibrinogen were found.

Review of general effects of intravenously administered procoagulants

Since the experiments of Naunyn (1868) using infusions of hemolyzed red cells and Wooldridge (1886) a very large number of investigations have been made on the effects of procoagulants upon blood coagulation in vivo Wooldridge injected intravenously ein Gemisch oder vielleicht eine Verbindung von Eiweiss und Lecithin" and obtained the whole circulation system filled with thrombi if doses large enough of the substance were injected. H noticed that the thrombotic effect was proportional to the amount of substance injected and also found that blood obtained from animals given smaller doses did not clot spontaneously In this blood furthermore he found only traces of "Fibrinferment"

Concerning the *primary effects* of procoagulants a very large number of observations have been published and reviewed in detailed monographs (McKay 1965 Hardaway 1966, Selye 1966) The main symptoms of clinical intravascular coagulation are hypotension or shock, bleeding, and diffuse fibrin deposition in one or several organs. Extensive clotting in vivo like in vitro produces thrombocytopenia and reduced levels of fibrinogen, factor V and factor VIII As to prothrombin and the so called "serum factors —factors VII IX and X—their behaviour in such states has been somewhat disputed However later investigations have confirmed that also these are consumed (Rapaport et al. 1966) Anyhow in clinical states of intravascular coagulation as well as during experimental conditions the level of platelets, fibrinogen, factors V and VIII seem to be the most useful in the diagnosis of consumption coagulopathy

Evidence has been obtained, that *pathological fibrinolysis* can appear in connection with or as a consequence of intravascular coagulation, which in some way triggers plasminogen activation as a compensatory response (Fletcher et al. 1962, Mersky et al. 1964 Kowalski et al. 1965 Izak 1965 Girolami et al. 1966, Leandoer and Nilehn 1969) As expressed by Penick et al. (1965) it may be that both mechanisms are simultaneously or sequentially operative. The appearance of an *anticoagulant* has also been observed after intravenous infusion of thromboplastin (Ratnoff and Conley 1951 Lewis and Sreto 1962) and thrombin into dogs (Kowalski et al. 1965)

Concerning the *fate of fibrin and/or fibrinogen fibrin degradation products* formed as a result of intravascular coagulation special interest has been focused on the role of the reticuloendothelial system (RES) A basic observation was that of Monkhouse and Milojevic (1960) that in low-grade intravascular coagulation, although insufficient to provoke intravascular thrombosis, still conversion of fibrinogen to fibrin goes on. Spaet et al. (1961) in studies on rats showed that blood thromboplastin is selectively taken up by reticuloendothelial cells following intravenous injection and also demonstrated that blockade of the RES resulted in

enhancement of defibrination produced by blood thromboplastin In 1962 investigations by Lee led him to the assumption that the bulk of fibrin aggregates found in the circulating blood are rapidly removed by the RES In further studies, where immunohistochemical methods (Lee and McCluskey 1962) as well as electron microscopy (Prose et al 1965) were applied it was clearly demonstrated that the RES can operate as an efficient fibrin clearing mechanism in states of diffuse, low grade intravascular coagulation, where fibrin is formed in an incompletely polymerized state and consists of minute shreds, capable of being phagocytized (Lee et al. 1965) The phagocyte action was found to be exerted by the Kupffer cells (Prose et al. 1965) Later Gans and Lowman (1967) in studies on the uptake of fibrin and fibrin-degradation products by the isolated perfused rat liver using ^{75}Se labelled rat fibrin, found that this fibrin in the perfusate was eliminated at a rate comparable to that of aggregated ^{131}I BSA (bovine serum albumin) and colloidal gold in the same system. The loss of activity from the blood closely paralleled the increased activity recorded in the liver Thus, there is evidence that the RES plays a significant role in the clearance of fibrin, and possibly also of other coagulation products (Gans 1966)

With respect to potential protection mechanisms against the effects of intravascular coagulation an important contribution has been given by Lipinski et al. (1967) Using isotope-labelled fibrinogen these authors showed that fibrinogen, fibrinogen-fibrin intermediates and fibrinogen degradation products (FDP) in vitro may form soluble complexes, which are unclottable by thrombin. They presumed that such complexes may explain the occurrence of cryofibrinogen in various pathological states and postulated them to be an important factor involved in the development of the hemostatic defect. The authors thought that such complexes might be the expression of a defence mechanism against intravascular fibrin formation by rendering unclottable the intermediates of the fibrinogen fibrin conversion.

Of great general interest to clinical medicine have been also investigations on the effects of procoagulants with respect to *tissue damage* in different organs. Thus, a number of studies have been made on pulmonary vascular lesions following repeated intravascular administration of thromboplastin (Gore et al. 1962, 1963) or thrombin (Studer and Lorez 1965) into rabbits. Gore et al. found that repeated intravenous injections caused thrombi in the pulmonary arteries predominantly localized to medium and small arteries. By organization of the thrombi intimal fibrosis developed. As in the test tube thromboplastin was found to form an insoluble complex with arterial acid mucopolysaccharides, Gore et al. suggested that this reaction also in vivo was responsible for the intimal injury Cholesterol was found to accumulate in the changed intima. Studer and Lorez in studies by means of intravenous thrombin infusion, found that this gave rise to embolization in pulmonary arteries with mural incorporation and finally intimal fibrosis. In their experiments inhibition of fibrinolysis by epsilon aminocaproic acid (EACA) in doses corresponding to those used in the clinic, did not influence upon the results. They therefore suggested that fibrinolysis is of minor importance for the fate of pulmonary emboli

in rabbits Of great interest are the studies by Vassalli et al. (1963) who found that slow intravascular coagulation produced by thromboplastin infusion in rabbits, caused ultrastructural lesions in the kidneys resembling those in toxemia of pregnancy The authors suggested that entrance of placental thromboplastin in the maternal circulation could be responsible for the glomerular changes in toxemia, which was further supported by the demonstration with immunofluorescence of large amounts of fibrinogen derivatives in toxemic glomeruli (Vassalli et al. 1964)

Finally a recent observation on the influence of procoagulants upon the *platelets* is the one by Farburzewski et al. (1968) that thrombin, administered intravenously to rabbits, releases large amounts of platelet factor 4 (PF_4) into the circulating blood. It has been suggested that PF_4 may be a potent and specific agent triggering platelet aggregation and blood clotting in vivo. A significant elevation of this factor was also found in patients with fresh coronary thrombosis, thrombophlebitis and thromboembolic complication Ultrastructural platelet changes after thrombin injection in rabbits have also been demonstrated (Vassalli et al. 1964)

Present investigation

Labelling of fibrinogen

The preparations used in 3 different series (II—IV) were labelled with ^{131}I using the jet iodination technique essentially as described by McFarlane (1956) or with ^{125}I according to the monochloride method of the same author (McFarlane 1958) The coagulability of the fibrinogen preparations after labelling was 90—95 per cent. The radioactivity in fibrin in per cent of that in fibrinogen was 80—85 The yield of isotope in the preparations was for ^{131}I fibrinogen around 15 per cent and for ^{125}I fibrinogen 50—60 per cent of the isotope added. Between 0.2 and 2.6 atoms of iodine were introduced per mole of fibrinogen.

In comparison to ^{131}I-labelled human fibrinogen (I A) the radioactivity in fibrin in per cent of that in fibrinogen is for ^{131}I and ^{125}I-labelled dog fibrinogen around 10 per cent less than in the labelled human protein. This is explained by the finding that on iodination of dog fibrinogen about 15 per cent of the isotope is bound to material released by thrombin during the fibrinogen fibrin transition. Of this material, in turn, about 50 per cent, i.e. around 9 per cent of the total label in dog fibrinogen, seems to be associated with dog fibrinopeptide B, The other half of the radioactive unclottable material most likely is bound to denatured fibrinogen or to other proteins, present as contaminants in the fibrinogen preparations (VI)

Experimental conditions

Dog with a weight of 7—21 kg were injected with iodine-labelled fibrinogen in doses giving an initial radioactivity of 40—60 $\mu C \times 10^{-3}$ per ml plasma. For blocking

of the thyroid the dogs were given potassium iodide tablets from 2—3 days before the injection. Blood samples were drawn from the 1st to the 5th or 7th day to permit determination of the turnover of the labelled fibrinogen. On the 5th—7th day after the injection, experiments with procoagulants were made. After i.v anesthesia, bovine thrombin was given as i.v infusion during 1 hr whereas dog brain thromboplastin and a procoagulant from human postpartum serum (PPS) were injected i.v during 10—20 sec. The dogs given thromboplastin and PPS were ventilated artificially from 15 to 45 min after the injection. Blood samples were taken before anesthesia, then at 15 30 60 min and 2, 4 and 6 hrs after the start of thrombin infusion or injection of the other procoagulants, respectively usually also on the following day Hematocrit, platelet count, fibrinogen concentration, fibrinolytic activity radioactivity in plasma and in the coagulated fibrinogen were determined. In some of the dogs given thrombin infusions and thrombin together with epsilon aminocaproic acid immunological studies with respect to the appearance of fibrinogen-fibrin degradation products as well as measurements of radioactivity in serum were made on the samples obtained on the day of the experiment (V)

As *controls* 9 dogs were used In 4 of these the radioactivity decay in plasma and in fibrinogen was followed up to 10 days for determination of the basic half life time. For studies on the influence of anesthesia and indwelling catheter 2 dogs were used On the 6th day after injection of ^{131}I fibrinogen, one of these dogs was only anesthetized in the other also a catheter was inserted, through which a saline infusion was given during 1 hr Three dogs were given iodinated fibrinogen without isotope and followed during 10 days.

Results obtained in control dogs (II)

The mean half life times as measured in plasma and in coagulated fibrinogen were 2.0 and 1.9 days (range 1.2—3.0 and 1.2—2.8) respectively The values are in good agreement with those obtained by other investigators (II)

Anesthesia, saline infusion or catheters inserted were not found to influence upon the half life time to such a degree that the results obtained in the experiments with procoagulants could be markedly affected. However it must be pointed out that the information obtained in another investigation indicates that indwelling polyethylene catheters for 8 hrs may double the elimination rate of iodine labelled fibrinogen (Zetterqvist, Carlson, Liljedahl 1968) Such an effect would not, however influence upon the evaluation of the results of the present studies.

In the dogs given I fibrinogen without isotope, there was a transient fall in the platelet number and a simultaneous rise in the fibrinogen concentration.

The *fibrinolytic activity* in 20 normal dogs was found to be 89 7 μg/ml/hr and the s.d. 19.6.

in rabbits. Of great interest are the studies by Vassalli et al. (1963) who found that slow intravascular coagulation, produced by thromboplastin infusion in rabbits, caused ultrastructural lesions in the kidneys, resembling those in toxemia of pregnancy. The authors suggested that entrance of placental thromboplastin in the maternal circulation could be responsible for the glomerular changes in toxemia, which was further supported by the demonstration with immunofluorescence of large amounts of fibrinogen derivatives in toxemic glomeruli (Vassalli et al. 1964).

Finally a recent observation on the influence of procoagulants upon the *platelets* is the one by Farbrazewski et al. (1968) that thrombin administered intravenously to rabbits, releases large amounts of platelet factor 4 (PF_4) into the circulating blood. It has been suggested that PF_4 may be a potent and specific agent triggering platelet aggregation and blood clotting in vivo. A significant elevation of this factor was also found in patients with fresh coronary thrombosis, thrombophlebitis and thromboembolic complication. Ultrastructural platelet changes after thrombin injection in rabbits have also been demonstrated (Vassalli et al. 1964).

Present investigation

Labelling of fibrinogen

The preparations used in 3 different series (II—IV) were labelled with ^{131}I using the jet iodination technique essentially as described by McFarlane (1956) or with ^{125}I according to the monochloride method of the same author (McFarlane 1958). The coagulability of the fibrinogen preparations after labelling was 90—95 per cent. The radioactivity in fibrin in per cent of that in fibrinogen was 80—85. The yield of isotope in the preparations was for ^{131}I-fibrinogen around 15 per cent and for ^{125}I fibrinogen 50—60 per cent of the isotope added. Between 0.2 and 2.6 atoms of iodine were introduced per mole of fibrinogen.

In comparison to ^{131}I labelled human fibrinogen (I A) the radioactivity in fibrin in per cent of that in fibrinogen is for ^{131}I and ^{125}I labelled dog fibrinogen around 10 per cent less than in the labelled human protein. This is explained by the finding that on iodination of dog fibrinogen about 15 per cent of the isotope is bound to material, released by thrombin during the fibrinogen-fibrin transition. Of this material, in turn, about 50 per cent, i.e. around 9 per cent of the total label in dog fibrinogen, seems to be associated with dog fibrinopeptide B_1. The other half of the radioactive unclottable material most likely is bound to denatured fibrinogen or to other proteins, present as contaminants in the fibrinogen preparations (VI).

Experimental conditions

Dog with a weight of 7—21 kg were injected with iodine labelled fibrinogen in doses giving an initial radioactivity of 40—60 $\mu C \times 10^{-3}$ per ml plasma. For blocking

From the values for fibrinogen concentration and radioactivity in plasma and fibrinogen at different times the amounts of degraded fibrinogen-fibrin (in III called nonclottable labelled fibrinogen products, NCLP) could be calculated and were expressed as equivalent amounts of fibrinogen (II III) For the thrombin and thromboplastin groups at the time of the plasma peak the degradation products amounted to between 40 and 100 per cent of the fibrinogen decrease up to that point. The true amounts of degradation products are probably larger than the calculated ones, as part of them may escape rapidly from the circulation by excretion and other clearing mechanisms. As indicated from the specific activity (μC/mg) new synthesis of fibrinogen in the dogs given thrombin began soon after the start of the infusion. At 4 hrs after that point the de novo synthesis seemed to account for up to 50 per cent of the circulating fibrinogen.

As to the dose response relations it was found for both thrombin and thromboplastin that with increasing doses, the fibrinogen concentration was more depressed and proportionally larger amounts of nonclottable labelled fibrinogen products appeared in the circulation. This indicates an intimate relation between the intensity of the coagulation trauma and a process of fibrinogen degradation.

With respect to comparative aspects the effects obtained with thromboplastin and PPS in general, were similar to those produced by thrombin. In dogs infused with thrombin during 1 hr the initial plasma radioactivity decrease was followed by an increase, with a maximum at 2 hrs after the start of the infusion. Although in the experiments with thrombin, no significantly increased fibrinolytic activity could be demonstrated in the circulating blood there was evidence that the subsequent plasma radioactive increase could have been caused by a fibrinolytic process, probably induced secondarily to intravascular coagulation. Evidence for this is given by the demonstration of fibrinogen degradation products in separation studies and the immunological behaviour of serum (V) as well as by the effects of simultaneously administered fibrinolysis inhibitors (II III V) This is also in accordance with the suggestions of Kowalski et al. (1963) The thromboplastin- and PPS-doses were given within half a minute and the maximum reactions occurred earlier and more dramatically than in the dogs given thrombin. In contrast to the findings in the thrombin experiments, an elevated fibrinolytic activity was recorded in the circulating blood. Because of the shorter injection time of thromboplastin, the coagulation trauma was probably more intense. This might also explain why a fibrinolytic process could be more intensively evoked and therefore demonstrable in the circulating blood.

I v injections of PPS caused a drop in blood pressure from about 160 to around 60 mm Hg, the pressure returned to near initial values within 10 to 20 min The femoral arterial blood flow showed a subsequent decrease in most instances to zero Infusions into the femoral artery did not produce any appreciable changes in the local blood flow indicating that PPS has no direct action on the peripheral blood vessels, and was not contaminated with vasoactive material.

Effects of thrombin and PPS in heparinized dogs

In dogs given an i.v. injection of heparin in a dose corresponding to 1 000 units per kg b.w. before thrombin infusion or PPS-injection, respectively most of the changes induced in the groups mentioned were prevented. A slight to moderate decrease in the platelet number was observed early after the start of the thrombin infusion. Heparinized animals injected with PPS showed a fall in blood pressure from 140—180 mm Hg to 90—150 mm Hg. The pressure reached 90 per cent of the preinjection value in 1—6 min (IV).

According to Hardaway (1966) the immediate arterial hypotension after i.v. administration of procoagulants is caused by occlusion of the microcirculation with subsequent decrease in cardiac return and therefore also in cardiac output. The decrease in blood pressure following injections of PPS also in the heparinized animals, indicates that part of the hypotensive effect may be due to other mechanisms than intravascular coagulation. It is reasonable to conclude that part of the hypotension is secondary to activation of the plasma coagulation system, with thrombin formation and subsequent peripheral vasodilatation (Delin et al. 1967, Olsson et al. 1969—see IV).

Summary

Intravenous administration of bovine thrombin, dog brain thromboplastin and a procoagulant from human postpartum serum (PPS) provoke similar effects. There is a decrease in platelet count, fibrinogen concentration and, as followed only after PPS a decrease also in the concentration of prothrombin. After injection of ^{131}I dog fibrinogen there is a difference between the radioactivity of plasma and that of thrombin-coagulated fibrinogen of around 10—15 per cent. This is explained by the fact, that by thrombin-coagulation around 15 per cent of the radioactivity is released into the clot supernatant. Thus, when determined as fibrin, a corresponding amount of radioactivity has been lost from the fibrinogen. Soon after the start of thrombin infusions or after short time injection of the other procoagulants, there is a rapid fall of the radioactivity in both plasma and fibrinogen. A following secondary increase of the plasma radioactivity is suggested as reflecting the appearance of degradation products of fibrinogen or fibrin, obtained through a fibrinolytic process. Most of the effects are inhibited if the dogs are heparinized before administration of procoagulants. The amounts of degradation products can be calculated from the radioactivity values and the specific radioactivity of the fibrinogen before the experiments. A strong capacity for resynthesis of fibrinogen after partial defibrination is demonstrated. With short time injections of thromboplastin and PPS more drastic effects are obtained with respect to symptoms of intravascular coagulation than those obtained with thrombin infusion during 1 hr. Also, after the more rapid coagulation traumata an increased fibrinolytic activity in vitro can be demonstrated, which is not the case after thrombin. The effects upon aortic blood pressure and

femoral arterial blood flow studied only after PPS-injections, demonstrate a pronounced decrease of the pressure returning to near the normal within 10—20 min. The femoral arterial blood flow decreased usually the zero. In heparinized animals the effect upon the blood pressure was smaller PPS-injections in the femoral artery did not produce major changes in the local blood flow indicating that PPS has no direct action on the peripheral blood vessels and is not contaminated with vasoactive material acting in this region.

INFLUENCE OF FIBRINOLYSIS INHIBITORS ON FIBRINOGEN TRANSFORMATION AND DEGRADATION IN EXPERIMENTAL INTRAVASCULAR COAGULATION

Review of other investigation

With a growing interest in fibrinolysis on the whole and not least in its pathological manifestations, a great number of studies have been made on the effects of increased fibrinolysis in vitro and in vivo. Because there seems to be in clinical fibrinolysis close connections between coagulation and fibrinolysis, it is important to reveal if after defibrination with procoagulants, fibrinogen products appear as a consequence of primarily thrombin action or if they are unrelated to the fibrinogen-fibrin transformation.

The conversion of fibrinogen to fibrin is initiated by thrombin through the release of peptides A and B from the fibrinogen molecule. Aggregation of "activated" fibrinogen molecules (fibrin monomers) proceeds by end to-end and side to-side aggregation. As a consequence of this process fibrin is formed. A suggestion was made by Hammarsten (1876) of the existence of a soluble intermediate in the fibrinogen-fibrin transformation. Blombäck and Laurent (1958) concluded that, during the action of thrombin on fibrinogen, mainly peptide A is released in the initial stage. They found that purified fibrinogen could loose as much as 40 per cent of its A peptide before visible coagulation occurred. Abildgaard (1965) calculated that in plasma only 6 per cent of fibrinogen from which peptide A had been removed was necessary to start aggregation.

As to the implication of occurrence of fibrin intermediates in clinical states, several observations have been made on such components in various thrombotic disorders (Cummine and Lyons 1948, Korst and Kratochvil 1955, Campbell 1959, Kalbfleisch and Bird 1960, Boros et al. 1962). Godal and Abildgaard (1963) demonstrated a good clinical effect of heparin in a patient having in plasma a substance which according to the authors most likely represented a mixture of fibrinogen and fibrin.

Degradation of fibrinogen-fibrin by plasmin gives rise to degradation products of varying size and behaviour (Fletcher et al. 1962, 1966, Fisher et al. 1967). Concerning the states of pathological fibrinolysis there have been much conflicting views on all aspects as underlying mechanisms, diagnosis, importance as a cause of bleeding as well as its treatment. With respect to especially the connection between coagulation and fibrinolysis important contributions were given by Schneider (1951, 1952) and Müllertz (1957). They found that when tissues are damaged by trauma or anoxia both systems are activated or accelerated by the release of tissue thromboplastin and/or fibrinolytic tissue activator. Similar effects were obtained after trauma by Bergentz and Nilsson (1961), after thromboplastin by Izak (1965) and after thrombin by Girolami et al. (1966). Weiner (1953) suggested that fibrinolytic activity could be released from the vascular endothelium as a result of intravascular clotting. Both phenomena do not, however, always develop in parallel.

Important for the understanding of the pathogenesis of fibrinolysis was the finding made in 1957 independently by Triantaphyllopoulos, Niewiarowski and Kowalski as well as of Stormorken that spontaneously lysed fibrinogen besides losing its thrombin clottability acquires in addition anticoagulant properties. The fraction responsible for this phenomenon was called by Triantaphyllopoulos AFIF (anticoagulant fraction of incubated fibrinogen) and antithrombin VI by the Polish authors. Later similar products of fibrinogen, also showing an antithrombin effect, were found responsible for a coagulation anomaly termed "defective fibrin polymerization" (Fletcher et al. 1962 Fisher et al. 1967) Besides their action upon the later stages of fibrin formation fibrinogen degradations products have also effects upon the platelets. Kowalski et al. (1964) found that aggregation, viscous metamorphosis as well as adhesivity in vitro were influenced by FDP the effects being dependent on the concentrations of split products and of activating agents (ADP thrombin, connective tissue extract) The authors discussed the possible significance of the described findings for the hemostatic functions, referring to investigations by Salmon (1961) and Salmon et al. (1962) which had been in favour of a relationship between enhanced fibrinolysis, platelet function and bleeding These investigators had noticed that bleeding only appeared when fibrinolysis and thrombocytopenia were observed together

With respect to connections between intravascular coagulation and fibrinolysis the findings of Lipinski et al. (1967) are interesting. These authors demonstrated that fibrinogen with intermediates and degradation products may form soluble complexes, unclottable by thrombin. They found that paracoagulation, i.e. formation of a clot upon protamine sulphate addition to partially digested fibrinogen, unclottable with thrombin (Derechin 1935 Derechin and Szuchet 1956) occurs when defibrination is caused by excessive intravascular coagulation. On the other hand, when proteolytic digestion of fibrinogen is predominant, paracoagulation occurs after combined action of thrombin and protamine sulphate. Lipinski et al. suggested that formation of such complexes may explain the occurrence of cryofibrinogens in various pathological states

Based on suggestions of a secondary compensatory fibrinolysis after coagulation trauma, studies have been made on the influence of fibrinolysis inhibitors administered simultaneously with procoagulants It has been demonstrated that EACA given together with thrombin, promotes the development of the generalized Shwartzman phenomenon in rabbits (Lee 1962) and also the persistence of fibrin in the glomeruli of the rat. Beller et al. (1967) tested the effects of several different proteolysis inhibitors together with thrombin in rabbits and found all of the inhibitors to result in fibrin deposition in the glomeruli of rabbit kidney However as earlier mentioned, Studer and Lorez (1965) found that administration of EACA did not influence upon the fate of pulmonary emboli, obtained by i.v. thrombin infusion into rabbits.

Present investigation

The aims of these studies were 1 to find out if substances with antifibrinolytic action would influence upon the secondary changes obtained after i v administration of procoagulants, and 2. to investigate, whether an anticoagulant effect demonstrated in vitro for Trasylol (a kallikrein inhibitor with antifibrinolytic action) could be obtained also in vivo after injection of procoagulants.

Experimental conditions

Dogs were treated and coagulation parameters followed as described earlier with the addition that antifibrinolytic drugs were administered together with procoagulants. Four groups of animals were given simultaneous infusions of 1 thrombin and epsilon aminocaproic acid (EACA) 2. thrombin and Trasylol, 3 thromboplastin and EACA, and 4 *thromboplastin and Trasylol. The dose range was for* EACA 0 ? to 0.8 g per kg b.w and for Trasylol 6,500 to 100 000 K.I U (kallikrein inhibitor units) per kg b w The number of dogs in each group varied between 5 and 11 In 3 dogs, not included in the series mentioned, the radioactivity and immunological behaviour of serum during simultaneous infusions of EACA and thrombin were followed (V)

Results and discussion

With the largest doses of EACA and Trasylol the secondary plasma radioactivity increase, obtained after thrombin and thromboplastin (II III) was abolished and the amount of calculated fibrinogen degradation products was reduced. However although a fibrinolytic activity seemed to be inhibited, still significant amounts of degradation products were calculated. This is in accordance with the findings made by Barnhart (1966) who identified and quantitated by means of immunological methods degradation products after combined administration of EACA and thrombin in dogs. The author concluded that a dose of EACA large enough to inhibit effectively a general plasma fibrinolytic activity could not block a local fibrinolysis going on in microthrombi in the circulation. In the present study a correlation was obtained between the dose of the antifibrinolytic drugs and the effect upon the induced fibrinolytic activity With medium and smaller doses there was a secondary plasma radioactivity increase but it was delayed like also the increased plasma fibrinolytic activity appearing after thromboplastin. The effect of 10,000 K.I U of Trasylol was greater than that of 0 2 g of EACA, which implies that on a molar basis, Trasylol is a more effective fibrinolysis-blocking substance than EACA This is in accordance with the observations by Dubber et al. (1968) finding the molar potency of Trasylol as an inhibitor of fibrinolysis to be 1,000 times that of EACA.

The evidence obtained of a secondary fibrinolysis after procoagulants was further

strengthened by the information obtained in studies performed by means of gel filtration of plasma and immunoelectrophoresis of serum in connection with thrombin infusions (V) As presented later a clear effect of EACA upon fibrinogen degradation products was noticed.

Trasylol, besides its antifibrinolytic effect, has also been demonstrated to possess an anticoagulant activity in vitro. This latter effect, however is directed against the initial phase of coagulation and not towards thrombin (Amris 1964 Blombäck et al. 1964) In the present study no effect on the disappearance of fibrinogen in dogs given thrombin was found (II) which is in conformity with the information obtained from the in vitro studies. A comparison with respect to early changes after thromboplastin injection alone and combined with EACA and Trasylol, respectively indicated a slightly less decrease of fibrinogen radioactivity and concentration in the Trasylol-thromboplastin group if all dogs surviving 15 min were considered (III) This could speak for a slight anticoagulant effect of Trasylol during the conditions of this study However in those dogs surviving 4 hrs only small differences between the groups were observed. Our results do not contradict those of Dubber et al. (1968) which authors from studies in humans concluded that Trasylol has an anticoagulant effect.

Among the dogs given thrombin as procoagulant, the mortality rate was highest in the Trasylol thrombin group (3 of 8) One of 6 dogs given only thrombin died and none in the EACA-thrombin group With thromboplastin, the highest mortality (6 of 8) was in the group given only procoagulant. Half of the dogs in the Trasylol-thromboplastin group died and 1 of 6 in the EACA-thromboplastin group. As to the higher mortality rate in Trasylol than in EACA treated dogs, one might speculate that the difference could be due to the fact that EACA does not, as Trasylol, directly inhibit plasmin. Thus, with respect to the influence upon thrombi formed after procoagulants, Trasylol is probably sometimes more unfavourable because of its stronger antifibrinolytic effect. An inhibiting effect by EACA upon fibrin polymerization (Godal and Helle 1963 Godal and Theodor 1965) might also have contributed to the protective action by this substance. Studying the effects of Trasylol in dogs injected with thromboplastin, Mammen and Poucho (1966) suggested that the protective action of Trasylol in decreasing thrombus formation was also by interference with the cross-linking of fibrin monomers rather than by its antithromboplastic activity

An interesting finding was, that administration of EACA resulted in a temporary increase of the hematocrit. Cummings and Welter (1966) found that large doses of aminocaproic acid evoked a syndrome resembling dehydremic shock. They suggested that this was possibly an effect of histamine, release by catecholamines through the action of aminocaproic acid.

In separate studies (Zetterqvist, Carlson, Liljedahl 1968) it was demonstrated, that indwelling polyethylene catheters for 8 hrs may double the turnover rate of iodine-labelled fibrinogen. As earlier mentioned, such an effect would not, however influence upon the evaluation of the results of the present studies.

Summary

After intravenous administration of procoagulants to dogs a "secondary fibrinolysis" seems to appear The effects obtained by large doses of fibrinolysis inhibitors epsilon aminocaproic acid (EACA) and Trasylol support this assumption. On a molar basis the antifibrinolytic effect of Trasylol is larger than that of EACA. When these drugs are administered simultaneously with thrombin no anticoagulant effect by either is detectable. Trasylol seems to exert some anticoagulant action when injections of thromobplastin are given As indicated from studies in dogs in clinical practice antifibrinolytic drugs should be given in combination with anticoagulants when fibrinolytic bleeding is suspected to be secondary to intravascular coagulation. Like in earlier studies an increasing hematocrit after administration of EACA is observed

SEPARATION BY GEL FILTRATION OF FIBRINOGEN AND DEGRADATION PRODUCTS IN THROMBIN INDUCED INTRAVASCULAR COAGULATION

Previous investigations

In later years clinical experience and laboratory findings have brought evidence for a connection between intravascular coagulation and fibrinolysis The differential diagnosis of these states of abnormal coagulation is, however difficult.

Valuable information for diagnosis and treatment has been obtained through a number of investigations devoted to the mechanisms of abnormal conversion as well as pathological degradation of fibrinogen-fibrin. Already Hammarsten (1876) suggested the existence of a soluble intermediate in the formation of fibrin from fibrinogen. In the previous chapter several observations on such intermediates, occurring in vitro or in clinical thrombotic disorders have been mentioned.

Activation of fibrinolysis has been demonstrated after trauma (Schneider 1951 1952, Müllertz 1957 Bergentz and Nilsson 1961) and also after administration of procoagulants (Kowalski et al. 1963 Izak 1965 Nordström and Zetterqvist 1966 Leandoer and Nilehn 1969 and others) Following the discovery of the anti thrombin effect of spontaneously lysed fibrinogen (Niewiarowski and Kowalski 1957 Stormorken 1957 Triantaphyllopoulos 1957) a similar in vivo effect exerted by split products was demonstrated by Fletcher et al. (1962) During pathological degradation of fibrinogen-fibrin a wide variety of products may appear (Fletcher et al. 1962 Nilehn and Nilsson 1964 Fisher et al. 1967 Nilehn 1967) In experimental studies with thrombin infusions to dogs a variety of degradation products (Leandoer and Nilehn 1969) as well as the appearance of fibrinopeptide A (Teger Nilsson 1969) have been demonstrated.

As mentioned above, complexes between fibrinogen and fibrin monomer or between these and fibrinogen degradation products are also involved in the pathophysiological phenomena observed during intravascular coagulation and fibrinolysis (Shainoff and Page 1962, Copley and Luchini 1964 Lipinski et al. 1967) Such products have been suggested to have relations to cryofibrinogens.

Present investigation

In earlier studies (II—IV) on the elimination of iodine labelled fibrinogen after procoagulants, a secondary rise in plasma radioactivity was demonstrated, following an initial decrease in the radioactivity of both plasma and fibrinogen. This finding was postulated to reflect a secondary fibrinolysis.

The aim of this investigation was to try to identify by means of ^{131}I-fibrinogen, fibrinogen degradation products and possibly also complexes after thrombin infusions into dogs. This was made by studying: 1 the radioactivity distribution in

plasma, filtered through Sepharose columns, before and after administration of thrombin, 2. the molecular size distribution and immunological behaviour of labelled components, and 3. the influence of epsilon aminocaproic acid (EACA) administered simultaneously with thrombin.

Experimental conditions

Nine dogs were injected with ^{125}I fibrinogen. After complete distribution at steady state catabolism, the animals were anesthetized and catheters inserted into the leg veins. Three dogs in each of 2 groups were given 1. thrombin infusion during 1 hr and 2. thrombin infusion together with epsilon aminocaproic acid (EACA). Before, during and after the thrombin infusions blood samples were taken for determination of radioactivity in plasma, fibrinogen and serum as well as fibrinogen concentration, platelet count and hematocrit. On the serum samples immunological studies were also performed.

For separation of fibrinogen and degradation products on Sepharose columns, plasma from only 3 dogs was used. Plasma and clot supernatant of thrombin-coagulated plasma obtained before thrombin infusion as well as plasma from the point of maximum secondary plasma radioactivity increase, were filtered through the column. As a control radioactive fibrinogen was added to normal plasma and filtered through the same column. The distribution patterns for one dog given only thrombin and for one given thrombin together with EACA were compared. Immunoelectrophoresis was performed on eluate fractions obtained at different effluent volumes. For further separation of corresponding fractions of low molecular weight products obtained with Sepharose, Sephadex G-25 columns were used. Finally after Sephadex filtration, thin layer electrophoresis was performed on the fractions, which from the radioactivity profile and effluent volume were expected to contain fibrinopeptide B.

Results and discussion

Radioactivity elimination and immunological behaviour of serum during experiments — The radioactivity curves for plasma and fibrinogen were similar to those in earlier studies (II—IV) described in the previous chapters. During infusion of thrombin alone an initial steep slope of both curves was followed by a secondary rise of the plasma curve. When EACA was given simultaneously with thrombin the curves diverged only slightly after the initial phase. The mean value for the initial serum radioactivity in 9 dogs was 25 %. In the dog given only thrombin the serum curve rose to around 50 % at the time of maximum plasma value thereafter running parallel with the plasma curve. In the dog given thrombin and EACA the serum radioactivity did not change during the first 2 hrs, then it rose slowly to a value about 5 % above the initial.

Immunoelectrophoresis demonstrated faint precipitates in both dogs before the infusions. In the dog given only thrombin strong arches were obtained with serum taken from 1 to 6 hrs after the start. On the following day there was still a faint precipitate. In the dog given EACA in addition to thrombin there were precipitates, weaker and appearing later than in the dog given only thrombin. Thus after thrombin infusions increasing amounts of products containing the antigenic determinants of fibrinogen seem to appear

Radioactivity distribution before thrombin infusions — Of the total radioactivity 87 % was recovered in thrombin-coagulated fibrinogen and 21 % in serum, obtained after spontaneous coagulation. After Sepharose filtration 61—64 % of the radioactivity was recovered in a fraction (peak I) corresponding to fibrinogen, 14 % in a fraction (peak II) corresponding to material with lower molecular weight and 17 % in a region between the two mentioned. This showed that fibrinogen degradation products had been produced in the dogs during the time required to obtain "steady state" catabolism. The serum radioactivity was higher than could be expected from the figure for radioactivity recovered in the clot formed by addition of thrombin to plasma. This was explained as due to a higher extent of copolymerization or trapping of high molecular weight degradation products during the rapid fibrin formation in the presence of thrombin. This is supported by the finding, that in the clot supernatant after thrombin coagulation of a corresponding plasma sample, much smaller amounts of "high molecular weight" degradation products like those demonstrated in plasma were observed An alternative explanation, though less likely could be that enzymes other than plasmin have been acting during the time of formation of serum.

Radioactivity distribution after infusion of thrombin.—At 2 hrs after the start of thrombin infusion, 71 % of the radioactivity was recovered in plasma, 52 % in serum and 16 % in coagulable fibrinogen. After Sepharose filtration 30 % was found in the fibrinogen fraction (peak I) This value was higher than that for fibrinogen in plasma. The discrepancy might indicate the presence of labelled, non-clottable high molecular-weight fibrinogen derivatives. The radioactivity in material with lower molecular weight had increased, indicating that smaller degradation products had appeared. The radioactivity of the intermediary fraction was essentially unchanged. The amount of radioactivity confined to material of lower molecular weight, together with that of the intermediary region and of non-clottable products in the fibrinogen peak, corresponded fairly well with the value for serum radioactivity

Radioactivity distribution after infusion of EACA and thrombin. — At 2 hrs after the start of the infusion 32 % of the radioactivity was in plasma, 26 % in serum and 4 % in fibrinogen. After filtration, 5 % was in the fibrinogen fraction, 12 % in the peak of relatively lower molecular weight material (peak II) In the intermediary region the radioactivity was reduced in comparison with that before the experiment

It was concluded that the EACA treatment had inhibited the appearance of degradation products following thrombin infusion.

Immunoelectrophoresis on eluate after Sepharose filtration—Eight to nine fractions from every filtration experiment were tested. Material with the antigenic determinants of fibrinogen was recovered in samples corresponding to effluent volumes of fibrinogen and intermediary region but not in material with lower molecular weight. There were positive tests in these regions in samples obtained both before and 2 hrs after start of thrombin infusion. In the dog given EACA in addition to thrombin only material within the intermediary region gave faint precipitates. Thus, like the rise of serum radioactivity the immunological behaviour of the eluate indicates the appearance of increasing amounts of fibrinogen degradation products after thrombin infusion and also an inhibition of these by EACA. These findings confirm that the suggestion of a secondary fibrinolysis, made from the results of the earlier studies (II—IV) is valid

Gel filtration of lower molecular weight material—When pooled fractions of the radioactive material eluted at about the total volume of the Sepharose column and containing no antigenic determinants of fibrinogen, were filtered through Sephadex G-25 two radioactivity peaks were obtained. With respect to the fractionation range of the column, the radioactive material eluted in between the void and total volumes of the column could be expected to contain fibrinopeptide B Electrophoresis of this material failed, however to demonstrate the presence of fibrinopeptide B. It might be that this peptide is released at a slow rate or rapidly degraded to smaller fragments escaping detection with the methods used. Spots with mobility close to that of fibrinopeptide A were found. However as they were present in both plasma and serum obtained before thrombin infusion, the significance of this observation is doubtful. It seems reasonable to assume that the radioactivity in the fraction containing low molecular weight material (peak II) is bound to material released as a result of common catabolism of fibrinogen.

Summary

After thrombin infusion to dogs, injected with ^{125}I fibrinogen, there is first a rapid decrease of the radioactivity in plasma and fibrinogen followed by an increase of plasma and serum activity The initial amount in serum of 20—25 per cent of the total plasma radioactivity is about the double 2 hrs after the start of thrombin infusion. With large doses of fibrinolysis inhibitor the secondary rise in plasma and serum radioactivity is almost blocked Immunological studies indicate the appearance after thrombin infusion of increasing amounts of products with the antigenic determinants of fibrinogen. This effect is almost completely abolished in the presence of the fibrinolysis inhibitor The radioactivity distribution after gel filtration indicates the occurrence of fibrinogen degradation products of varying size Except those of

the lowest molecular weight, the products contain antigenic determinants of fibrinogen. Degradation products have been produced in the dog even before thrombin infusion but appear in increased amounts after defibrination. No products with larger molecular weight than that of fibrinogen are observed after thrombin. This speaks against the appearance in our experiments of complexes between fibrinogen and fibrin or degradation products. Fibrinopeptides could not be demonstrated during the conditions of the experiments.

Other investigations

In the fibrinopeptide B of fibrinogen from several species there are tyrosine residues (Blombäck et al 1966) capable of being iodinated. It has been demonstrated for some fibrinogens that labelling of this peptide can be obtained (Nordström et al. 1966 Regoeczi and Walton 1967) From their results Regoeczi and Walton suggested that labelling of fibrinopeptide B was depending on the occurrence of non esterified tyrosine residues.

Present investigation

In connection with studies on the elimination of ^{131}I dog fibrinogen after i.v administration of procoagulants (II—IV) it was consistently observed that fibrin formed from iodinated fibrinogen by thrombin coagulation had a considerably lower specific radioactivity than fibrinogen. This difference could not be accounted for on the basis of impurities present in the fibrinogen preparations used for iodination. It was assumed that the difference might at least partly be due to iodination of fibrinopeptides split off from fibrinogen during clotting. Therefore, after ^{131}I labelling of dog fibrinogen, trials were made to isolate the dog fibrinopeptide B which because of its content of tyrosine residues would be capable of being iodinated.

Isolation and location of fibrinopeptides

Dog fibrinogen with a coagulability of 88—99 per cent was labelled as described for human fibrinogen (I A) Between 0.3 and 0 9 atoms of iodine were introduced per mole of fibrinogen. After thrombin coagulation of the labelled fibrinogen the clot supernatant contained around 16 per cent of the radioactivity introduced into the fibrinogen.

Gel filtration on Sephadex of clot supernatant was performed in some experiments. The supernatant contained ninhydrin-positive material, which was retained by the gel. In this material 50—60 per cent of the original radioactivity in the clot supernatant was recovered in a distinct peak. Paper electrophoresis of this fraction demonstrated the presence of 2 main components with the same mobility as authentic fibrinopeptides A and B_1 The radioactivity was almost exclusively associated with material having the same mobility as fibrinopeptide B

Chromatography of clot supernatants on a Dowex 50×2 1 mm revealed several ninhydrin-positive peaks. On the basis of chromatographic behaviour and electro-

phoretic mobility 2 main peptide fractions obtained (peaks II and III) identified with fibrinopeptides B_1 and A. Most of the radioactivity about 4 per cent of the original in fibrinogen, was recovered in a fraction (peak IV) which was only slightly ninhydrin-positive The latter was somewhat more retarded on the column than A and considerably more than fibrinopeptide B_1 Electrophoresis of the peak IV material mixed with reference peptides A and B_1 showed that the radioactivity completely overlapped with fibrinopeptide B_1

In order to obtain further evidence for the view that peak IV contained a radioactive, labelled fibrinopeptide B_1 an attempt was made to produce peak IV material from fibrinopeptide B_1 by iodination with ^{131}I according to the monochloride method (McFarlane 1958) Per mole of peptide 0 0022 atoms of iodine were introduced. A low label was aimed at to reduce the chance of obtaining more than one iodinated peptide derivative. This fibrinopeptide B_1 showed the same chromatographic and electrophoretic behaviour as its analogue obtained by iodination of fibrinogen.

For location of iodine incorporated in fibrinopeptide B the labelled fibrinopeptide B_1 was digested with pronase. Thin-layer chromatography revealed that most of the radioactivity was associated with material having the same Rf value as monoiodotyrosine. After alkaline hydrolysis a small radioactive component with a Rf value similar to that of monoiodohistidine was demonstrated by thin-layer chromatography Therefore it may be that histidine residues are to some degree iodinated in the peptide.

Discussion

The present study shows that ^{131}I-labelling of dog fibrinogen gives rise to incorporation of the isotope in the dog fibrinopeptide B By chromatography of the clot supernatant obtained after thrombin coagulation of the labelled fibrinogen, both the analogues of fibrinopeptide B (B_1 and B_2) present in dog fibrinogen, can be isolated. They differ only with respect to the degree of sulphation In B_1 only one, in B_2 both tyrosine residues are sulphated. The iodine isotope is incorporated in B_1 (but not in B_2) As to the chromatographic behaviour of the labelled B_1 it is clearly retarded on a Dowex 50 × 2 column in relation to its non-labelled counterpart. However the electrophoretic mobility of the two is the same. The fact that fibrinopeptide B_1 labelled in vitro on chromatography as well as in electrophoresis shows the same behaviour as the labelled peptide isolated from the iodinated dog fibrinogen, is further proof that the incorporation is really in B_1 As to the attachment of the label in the peptide mainly monoiodotyrosine is formed but some degree of iodination also of histidine residues can not be excluded.

The amount of radioactivity released into the clot supernatant after coagulation of the native protein with thrombin was 16 per cent of the activity in the fibrinogen the amount found by Regoeczi and Walton was somewhat lower The radioactivity content of the clot supernatant explains the greater part of the difference between the specific activity of fibrin and that of fibrinogen. As after Sephadex filtration

50—60 per cent of the radioactivity in the clot supernatant is confined to material which identifies with fibrinopeptide B_1 roughly 9 per cent of the total radioactivity in fibrinogen is incorporated in this peptide. The radioactivity in the supernatant that can not be accounted for by the label in fibrinopeptide B may derive from over iodinated fibrinogen or impurities present in the fibrinogen preparation. Our results suggest that iodination of fibrinopeptide B does not render the fibrinogen unclottable as the iodinated peptide is released from the molecule during the coagulation process. The labelled fibrinogen seems not either to be more rapidly eliminated from the circulation in vivo as the specific activity in fibrin in per cent of that in fibrinogen remains roughly constant during the whole time of distribution and steady state catabolism. These findings are in conformity with the results obtained by Regoeczi (1967) in studies on fibrinogen from the goat. This author suggested that the in vivo behaviour of a labelled fibrinogen does not depend on whether or not the fibrinopeptide B is labelled.

In investigations on the effect of thrombin coagulation upon the label in iodinated fibrinogen Regoeczi and Walton (1967) studied the protein from eight species. They showed that fibrinopeptides B from ox and rabbit, containing each one tyrosine-O-sulphate residue could not be iodinated. In goat and sheep fibrinogens, having one of two tyrosines sulphated, they found that the amount of iodine, released into the supernatant after thrombin coagulation, on a molar basis was only half of that obtained when dog fibrinogen was coagulated. This finding made them suggest that the fibrinopeptide B from dog contains two unesterified tyrosine residues. However as the bulk of dog fibrinopeptides contains at least one tyrosine-O-sulphate residue (Blombäck et al. 1966) this interpretation is not valid. It seems as if the iodination is not dependant only on the occurrence of free tyrosine residues but steric factors are also operative. In six out of eight fibrinogens studied by Regoeczi and Walton, tyrosine-O-sulphate is present in the fibrinopeptide B. They noticed that no label was introduced into those peptides having all tyrosine residues esterified with sulphate and suggested that labelling of sulphated tyrosine residues is not favoured. In the present study no incorporation was obtained in the fibrinopeptide B_3 where both tyrosine residues are sulphated.

The information obtained in the present study is important for interpretation of results obtained in studies on the turnover of fibrinogen in species, in which the fibrinopeptide B is labelled. As presented elsewhere (II) the loss of radioactivity from fibrinogen after thrombin coagulation in among other the dog protein must be taken into account. Release of radioactivity into serum might occur from fibrinopeptide B during coagulation in vivo and from the degradation of fibrinogen and fibrin. As presented (V) there was, under such conditions no evidence that radioactivity from fibrinopeptide B had been released as a consequence of coagulation in vivo.

Summary

When iodine labelled dog fibrinogen is coagulated with thrombin, around 16 per cent of the total radioactivity is released into the clot supernatant. From the latter fibrinopeptides A, B_1 and B_2 can be isolated by appropriate procedures. The B_1 peptide contains about 9 per cent of the original radioactivity in fibrinogen in the B_2-peptide no label can be demonstrated The part of radioactivity in the super natant not incorporated in fibrinopeptide B_1 might be contained in non-clottable, overiodinated fibrinogen or in impurities. On iodination the clottability of the fibrinogen is reduced by some 3 per cent. A constant difference in vivo between plasma and fibrinogen radioactivity indicates that the non-clottable contaminants are not screened out but show the same turnover as the clottable protein.

GENERAL SUMMARY

The half life time of iodine labelled fibrinogen in normal humans was around 4.5 days, which is in accordance with the results of most other studies. Like in previous investigations, patients with various coagulation factor deficiency states were found to have a normal fibrinogen elimination. This speaks for that the short half life time of fibrinogen as compared to that of other plasma proteins, is not to a considerable degree explained by consumption of fibrinogen in a continuous intravascular coagulation. An increased turnover rate of fibrinogen was found in some disorders, where hypercoagulability has been suggested to occur. Results obtained in some patients with polycythemia vera and in some with liver cirrhosis indicate that in these disorders intravascular coagulation with consumption of fibrinogen and other coagulation factors may occur.

Intravenous administration of procoagulants into dogs results in a consumption coagulapathy accompanied by a secondary fibrinolysis. This fibrinolysis can be effectively blocked by simultaneous treatment with large doses of fibrinolysis inhibitors.

A "spontaneous" fibrinolysis in the dog is suggested by the demonstration in plasma of fibrinogen degradation products in animals, subjected only to anesthesia and insertion of catheters. After i.v. administration of procoagulants degradation products of varying molecular size appear in increased amounts.

When dog fibrinogen is labelled with iodine around 9 per cent of the total iodine in fibrinogen is incorporated in the fibrinopeptide B. The possibility of labelling of fibrinopeptide B must be taken into consideration in connection with studies on the turnover of fibrinogen in several species.

ACKNOWLEDGEMENTS

This investigation has been carried out to the main part at the Department of Blood Coagulation Research, Karolinska Institutet Stockholm. I have a great debt of gratitude to the Chief of the Department, Laborator Birger Blombäck, for stimulation to this work, for his never failing enthusiasm, criticism, generous supply of facilities and readiness to share his great knowledge of blood coagulation. I want to thank Docent Margareta Blombäck for introducing me in methodology for valuable advice and interesting discussions.

For their invaluable technical assistance I am very thankful to Miss Ervor Holmberg, Miss Bodil Jonsson Miss Ingrid Soderman and Engineer Jan Reuterby

I want to thank especially Doctor Sam Nordström for friendly cooperation and for all stimulating discussions.

To Laborator Erik Berglund, Chief of the Thoracic Surgery Research Laboratory and Professor Gunnar Birke, Chief of the King Gustav V Research Laboratory I am very thankful for valuable advice, generous supply of facilities and skillful assistance by members of their staffs.

I heartily thank many colleagues for inspiring discussions and generosity—Docent Ann-Catrine Teger Nilsson, Doctor Irene von Francken, Doctor Ingrid Norén, Docent Per Olsson, Professor Lars Carlson, Laborator Sten-Otto Liljedahl Docent Sixten Franzén and Civil Engineer Lars-Olof Plantin.

The work was supported by grants from Karolinska Institutet, the Swedish Medical Research Council Nos. K66-13X 520-02, K67 19X 520-03 B69-61P 2598-01 the Swedish National Association against Heart and Chest Disease, Bayer Farma AB, Stockholm, Svenska Sällskapet för Medicinsk Forskning, Viktor och Albertina Molnder's Foundation, Carl Yngve Johnson's Foundation, Loo och Hans Osterman's Foundation, Gunnel and Svante Högboms Foundation.

INTRODUCTION

1 General considerations

The stomach subserves three important motor functions. First, it provides an adjustable reservoir by adapting quickly and markedly in volume in connection with food intake, without development of excessive pressure rises. Secondly gastric contents are mixed with gastric secretion. Thirdly the gastric contents are gradually passed into the intestinal tract for final digestion and absorption at a rate which is suitable for these processes.

As early as 1764 Haller observed alternating contraction and relaxation of the stomach (see Cannon 1898) Mainly on the basis of studies of intestinal motility starting with the classical investigation by Bayliss and Starling (1899) it has been generally accepted that intestinal motility is reciprocally controlled by vagal and sympathetic fibres, a concept that has been accepted to hold for the whole gastro-intestinal tract.

Studies on gastric motility responses, elicited by vagal and splanchnic stimulation also received wide attention during the first decades of this century Thus, Cannon and Lieb (1911—12) coined the term "receptive relaxation" for the suppressive effect on gastric motility which they observed in connection with deglutition. In a survey of the literature and by own observations of the nervous control of gastric motility McSwiney (1931) stressed that both vagal and splanchnic stimulation could produce excitatory responses if prevailing gastric tone was low while both types of stimulation tended to cause inhibitory responses if gastric tone was initially high This view has since been largely accepted in textbooks and reviews though the exact nature of these responses has not been fully understood (e g Youmans 1952, 1968 Kuntz 1953 Thomas and Baldwin 1968)

2. Arrangement of the gastric smooth muscle coat

From early morphological studies (e g Jefferson 1914—15 for ref see McSwiney 1931 Schofield 1968), it was clear that the arrangement of the gastric smooth muscles is a complex and differentiated one, which suggests that the muscle coat cannot be regarded as a simple functional unit. However the relation between gastric motor function and the arrangement of the smooth muscle cover is in several respects still not clear

The gastric muscle layers are less distinctly separated into complete sheaths than in most other parts of the gastro-intestinal tract. Thus, an incomplete outer layer of longitudinal fibres extends from the esophageal smooth muscles and forms well-developed bundles along the curvatures while only scattered fibre streaks are present in other parts of the gastric wall. The only sheath of muscle which is complete throughout is formed by the middle circular layer which increases progressively in thickness towards the pylorus. The internal layer of the gastric smooth muscle spreads from the fundus in a fan-like fashion over the anterior and posterior walls of the stomach where it connects with the middle circular coat. The functional implications of this arrangement of the muscle layers and their interactions are largely unknown An exploration by means of electro-physiological methods *in situ* may here prove fruitful.

3 Neural elements in the gastric wall

Gastric motility is certainly in part based on myogenic activity but co-ordinated gastric function calls for specific local and extrinsic nervous control mechanisms However the relationship between inherent smooth muscle activity and superimposed nervous control is still not well understood.

The stomach wall contains *ganglion cells* linked by fine nerve fibres in plexiform networks. The complicated anatomical arrangement of the smooth muscle layers of the stomach wall however makes the division of intramural nervous structures into different layers less distinct in the gastric wall than in the intestine (Schofield 1968)

Most ganglion cells in the gastric wall are reported to stain intensely with dyes for acetylcholine-esterase activity (Jacobowitz 1965) indicating that they are cholinergic. The majority of these cells evidently form the postganglionic link mediating extrinsic parasympathetic influences and intrinsic peristaltic reflexes.

The specific histochemical fluorescence technique for identification of adrenergic neurons and nerve fibres developed by Hillarp and Falck (see Falck 1962) enabled a widening of knowledge of the adrenergic innervation of the gastro-intestinal tract. No ganglion cells situated in the wall were found to display the specific catecholamine fluorescence (see Schofield 1968) thus, removal of the coeliac ganglia with subsequent degeneration of the axons of the ganglionic cells results in the disappearance of all catecholamine fluorescence in the cat's stomach (Jacobowitz 1965) This suggests that the cell bodies of all the adrenergic neurons are situated in

the sympathetic ganglia outside the stomach wall proper Cell bodies containing 5-HT in the gastric wall do not seem to exist as judged from studies on mouse by Gershon and Ross (1966)

Results by Norberg (1964) Jacobowitz (1965) and Schofield (1968) have shown that most of the adrenergic ramifications of these neurons terminate in close contact with the intramural ganglion cells. This strongly indicates — but is not *per se* unequivocal evidence of — a synaptic contact with these neurons. In contrast to this dense network of adrenergic fibres around the intramural ganglion cells, relatively few adrenergic nerves seem to penetrate into the smooth muscle layers. The majority of these fibres seem to innervate intramural blood vessels rather than the gastric smooth muscles proper (Norberg 1964 Jacobowitz 1965 Schofield 1968) Nerve endings containing 5-HT observed in the gastric wall of the mouse, also seem to terminate on intramural ganglion cells rather than on the smooth muscle cells (Gershon and Ross 1966)

To summarize, there is at present no evidence of monoaminergic intramural neurons in the stomach. Most of these neurons appear to be cholinergic. However it is possible that some of them utilize still another type of a so far unknown transmitter It is, for instance, not known how the vagal "relaxatory" fibres (see below) which appear to be neither adrenergic nor cholinergic in their *final* action on the gastric smooth muscles, exert their powerful effect on the stomach.

4 Extrinsic nerve supply to the stomach

The stomach has an extrinsic supply of nerve fibres running in the vagal and splanchnic nerves. These nerves contain both *efferent* fibres, emerging from extramural ganglion cells, and different sets of *afferent* nerve fibres emerging from the gastric wall

By means of the extrinsic efferent nerves, gastric motility is adjusted either reflexly from the gastro-intestinal tract itself and other parts of the body or from central autonomic structures of the brain. Present knowledge of the functional significance of the extrinsic nervous supply to the stomach is incomplete, especially with respect to the nervous mechanisms responsible for suppressive effects on motility (for ref see Youmans 1952 Thomas and Baldwin 1968)

a. Cholinergic fibres

As early as 1858 Hartung described gastric motor fibres in the vagal nerves. This excitatory fibre type has been extensively studied. Jansson

and Martinson (1965) and Martinson (1965 c) showed that the excitatory cholinergic fibres, whose responses are selectively blocked by atropine, are relatively low threshold and can therefore be stimulated separately from the vagal relaxatory fibres described below — In addition it has been found that the splanchnic nerves contain some cholinergic excitatory fibres to the stomach but their functional significance is unknown (see Thomas and Baldwin 1968)

b. Vagal relaxatory fibres

It has been much debated in what way the vagal nerves suppress gastric motor function (for ref see McSwiney 1931 Thomas and Baldwin 1968) According to Greff *et al* (1962) and Paton and Vane (1963) the vagal supply to the stomach contains adrenergic inhibitory fibres. Martinson (1965 c) has clearly shown that the vagal nerves contain a group of high-threshold efferent fibres. These fibres can produce a manifold increase in gastric volume (Jansson and Martinson 1965) an effect which is largely confined to the corpus-fundus region and mediated by a non-adrenergic transmitter mechanism (Martinson 1965 b) This "relaxatory" vagal path way is blocked by hexamethonium but not by atropine, guanethidine (Martinson 1965 a) bretylium or by pretreatment of the animals with reserpine (Martinson unpublished observations) These findings have been largely confirmed in studies of the stomach *in vitro* by Campbell (1966) Also on the basis of *in vitro* experiments, Bülbring and Gershon (1967) suggest that acetylcholine and 5-hydroxytryptamine may be involved as transmitters for this relaxatory pathway to the gastric smooth muscle cells. However the transmission at the final neuro-effector junction for this pathway remains unknown.

It should be emphasized that there is apparently no true *antagonism* between the vagal relaxatory fibres and the cholinergic excitatory ones with respect to gastric motor control. Thus, Martinson (1965 c) considered the excitatory gastric response to be facilitated by the action of the relaxatory fibres, which widens the reservoir part of the stomach It was suggested by Jansson and Martinson (1965) that the vagal relaxatory fibres may be involved in the "receptive relaxation" of the stomach. However no definite information was then available concerning their physiological significance, though their pronounced effects on gastric volume indicated a functional involvement closely associated with food intake

c. Adrenergic fibres

The splanchnic supply to the stomach contains nerve fibres which unlike the abovementioned vagal relaxatory fibres, are blocked by guanethidine (Martinson 1965 a) and bretylium (Campbell 1966) McSwiney and Wadge (1928) observed inhibition of gastric motility upon splanchnic nerve stimulation at high frequencies (10 to 60 imp/sec) In the acutely vagotomized stomach, splanchnic nerve stimulation at physiological frequencies (below 8—10 imp/sec) produced only a weak and slowly developing inhibition of the stomach after a latency of 10—30 sec, a response which became more substantial at "supraphysiological" frequencies of stimulation (Martinson 1965 a)

In the aforementioned study by Martinson (1965 a) comparisons were also made between the responses obtained by direct stimulations of the vagal relaxatory fibres and of the adrenergic inhibitory fibres. Martinson distinguished clear differences in effects by the two types of nerve fibres. First, already low frequency stimulation of the vagal relaxatory fibres elicited pronounced gastric relaxation and, secondly this relaxation appeared after a far shorter latency than that characterizing the weak and sluggish inhibitions obtained on the acutely vagotomized stomach which was produced by splanchnic stimulation Principally similar results were obtained on the stomach *in vitro* by Campbell (1966)

The high stimulation frequencies needed and the delayed and sluggish inhibitory responses to sympathetic stimulations in acutely vagotomized preparations, suggest some type of indirect mechanism (*cf* Celander 1959 Martinson 1965 a, c) such as diffusion of transmitter to the gastric smooth muscle from nerve endings around ganglionic cells or in vascular walls By contrast, the atropinized gastric smooth muscle responds promptly to the vagal relaxatory fibres. It should be stressed that in the results described above, cholinergic nervous activity was largely abolished either by acute vagotomy or by administration of atropine.

However if the adrenergic fibres exert their action on the ganglionic relay of the cholinergic system, the effect of adrenergic activity can only be clearly demonstrated when a cholinergic nervous activity is present. It should be remembered that the histochemical studies, referred to above, suggest that the majority of the adrenergic fibres take synaptic contacts with the intramural cholinergic neurons, which form the final link in the vagal excitatory control of gastric motility (Norberg 1964 Jacobowitz 1965 Norberg 1967 personal communication, Schofield 1968) This by no means denies the fact that considerable regional as well as species

differences in the pattern of innervation may occur. In conclusion, the mode of adrenergic influence on gastric motility and the functional significance of the central and reflex patterns, which involve the adrenergic fibres is not fully understood.

d. Afferent fibres

Afferent nerve fibres from the stomach run in both the vagal and splanchnic nerves, together with afferents from other visceral organs. The dominance of afferent fibres in the vagal nerve is noteworthy. Agostoni *et al.* (1957) have shown that in the cat about 90 % of the 31,000 vagal nerve fibres at the diaphragmatic level are afferent; thus, only about 3,000 fibres are efferent at this level. Paintal (1954) and Iggo (1955, 1957—58 a, b) have shown that afferent vagal fibres from the stomach and intestine can be activated from mechano- and chemoreceptors which are sensitive to *e. g.* stretch and pH-changes. Furthermore, Andrew (1957) has described sensory endings that cause discharge in vagal afferents upon esophageal distension. It appears as if most of the vagal afferents are "specific" ones, *i. e.* non-nociceptive. On the other hand, most — but not all — of the afferent fibres in the sympathetic supply seem to be nociceptive, *i. e.* signalling pain or discomfort as a result of distorsion, ischaemia, strong distension etc. (*cf.* Balchum and Weaver 1943).

5. Reflex and central nervous influences

Extensive literature describes reflex patterns affecting gastric motor function; these patterns also include suppressing influences, in the efferent direction conveyed both *via* the vagal and splanchnic nerves (for ref. see Youmans 1952, 1968, Thomas and Baldwin 1968). Reflex suppressive effects on gastric motility by stimuli emanating from the intestine have been studied (*e. g.* Brunemeier and Carlson 1914—15, Thomas and Mogan 1931, Lalich, Meek and Herrin 1936, Daniel and Wiebe 1966). Reflex effects of stimuli induced in the esophagus (Veach 1926) or as a result of electrical stimulation of afferent vagal nerve fibres have also been investigated (Harper, Kidd and Schratcherd 1959).

It appears, however, as if no experimental analysis has been undertaken to differentiate and characterize the reflex motility responses, with particular reference to the different sets of efferent nerve fibres involved and their peripheral interactions as outlined above. Most of the conflicting interpretations of pathways involved in the earlier literature can be ascribed to the fact that it was not until recently clearly shown that there

exist *two* distinct sets of efferent fibres producing suppressive effects on gastric motility. However, they appear to do so in very different ways and, presumably, in quite different response patterns. The vagal relaxatory fibres and their distinct differences in effects in contrast to adrenergic fibres require a re-classification of the peripheral nervous mechanisms and justify a re-evaluation of reflex and central response patterns.

With respect to central nervous structures and their influence on gastric motility, both augmentative and inhibitory influences have been shown to be conveyed *via* both the vagal and the splanchnic nerves (*e. g.* Eliasson 1952). However, it is not known whether the splanchnic effects can all be ascribed to adrenergic mechanisms, and then in which way the effects are brought about. It is known that *e. g.* hypothalamic stimulation can produce both an increase and decrease in adrenergic discharge to the cardiovascular system; for example, stimulation of the "defence area" produces excitation (Eliasson *et al.* 1951, Abrahams *et al.* 1960) and the cortical and hypothalamic "sympatho-inhibitory" structures produce inhibition (Folkow *et al.* 1959, Löfving 1961). In accordance herewith it is known that also different somatic afferents produce either a reflex inhibition of sympathetic tone ("somatic depressor" fibres) while activation of afferent C-fibres increases sympathetic discharge to the cardiovascular system ("somatic pressor" fibres) (see Johansson 1962). It appears likely that these central nervous structures and somatic afferents affect gastrointestinal adrenergic control as well, but in different directions.

It should in this connection be stressed that a widening of the stomach, evoked by extrinsic efferent nerves, may be due to an activation of the vagal relaxatory fibres or the sympathetic adrenergic fibres, as well as by inhibition of prevailing activity in the vagal excitatory fibres or in the little known splanchnic cholinergic fibres. Thus, many types of responses can be distinguished that — with respect to functional importance and significance of the response patterns involved — may be widely different. Likewise, augmentation of gastric tone and motility may be due to excitation of the two aforementioned sets of cholinergic fibres or to inhibition of a prevailing activity in the vagal relaxatory fibres or the adrenergic fibres. Again, these are responses that may be of widely different physiological significance, which must be thoroughly analysed to be fully understood.

AIM OF THE PRESENT STUDIES

As mentioned, earlier studies from this department (Martinson and Muren 1963, Jansson and Martinson 1965, Martinson 1965 a, b, c) have shown two types of efferent vagal fibres to the stomach affecting its motility. The low-threshold excitatory fibre group can be separately activated because of its particular stimulation threshold. This fibre group enhances gastric motility by a cholinergic mechanism and is identical with the "conventional" vagal excitatory fibres, while the high-threshold relaxatory fibres produce marked corpus-fundus relaxation by a non-adrenergic mechanism.

In the vagally decentralized stomach, the effect of the relaxatory fibres is far more prominent and immediate in onset also at low frequency stimulation than are the inhibitory responses produced by sympathetic stimulation (Martinson 1965 a). Such quantitative differences are, however, first fully revealed when isotonic volume recordings are used at low transmural pressures, as inhibitory neurogenic responses are then more easily recorded than when intragastric pressure recordings are used, as was the case in most earlier investigations. It has for such reasons been difficult to interpret the often varying gastric responses obtained upon vagal (for ref. see Martinson 1965 c) and splanchnic stimulation (for ref. see McSwiney 1931).

The question arises as to what is the physiological significance and involvement in reflex and central nervous patterns of the high-threshold vagal relaxatory fibres to the stomach and what is their relationship to cholinergic excitatory effects on stomach motility, as compared with the inhibitory effects produced by the adrenergic fibres.

In order to study these questions a modification of the method described by Jansson and Martinson (1965) was worked out by which gastric motility could be studied without such disturbances as are produced by the "unphysiological" reflex activity in connection with abdominal surgery. *The present investigation was primarily concentrated on the reflex involvement of the vagal relaxatory fibres and their significance for gastric motility control, as contrasted to the role played by the adrenergic fibres.*

The first two studies (I, II) deal with the reflex activation of the vagal relaxatory fibres to the stomach, either produced by electrical stimulation

of vagal afferents (I) or by "adequate" receptor stimulation in the esophagus and pharynx (II).

Studies III—VI deal with the mode of local action and the reflex and central engagement of the adrenergic fibres to the stomach, as compared with the effects mediated by the vagal relaxatory fibres. As mentioned in the introduction, it appears as if the inhibitory effect produced by the adrenergic fibres calls for prevailing cholinergic activity in order to be fully displayed; if such activity is not present the adrenergic fibre effects on gastric motility seem to be feeble, considerably delayed and sometimes even absent. Attempts were therefore made to explore the influence of the adrenergic fibres, not only when directly stimulated (III, IV) but also when reflexly (III, IV, VI) and centrally engaged (V), both when vagal cholinergic activity was present and largely absent.

By such studies it proved possible to obtain some information about principal differences in the mode of local action of the aforementioned three sets of efferent fibres to the stomach and to reveal some aspects of their functional significance and involvement in central and reflex response patterns.

METHODOLOGICAL CONSIDERATIONS

Gastric motility was, as mentioned briefly above, assessed from measurements of the volume of the stomach at constant low intragastric pressure ("isotonic" recording). This recording principle was considered to mimic the physiological situation far better than the conventional recording of intragastric pressure at constant volume ("isometric" recording). The original method was described in detail by Jansson and Martinson (1965) and is outlined also in III.

The isotonic recording of volume is especially suitable for evaluation of gastric relaxatory responses. Manifold increases of gastric volume may be induced, which with "isometric" recording technique may even escape detection, as only slight pressure reductions may ensue thanks to the particular pressure-volume characteristics of the stomach.

In attempts to reflexly activate the vagal relaxatory fibres, the original "direct" method involving recording from a pyloric cannula (III) proved to be less suitable in many situations, as it requires extensive abdominal surgery and handling of the stomach. This may *per se* cause marked reflex activation of the vagal relaxatory fibres and of the adrenergic fibres as well. It may then be difficult to produce further reflex widening of the stomach due to activation of the vagal relaxatory fibres.

In an attempt to eliminate these drawbacks of abdominal surgery, a modification of the original method was devised (see I). The principle of recording gastric volume at isotonic conditions is largely the same, but is instead achieved by introducing a large thinwalled ballon *via* the esophagus, leaving the abdominal cavity intact. Recordings of gastric volume by means of this balloon technique, proved to adequately reflect gastric relaxation, at the same time as disturbances by means of reflex effects induced from the abdominal cavity were avoided. Also excitatory responses could be adequately recorded by this method (I, II, IV, VI). The presence of even a thinwalled balloon may to some extent induce reflex or local changes in gastric motility. However, when such changes are present, they may be considered to be more "physiological" in nature and in all likelihood less extensive than in recording techniques which involve a greater interference with the tissues.

It is furthermore obvious that the volumetric recordings of gastric

motility will hardly reveal *all* forms of local contractions, but only net changes in total gastric volume, where those of the essential reservoir section, the corpus-fundus regions, will dominate. No doubt some types of local contractions of great functional importance, *e. g.* in the antral-pyloric sections, may here produce regional reductions in volume which may be largely offset by a simultaneous slight relaxation in other, more voluminous, parts of the stomach so that no net change in *total* volume is obtained. The present experimental analysis therefore preferentially deals with the nervous control of the reservoir function of the stomach and hardly with such motility that is more directly involved in *e. g.* antral-pyloric control.

Excitations of the various sets of extrinsic nerves to the stomach always produced clear-cut responses in terms of net volume changes (I—VI). Therefore, the recording principle used, was considered to serve its purpose for the present investigation, *i. e.* to record both suppressive and augmentative effects on motility in the main reservoir part of the stomach, as produced by experimental activations of the various sets of extrinsic nerves.

One great advantage of the recording principle used is the possibility of assessing the level of gastric tone. Such an assessment was shown to be necessary for the correct interpretation of whether a fibre set has been reflexly involved or not. For example, an already relaxed stomach cannot be further relaxed, and an excitatory motor influence cannot be properly demonstrated if the stomach is already strongly contracted. Pressure recordings alone will hardly be able to adequately reveal the level of gastric tone. Further, the effects of the vagal relaxatory fibres are poorly reflected by a conventional pressure-recording balloon, despite the fact that excitatory effects of the vagal cholinergic fibres are reasonably well recorded (Martinson and Muren 1963, Martinson 1965 b). It can be implied that open-tip tubes or small pressure transducers must provide still more incomplete information about effects produced by *e. g.* the vagal relaxatory fibres, despite the fact that these fibres may produce manifold increases of gastric volume. These shortcomings of the conventional techniques for recording gastric motility appear, in fact, to be one of the main reasons why the vagal relaxatory fibres and their function were not clearly defined long ago.

The following drugs were used as experimental aids for pharmacological blocks of some of the efferent fibre sets to the stomach. For blocking the vagal cholinergic excitatory fibres, atropine (Atropine sulphate, Merck)

was used while adrenergic fibre effects were blocked by guanethidine (Ismelin®, CIBA). Further, the α-receptor blocker phenoxibenzamine (Dibenzyline®, Smith, Kline & French) was sometimes used to minimize the vasoconstrictor fibre effects on gastric blood supply. In addition, intra-arterial infusion of acetylcholine was used in III to initiate gastric contractions by a direct action on the gastric smooth muscles. Lastly, some animals in each series were studied after treatment with gallamine triethiodide (Flaxedil®, May & Baker) to exclude the possibility that skeletal muscle effects had interfered with the recordings of gastric motility.

RESULTS AND COMMENTS

1. Gastric motility in intact anesthetized animals (balloon technique)

In anesthetized and tracheotomized but otherwise intact animals, the balloon technique often reveals the presence of large oscillations in volume (*e. g.* Fig. 1, upper left part). When present, such waves are usually superimposed on a fairly constant level. At times, the rhythmic contractions are absent so that only the steady level, for convenience called "*gastric tone*",

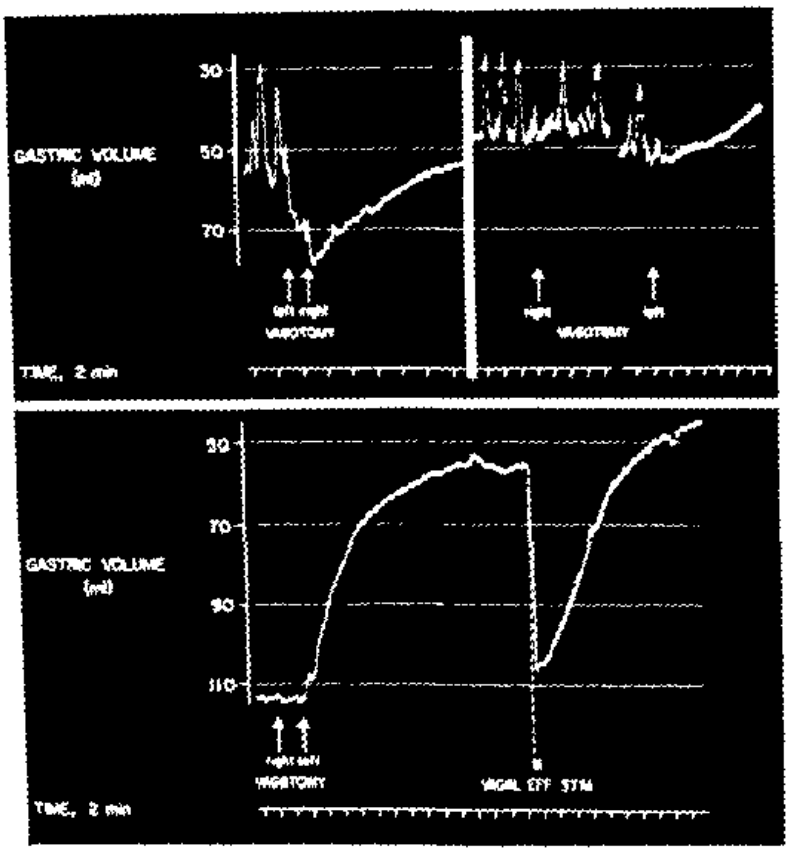

Fig 1. Effects of acute cervical vagotomy on gastric motor function. *Upper panel, left part.* Cat 3.2 kg. Recording with a large balloon introduced *via* esophagus (intragastric pressure 4.5 cm H_2O). Disappearance of gastric contractions on cervical vagal transection. *Upper panel, right part.* Cat 2.6 kg. Recording with the "direct" intragastric volume method (intragastric pressure 4.5 cm H_2O). The splanchnic nerves transected. Note the disapperance of gastric contractions on cervical vagotomy followed by a volume decrease. *Lower panel* Cat 3.0 kg. "Direct" intragastric recording (intragastric pressure 5 cm H_2O). Atropine 0.5 mg/kg i.v.; artificial respiration; Flaxedil® administered i.v. in repeated small doses. Cervical vagotomy results in a pronounced volume decrease. Electrical stimulation of the cut distal ends of the vagal trunks (8 imp/sec, 3 msec, 7 V) elicits gastric relaxation.

is reflected in the volume recording. However, direct observation of the stomach in such experiments in which the abdomen was opened usually revealed a faint rhythmic activity, which does not show up in the volume recording.

The large oscillations vanish after administration of atropine (II) or upon vagotomy (Fig. 1, upper left panel) indicating that they are dependent upon the vagal cholinergic excitatory fibres. The gastric contractions can be closely mimicked by stimulation of the cholinergic vagal excitatory fibres (I, *cf.* Jansson and Martinson 1965). Chronically vagotomized animals showed re-appearance of similar contractions, which represents synchronized movements induced and integrated by the intramural cholinergic neurons (IV). These rhythmic contractions are abolished by administration of atropine.

2. Gastric motility after abdominal surgery (direct recording technique)

The experimental approach, necessitating abdominal surgery and manipulation of the abdominal organs, was used in many experiments and some observations concerning gastric motility in this situation will be briefly outlined. Fig. 1, lower panel, shows a recording of gastric volume *via* a pyloric cannula. Atropine had been administered to block the vagal excitatory fibres. Gastric volume is here large with few signs of rhythmic activity. However, sectioning of the vagal nerves leads to a marked *decrease* of gastric volume, *i. e.* gastric tone becomes markedly increased. A brief stimulation of the peripheral ends of the vagal nerves leads to a phasic increase of volume to the level present before the vagal section. These results indicate that the vagal relaxatory fibres were tonically active in this preparation. This was often the case whenever abdominal organs had been manipulated and suggests an activation of gastro-intestinal and/or other types of abdominal receptors. Thus, the presence of "background discharge" in the vagal relaxatory fibres could be revealed in such situations by cooling or cutting the vagal nerves. However, such tonic activity could sometimes also be observed in animals where the balloon technique was used, thus without any abdominal surgery (II) though the activity was generally far less pronounced in this situation. Moreover, on plotting intragastric pressure *versus* volume of fluid introduced into the stomach in experiments similar to the one illustrated in Fig. 1 (lower panel), it was noted that the organ was "hypotonic" before vagotomy, but "hypertonic" after vagotomy (Jansson and Martinson unpublished

observations). This observation might suggest that mere distension of the stomach by its contents can produce reflex activation of the vagal relaxatory fibres, then presumably initiated by mechanoreceptors in the stomach wall. Such reflex effects seem to be greatly enhanced when the stomach is manipulated in connection with abdominal surgery.

On recording of gastric motility *via* a pyloric cannula ("direct" recording) (III) after splanchnicotomy, rhythmic contractions of the stomach were often seen (Fig. 1, upper right panel). Vagal section (Fig. 1, upper right panel), atropine, as well as low frequency splanchnic stimulation (Fig. 2) abolishes such rhythmic gastric motor activity, showing that it is dependent on the vagal cholinergic excitatory fibres and that adrenergic discharge can suppress their effect. The rhythmic waves can be re-induced by stimulation of the vagal nerves in preparations where these nerves had been cut but where atropine had not been given. After vagotomy, however, such rhythmic waves are seen only in chronically decentralized preparations where sufficient time has elapsed after vagal section. In such preparations the rhythmic activity appears to emanate from the cholinergic ganglion cells in the stomach wall, which upon chronic denervation display a more vivid activity (IV).

Comments: Cooling or section of nerve trunks usually has only negligible effects unless the nerves convey some background activity, though nerve section may itself produce a brief fibre stimulation and a transient effect. The two types of vagal efferent fibres affecting gastric motility are in many situations tonically active, producing their characteristic effects which are easily detected by the recording techniques used. In the upper left panel of Fig. 1 (balloon recording) the cholinergic excitatory fibres appear to be most active, since vagotomy eliminates the rhythmic contractions. In addition, nerve section *per se* appears to have caused a brief excitation of the relaxatory fibres, to judge by the immediate transient volume increase after nerve section, whereupon gastric tone returns to the level present before vagotomy. On the other hand, it is possible that some slight tonic discharge of the relaxatory fibres was present as well, largely balanced by that in the vagal excitatory fibres.

Such background discharge in the different fibre sets to the stomach often seems to be due to reflex activation, particularly associated with the experimental manipulations themselves, such as abdominal surgery, distension of abdominal organs etc. Such manipulations may produce considerable reflex activations of especially the vagal relaxatory fibres,

which may explain the low level of gastric tone shown in Fig. 1, lower panel.

Further, surgical trauma could cause considerable reflex activation of the adrenergic fibres as well (IV). Elimination of the adrenergic fibre influence on the stomach leads to increased gastric motility due to the withdrawal of the inhibitory influence of these fibres on the cholinergic excitatory mechanisms (Fig. 2). It is well-known that peritoneal irritation causes generalized suppression of gastro-intestinal motility (*e. g.* Cannon and Murphy 1906, Douglas and Mann 1941, Perret and Hesser 1960). Furthermore, spinal anesthesia (Markowitz and Campbell 1927) as well as splanchnicotomy or splanchnic anesthesia (Douglas and Mann 1941) usually prevent intestinal inhibitions.

If pronounced, reflex tonic discharge of the adrenergic inhibitory fibres and of the vagal relaxatory ones can make it impossible to elicit additional reflex responses in any of the efferent fibre sets supplying the stomach. The stomach may already be exposed to nearly maximal activities of the vagal relaxatory and adrenergic inhibitory fibres (I, IV).

From these considerations it seems clear that — during recordings of gastric motility in preparations with an intact nervous supply — it may be impossible to assess the "normal" level of discharge of the various efferent fibre sets to the stomach, since a series of uncontrollable factors may influence the level of this activity if great caution is not exercised.

3. Effects on gastric motility by direct stimulation of the efferent nerve supply

a. Vagal stimulation

Recording of gastric motility with the balloon modification of the isotonic volume upon electric stimulation of the cut vagal nerves (I), confirm Martinson's findings (1965 c) that the vagal supply to the stomach contains two types of efferent nerve fibres. The excitatory cholinergic fibres could be selectively activated if comparatively weak stimuli were used (I). Excitatory vagal responses were more easily elicited and stronger when gastric motility was measured with the balloon method, as this does not require abdominal surgery thus avoiding undue reflex sympathetic activation. It was observed that gastric contractions, produced by vagal stimulation, were briefly suppressed by an abdominal wall incision; handling of the intestines resulted in prolonged and intense suppression of the vagal excitatory effects. Administration of guanethidine, which

blocked the adrenergic influence, enhanced the effects of the vagal excitatory fibres (III, V).

If the strength of vagal electrical stimulation was increased, the high-threshold vagal relaxatory fibres were activated as well (I, III). The characteristic effect of this fibre type on the stomach was fully revealed after blocking the cholinergic excitatory fibres with atropine; vagal stimulation of sufficient strength then produced prompt gastric relaxation (Fig. 1, lower panel).

b. Splanchnic stimulation

The effects of direct sympathetic stimulation on gastric motility was studied particularly in respect to the effect of various frequencies of stimulation and the latency of the responses. Such stimulations were performed at different levels of activity in the intramural cholinergic neurons and when their influence was blocked.

In the acutely vagotomized and adrenalectomized cat, a mixture of excitatory and inhibitory responses was usually observed as a result of splanchnic nerve stimulation (III). The *excitatory* motor response to splanchnic stimulation, which was blocked by atropine, was not regularly obtained, but when present, it was seen at low frequency stimulation (1—4 imp/sec). After an adrenergic fibre block (guanethidine) higher stimulation frequencies also produced excitatory responses. The splanchnic nerves evidently carry some excitatory fibres to the stomach, but their site of action and functional significance is not known (*cf.* Thomas and Baldwin 1968).

The nature of the *inhibitory* effects of sympathetic stimulation varied greatly in magnitude as well as in latency with the presence or absence of prevailing activity of the intramural cholinergic neurons. Thus, prompt and usually pronounced inhibitions were even produced at low frequencies of sympathetic stimulation when the vagal excitatory fibres were active (III). This is illustrated in the left panel of Fig. 2, where in an animal with vagal nerves intact, gastric contractions were promptly inhibited by low frequency splanchnic stimulation. Gastric contractions induced by spontaneous intramural cholinergic neurons in chronically vagotomized cat were also inhibited (IV).

In sharp contrast to these prompt inhibitory responses to splanchnic stimulation, only retarded and weak inhibitory responses were obtained in acutely vagotomized or atropinized animals and mostly high frequencies (8 imp/sec or above) had to be used, in agreement with Martinson's

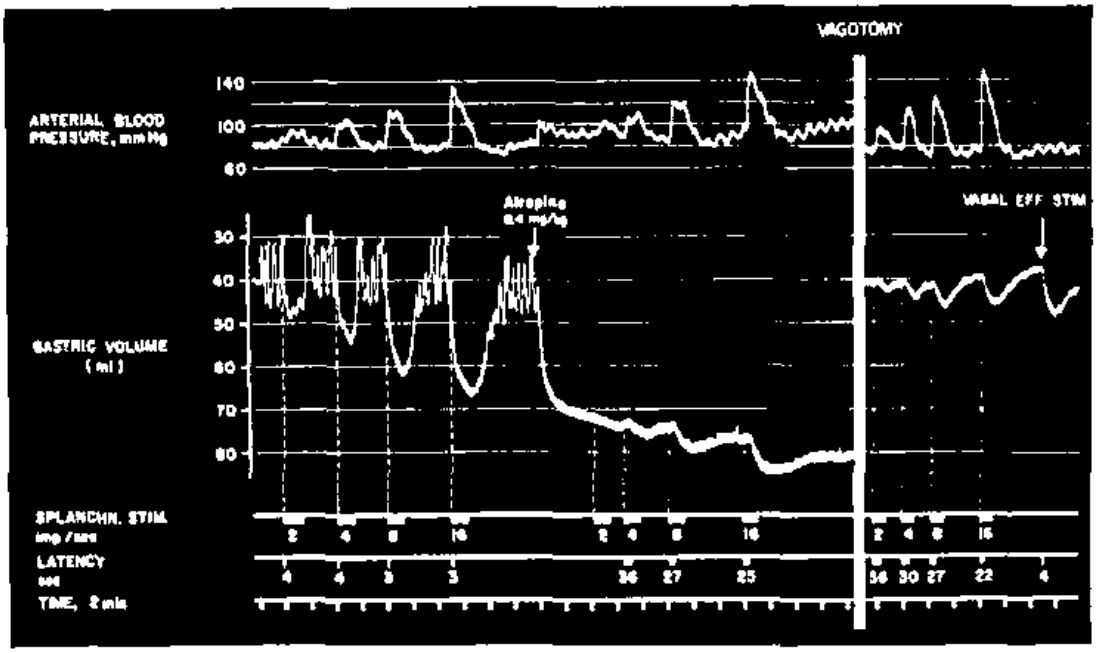

Fig. 2. Cat 2.3 kg. "Direct" recording of gastric volume by means of a pyloric cannula. Adrenalectomized. Splanchnic nerves bilaterally transected. Efferent electrical stimulation (2 msec, 6 V) of right splanchnic nerve elicits prompt inhibition of gastric contractions as long as cholinergic activity is present (left panel). Note the marked increase of latency of the response to splanchnic stimulation after administration of atropine (left panel) *cf.* the short latency of a comparable gastric relaxatory response to vagal efferent stimulation (2 imp/sec, 2 msec, 6 V) (right panel). (Intragastric pressure left panel 6 cm; right panel 4 cm)

findings (1965 a). Occasionally retarded inhibitory responses could be seen at lower frequencies as well (Fig. 2). It was characteristic, however, that the latency of these inhibitory responses could be as long as 15—40 sec but never shorter than 10 sec. This long latency should be compared with the short latency (3—4 sec) for the vagal relaxatory responses or with that obtained upon sympathetic stimulation when the vagal cholinergic excitatory fibres were active, which was also 3—4 sec (Fig. 2). Confirming Martinson's results (1965), all the sympathetic inhibitory responses mentioned above were blocked by guanethidine (IV), while the effects of the vagal relaxatory fibres remained after administration of this drug (Fig. 7, upper panel).

In summary, the prompt inhibitory responses to sympathetic stimulation, obtained when the intramural cholinergic neurons were active, were strikingly different from the considerably retarded and usually feeble inhibitions seen when the postganglionic link of the cholinergic supply to the gastric smooth muscle cells had been blocked by atropine. However, in this same situation the vagal relaxatory fibres still produced immediate

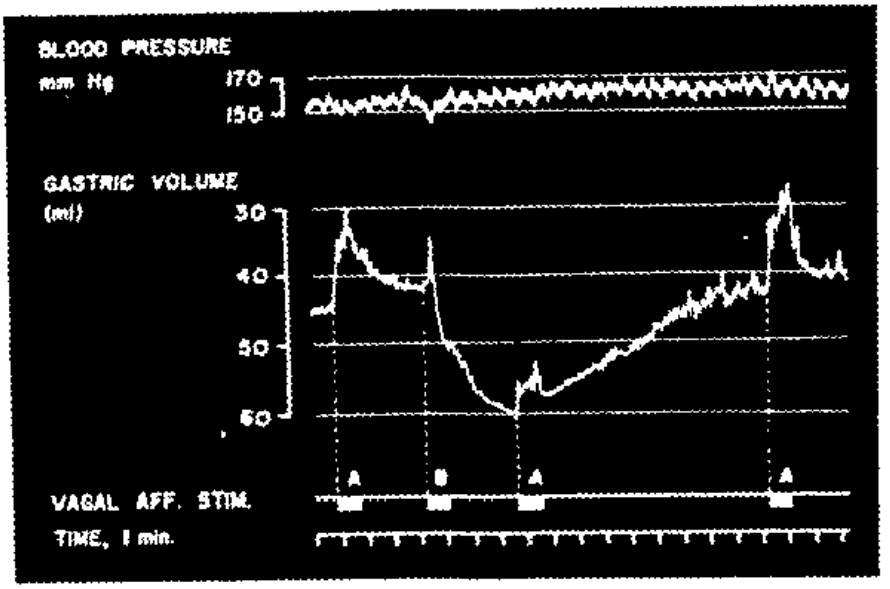

Fig. 3. Cat 3.2 kg. Balloon recording of gastric volume at an intragastric pressure of 4.5 cm H_2O. Continuous artificial respiration; repeated small doses of Flaxedil® were given intravenously. Electrical stimulation in afferent direction of a small vagal branch just cranial to the diaphragm. Stimulation A (10 imp/sec, 0.2 msec, 8 V) elicited an excitatory gastric response. Stimulation B (10 imp/sec, 1 msec, 8 V) elicited an initial excitation followed by relaxation.

and marked increase of gastric volume due to a strong suppression of gastric tone in the corpus-fundus section. These observations indicate that the sympathetic inhibitory influence is preferentially — possibly solely — exerted on the cholinergic intramural neurons, at least in the corpus-fundus sections. When these neurons are blocked, only weak and retarded sympathetic inhibitions were obtained and mainly by high frequency stimulation, suggesting an overflow of adrenergic transmitter to the gastric smooth muscles.

4. Reflex activation of the extrinsic nerve supply to the stomach

a. Reflex activation of vagal excitatory fibres

Harper, Kidd and Schratcherd (1959) reported gastric contraction on stimulation of afferent vagal fibres, effects which appeared to be conveyed also in the efferent direction by the vagal nerves. In accordance with these findings the present investigation showed that weak stimulation of vagal afferents just cranial to the diaphragm could produce weak excitatory motor responses (Fig. 3) which persisted after a sympathetic block (guanethidine 3 mg/kg), but were blocked by atropine. In the present study, such reflex excitatory effects produced by vagal afferents originating from abdominal structures have not been further analysed since the investigation

was mainly concentrated upon the reflex engagement of the relaxatory fibres and the sympathetic inhibitory fibres. The present results and those of Harper, Kidd and Scratcherd (1959) indicate, however, that the vagal excitatory fibres can also be reflexly activated by means of afferents of abdominal origin.

b. Reflex control of the vagal relaxatory fibres

The results reported in Papers I and II are mainly concerned with the reflex control of the vagal relaxatory fibres to the stomach. These nerve fibres, first clearly defined by Martinson (1965 c), have dramatic effects on corpus-fundus volume and the question arises as to what is their reflex involvement and general functional significance.

Since the existence of vagal fibres with such profound effects on gastric volume was unknown until recently, it is evident that considerable discrepancies in interpretation of recorded gastric responses exist in the earlier literature, not only with respect to the effects of efferent vagal stimulation (for ref. see Martinson 1965 c) but also concerning the nature of reflex changes of gastric motility (*e. g.* Harper, Kidd and Schratcherd 1959).

Paintal (1954), Andrew (1957) and Iggo (1955, 1957—58 a, b) have described increased discharge in vagal afferents on stimulation of mechano- and chemoreceptors in the esophagus, stomach and intestine, receptors which presumably are involved in reflex adjustments of the gastro-intestinal tract. Harper, Kidd and Scratcherd (1959) directly stimulated vagal afferents and recorded a reduced gastric tone with superimposed contractions, measured by recordings of gastric pressure; these gastric effects were abolished by vagotomy. Although their results show the existence of a vago-vagal inhibitory gastric reflex, the efferent pathways involved were not analysed. Further, considering the large number of different types of afferent fibres in the vagal nerves, the physiological significance of the described reflex was unclear. However, Andrew (1957) showed afferent vagal discharge upon esophageal distension and Veach (1926) described that such distension can produce a relaxation of the stomach, suggesting a reflex suppression of gastric tone.

As it was not clear from earlier studies exactly which efferent fibres conveyed the reflex responses studied, it was thought to be of interest to eliminate the activity of all efferent fibres to the stomach other than the vagal relaxatory ones. It would then be easier to define the circumstances in which these fibres are reflexly activated, and what their functional significance is.

Mode of reflex excitation. In I it is shown that electrical stimulation of afferent fibres at different levels along the vagal nerves produce reflex activation of the vagal relaxatory fibres to the stomach. However, the vagal nerves contain so many afferent fibres from many different organs that it is difficult to assess the physiological significance of the results of such electrical stimulations alone (*cf.* Thomas and Baldwin 1968). This type of afferent stimulation of the proximal end of a cut vagal nerve, has also the disadvantage that many of the efferent fibres normally involved in such reflexes have then been cut as well. Preparation of fine vagal filaments just above the diaphragm, calls for extensive surgery with thoracotomy, implying disturbance of respiration and circulation during prolonged experiments.

In search of a receptor mechanism that allowed reflex excitation of the vagal relaxatory fibres, it became evident that esophageal distension was suitable (II). This type of afferent fibre activation by means of the receptors is also of advantage because no surgical interference is needed and only weak distension proved sufficient to elicit pronounced and well graded reflex relaxations of the stomach. Furthermore, no nerves had to be cut and well reproducible reflex responses to graded distension could be elicited over a long time of study. The different ways in which the vagal relaxatory fibres could be reflexly activated are schematically illustrated in Fig. 4.

The esophageal receptors inducing reflex relaxation of the stomach were not only sensitive to even weak distension, but seemed to be rather slowly adapting, since prolonged steady distension caused a well sustained reflex gastric relaxation. Whether the receptors involved were sensitive only to distension or to contractions of the esophageal wall as well (Andrew 1957) was not settled.

Different types of mechano- and chemoreceptors in the gastric and intestinal wall have earlier been explored electrophysiologically (for ref. see Paintal 1963). Electrical stimulation of vagal afferents, presumably originating from such receptors, can produce reflex excitation of the relaxatory fibres (I). Further, abdominal surgery, involving handling of the stomach and intestines elicits a marked and often quite prolonged reflex discharge of the vagal relaxatory fibres (Fig. 1, lower panel), sometimes to the extent that it is difficult to produce significant additional vago-vagal reflex relaxation. However, little is known about the nature and specificity of the receptor mechanisms involved in such situations, though investigations are in progress to explore these problems. Thus, an

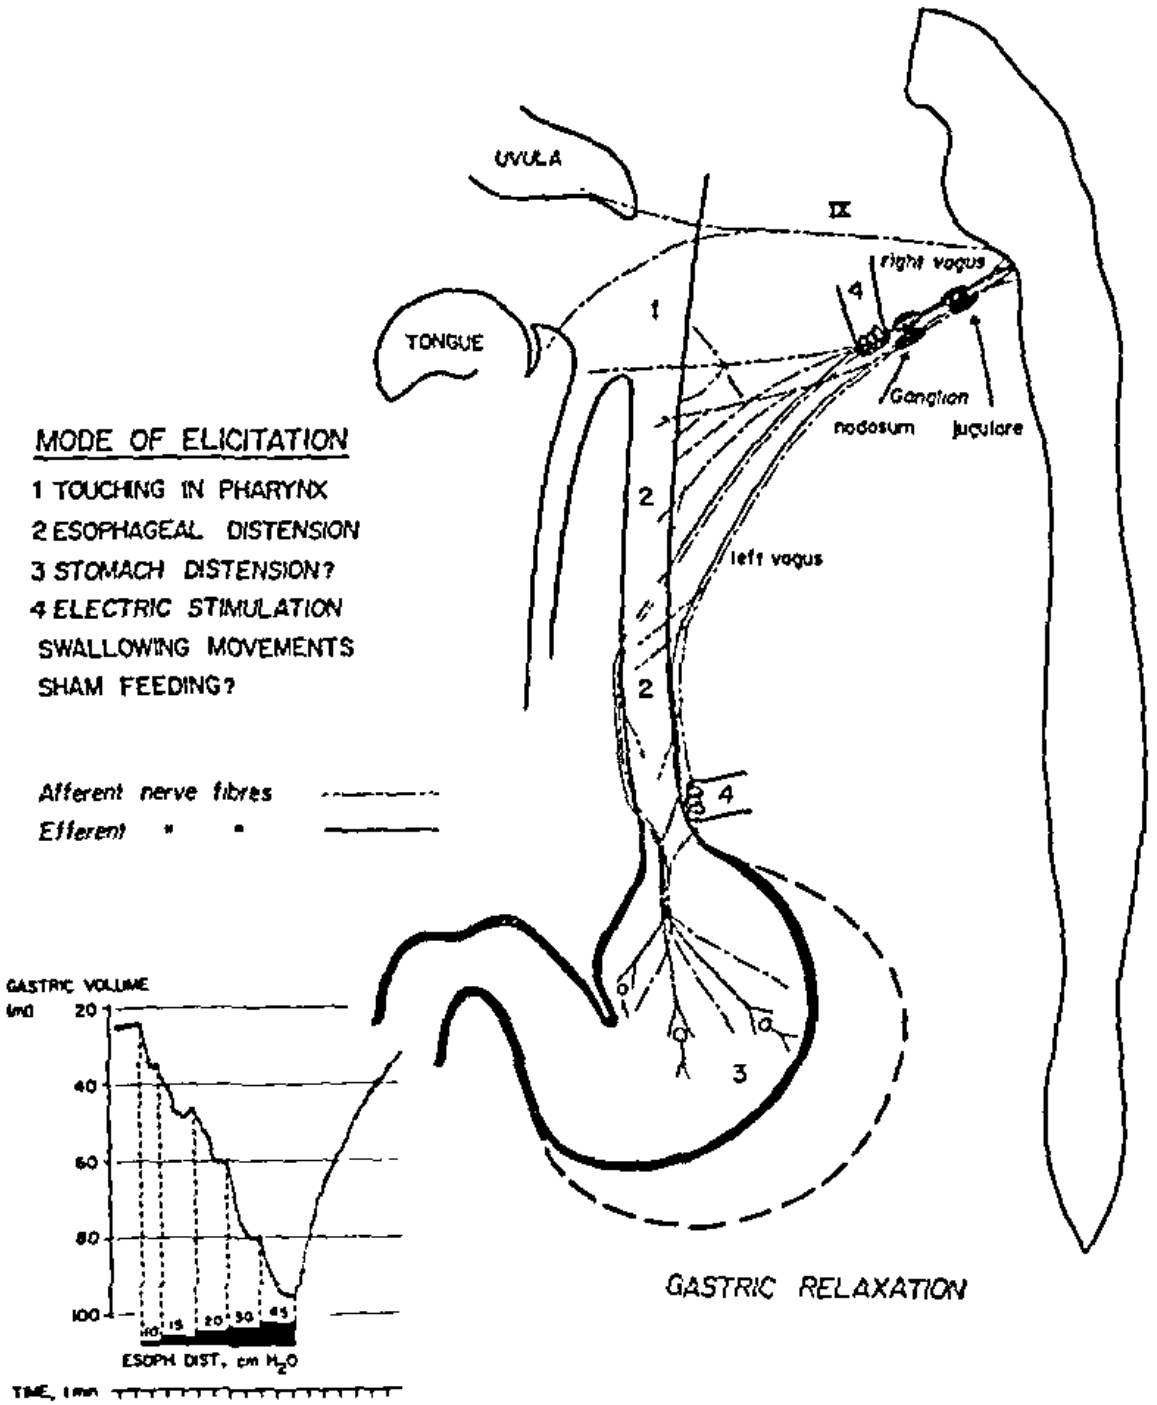

Fig. 4. Schematic drawing of different modes of eliciting gastric relaxation *via* the vagal relaxatory fibres. The lower left part of the figure illustrates a recording of effects produced by the vagal relaxatory fibres when reflexly activated by graded esophageal distension in an anesthetized atropinized cat. Complete disappearance of reflex relaxation after vagotomy.

attempt is being made to define which stimuli in the stomach and intestine that produce reflex excitation of the vagal relaxatory fibres in the form of either intestino-gastric or gastro-gastric vago-vagal relaxatory reflexes (*Abrahamsson and Jansson* to be published).

The arrangement of the reflex arcs. In most of the experiments presented in I, the proximal end of the cut cervical vagal trunk was used for afferent electrical stimulation, leaving the opposite vagal nerve intact for efferent discharge to the stomach. Furthermore, electrical stimulation of thin vagal nerve filaments, situated just cranial to the diaphragm, induced reflex excitation of the vagal relaxatory fibres; thus far, only vagal afferents have been studied.

The experiments presented in II suggest that vagal fibres constitute the major afferent pathway for eliciting reflex excitation of the vagal relaxatory fibres, at least when thoracic parts of the esophagus are distended. On the other hand, pharyngeal stimulation may also involve the glossopharyngeal and trigeminal nerves as afferent pathways (*II*; Doty 1968).

The location of the central relays involved in the vago-vagal gastric relaxatory reflex was not studied in detail in the present series of experiments. However, the reflex relaxation produced by afferent vagal stimulation persisted after intercollicular decerebration and spinal cord transection at C1—C2 (unpublished observations), but vanished after cutting the vagi cranial to the nodose ganglia; furthermore, afferent vagal stimulation on one side elicits reflex relaxation *via* the other vagal nerve. These observations indicate that the vago-vagal relaxatory reflex is conveyed *via* the vagal nuclei at the brain stem level, though it is likely that still higher autonomic centres may influence the bulbar relay station.

Definition of the vago-vagal relaxatory reflex presupposes that vagal relaxatory fibres constitute the efferent pathway; other efferent pathways had been excluded as possible routes. The described type of reflex relaxation was not due to any inhibition of a prevailing activity of the cholinergic vagal excitatory fibres, since the response remained after administration of atropine which totally blocks the cholinergic fibres. Further, an adrenergic block by guanethidine did not affect the reflex relaxation and moreover, the response persisted after cervical spinal transection. Gastric relaxation could be reproduced after vagotomy in all experiments when the peripheral ends of the vagal nerves were electrically stimulated at adequate strength (*e. g.* Fig. 3 in II).

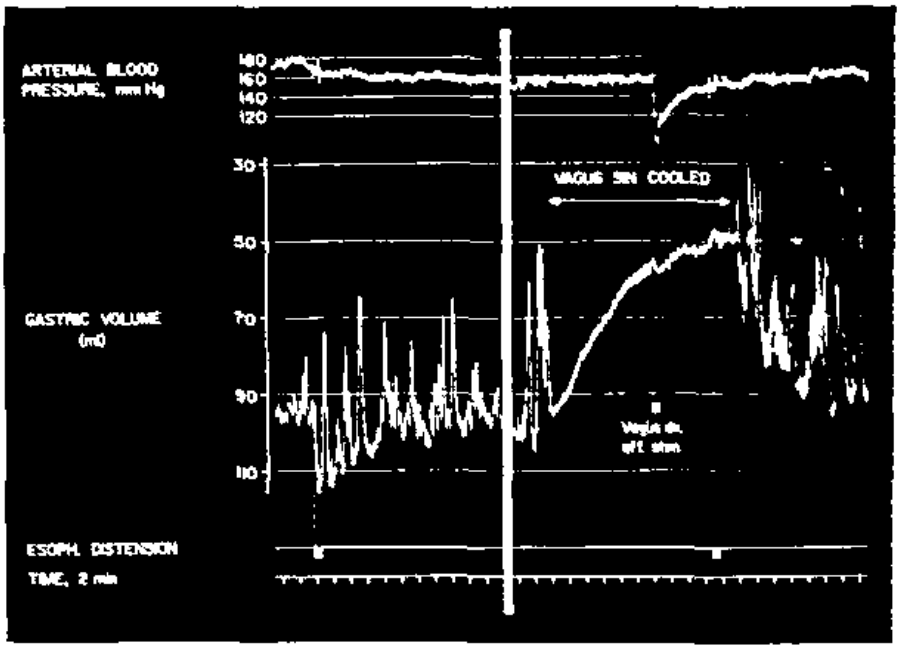

Fig. 5. Cat 3.4 kg. Balloon recording of gastric volume at an intragastric pressure of 5 *cm* H_2O. *Continuous artificial respiration; repeated small doses of Flaxedil®. Effect* of cooling the left cervical vagal nerve, the right one being cut. Note that vagal cooling leads to disappearance of pronounced gastric contractions and to a volume *decrease*. Rewarming of the nerve leads to reappearance of contractions and to gastric relaxation. Vagal afferent stimulation 8 imp/sec, 2 msec, 8 V; reflex activation of vagal fibres by esophageal distension (balloon distended 10 ml).

Extent of gastric reflex response. Reflex activation of the vagal relaxatory fibres elicited pronounced gastric relaxation in all experiments, often of the magnitude of 50—100 ml; sometimes implying a manifold increase of volume. The latency of the reflex response was about 5—7 sec; after termination of afferent stimulation, the stomach gradually regained the prestimulatory volume during a period of 3 to 20 min.

The magnitude of the reflex gastric relaxations varied considerably from one experiment to another, due mainly to varying degrees of reflex "background discharge" in the vagal relaxatory fibres. Such background discharge was caused by usually unidentified stimuli associated with the experimental conditions. Efforts were made, however, to standardize these conditions by avoidance of extensive surgery and traumatic recording techniques. Nevertheless, it appears from II that the receptor mechanisms producing reflex relaxatory fibre discharge are so sensitive that the introduction of the thinwalled recording balloon into the stomach may also produce some reflex background discharge. This was sometimes fairly pronounced despite cautious preparation of the animals; thus deliberately induced reflex relaxations of the stomach were correspondingly less pronounced. As illustrated in Fig. 5, the presence of such a background reflex

discharge was evident by the obvious but gradual volume decrease that sometimes followed vagotomy or vagal cooling (II).

During the balloon recordings of gastric volume, regular contractions of the stomach were often seen. These were evidently dependent upon activity of the vagal excitatory fibres since they disappeared after atropine and upon vagal cooling. However, their presence was by no means any prerequisite for the demonstration of pronounced reflex relaxatory responses (Fig. 1—3 in II); such responses were pronounced also after atropine.

In summary then, graded reflex excitations of the vagal relaxatory fibres to the stomach were elicited either by afferent vagal stimulation or by weak esophageal distension. The receptor mechanisms are so sensitive that even weak esophageal distension elicits well graded reflex relaxation of the stomach; this relaxation is caused by an efferent nervous discharge in the high-threshold relaxatory fibres of the vagal nerves.

Relaxation of the stomach in connection with swallowing. As early as 1911—12, Cannon and Lieb observed that gastric relaxation, dependent on the vagal nerves, was produced during sham-feeding in cats (*cf.* Lind *et al.* 1961). In a patient with esophageal atresia and gastrostomy, Carlson (1916) showed that swallowing movements with only saliva, thus not necessarily reaching the stomach, produced a suppressive effect on gastric motility. However, the nervous mechanisms involved in these earlier studied suppressive effects on gastric motility were not clearly revealed; the relaxatory fibres were not known and a reflex inhibition of the vagal excitatory fibres might have been involved.

The results presented in II indicate that reflex gastric relaxation induced *via* the vagal relaxatory fibres is regularly obtained by pharyngeally elicited swallowing, also in the anesthetized cat. Repeated swallowing in the atropinized cat produced repeated reflex relaxations of the stomach which, if occuring in a rapid sequence, were mostly superimposed on each other until a profound gastric relaxation was obtained (II). After vagal transection at low cervical levels, the swallowing movements could still be produced but no gastric relaxation followed.

It may be questioned whether the induced swallowing movements produce reflex gastric relaxation from a pharyngeal site proper, relayed *via* the bulbar structures, or if more peripherally situated receptors are activated in the esophagus. Experiments on unanesthetized cats with esophagostomy and gastrostomy (Jansson and Lisander, to be published) show that prompt and intense gastric relaxation may occur upon sham-

feeding and in such a preparation the reflex probably emanates from the pharynx. Therefore, both pharyngeal and esophageal receptors seem to produce reflex activations of the vagal relaxatory fibres.

Functional significance of the vagal relaxatory fibres. It seems clear that even slight physiological stimuli in pharyngeal and esophageal sections of the gastro-intestinal tract elicit reflex relaxation of the stomach. As shown in II, repeated swallowing and esophageal distension produce a relaxation of the stomach in a manner that implies a graded increase of the gastric lumen for the accomodation of increasing amounts of swallowed food. Such a widening of the reservoir conveyed *via* the vagal relaxatory fibres thus occurs without any increase in intragastric pressure, producing true "receptive relaxation". Furthermore, pronounced rhythmic contractions of the stomach dependent upon cholinergic neurons are often present and obviously involved in the mixing of food with gastric secretion and subsequent transport of the gastric contents from the stomach. These contractions may occur simultaneously with the pronounced reflex vagal relaxation of the corpus-fundus section of the stomach (Fig. 6).

Such a response pattern appears to be highly useful for the execution of the main motor functions of the stomach, *i. e.* that of "receptive relaxation" with graded accomodation of the corpus-fundus part for storing of the food, at the same time as enhanced rhythmic activity of the gastric wall produces a mixing of the contents with the gastric secretion and ultimately an emptying of the reservoir.

Furthermore, it is of interest to note the generally long-lasting relaxation followed by a slow progressive decrease in volume, often superimposed by rhythmic contractions as shown in Fig. 6. Such a slow and gradual regain of gastric smooth muscle tone superimposed by contractions, might also be physiogically meaningful in the process of *expelling* gastric contents into the intestine. If it can be shown that these mechanisms can be modified from duodenal-jejunal receptors, an important link in the understanding of gastric emptying would have been found. It is known that gastric emptying is modified by *e. g.* osmolarity, pH-changes and fat in the intestine (for ref. see Hunt and Knox 1968). The existence of duodenal chemo- and mechanoreceptors eliciting a spike discharge in afferent vagal nerve fibres has been shown (for ref. see Paintal 1963); further, electrical stimulation of afferent vagal nerve fibres from the abdomen elicits a vago-vagal relaxation (I). It is therefore suggested that the gastric response pattern shown in *e. g.* Fig. 6 (see also II) with the long-lasting relaxation and progressive

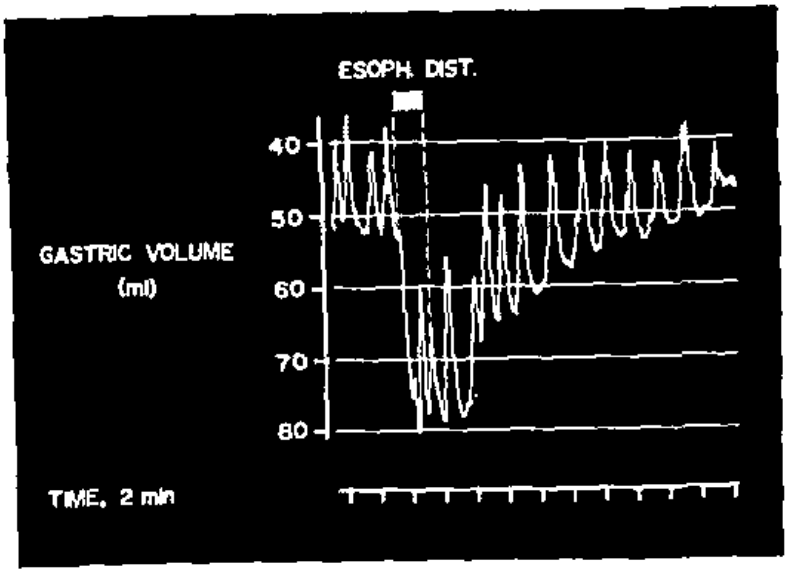

Fig. 6. Cat 2.9 kg. Balloon recording of gastric volume at an intragastric pressure of 6 cm H_2O. Vagal nerves intact. Reflex gastric relaxation produced by esophageal distension (40 cm H_2O). Note that the rhythmic contractions not only persisted but became more pronounced during the reflex relaxation of the stomach.

volume decrease together with simultaneous contractions may form an integral part of normal gastric emptying.

c. Extrinsic gastric control mediated by the adrenergic supply

Studies III—VI are mainly concerned with the extrinsic influence of the adrenergic outflow to the stomach.

Intestino-gastric inhibitory reflex. A reflex adrenergic discharge was not only present in the form of a "background discharge" as a result of abdominal surgery *per se* (IV), but could also be deliberately elicited from the intestine. In the present study, the "intestino-gastric inhibitory reflex", termed by Morin and Vial (1934), is used to designate a reflex elicited from different parts of the intestine which by means of splanchnic afferents and efferent adrenergic fibres affect the stomach (compare the intestino-intestinal inhibitory reflex; Youmans 1944, Johansson and Langston 1964). In III and IV it is shown that prompt reflex inhibitions of gastric motility (latency 3—4 sec) could be induced *via* the adrenergic fibres by graded distensions of either duodenal, jejunal or ileal loops, *provided that a cholinergic influence on gastric smooth muscles was present.* Similar reflexes could be induced by graded electrical stimulations of thin afferent nerve filaments around the superior or inferior mesenteric artery (III, IV).

However, when the stomach was not under cholinergic influence, intes-

part in the adjustment of the rate and extent of gastric emptying to the capacity of the intestine to receive food. Further studies are needed to elucidate these problems.

Influences on adrenergic fibre activity by hypothalamic and somatic afferent stimulation. The demonstration in III and IV of prompt reflex and pronounced adrenergic inhibitions of gastric motility — provided that the cholinergic fibres to the stomach were active — raises the question of how suprabulbar nervous structures and afferent fibres of somatic origin may influence such adrenergic mechanisms. For this purpose separate studies of the hypothalamic control of the adrenergic outflow to the stomach (V) and of the reflex effects of "somatic pressor" and "depressor" afferents (VI) were performed.

From the hypothalamus some well defined response patterns of known localization can be induced by topic stimulation *e. g.* the defence reaction (see Abrahams, Hilton and Zbrozyna 1960) and the sympatho-inhibitory response (Folkow, Johansson and Öberg 1959). In studying the adrenergic effects on gastric motility, blood pressure and skeletal muscle blood flow were also recorded for a functional identification of the responses.

Stimulation of the "defence area", or surrounding "pressor areas", produced — besides the characteristic circulatory effects — a prompt inhibition of gastric motility mediated *via* the adrenergic fibres to the stomach, which suppressed vagally elicited gastric contractions. Similar effects were obtained on stimulation of somatic "pressor" afferents (VI). On the other hand, topic stimulation of the hypothalamic sympatho-inhibitory area elicited an *increased* gastric motility; similar responses were obtained by stimulation of somatic "depressor" afferents. Evidence was presented to show that these augmentations were due to an inhibition of a tonic adrenergic discharge to the stomach (V, VI), thus releasing the excitatory influence of prevailing vagal cholinergic activity from suppression. The tonic adrenergic discharge was in this situation mainly the result of a spinal reflex induced by abdominal surgery (IV), a reflex discharge that was suppressed by the hypothalamic sympatho-inhibitory area (V) or by the somatic "depressor" afferents (VI). Thus hypothalamic structures, as well as the somatic afferents mainly mediating pain (see Johansson 1962), can affect adrenergic activity to the stomach in both directions; the adrenergic discharge acting in turn mainly — possibly only — by counteracting cholinergic effects on the gastric smooth muscles.

The hypothalamic defence area has, however, at least one other type of action. It appears also to inhibit the vagal preganglionic neurons in the

bulb, to judge from experiments on animals with a transected spinal cord at the cervical level (*Jansson and Lisander, unpublished observations*).

An enhancement of gastric motility mediated *via* the spinal cord was seen as a result of stimulation of the sympatho-inhibitory area in the vagotomized cat when electrical vagal stimulation produced a tonic cholinergic discharge, which in turn was counteracted by an adrenergic influence. Thus, guanethidine administration and interruption of the vagal stimulation or atropinization abolished the enhanced gastric motility produced by this type of hypothalamic stimulation. Had only the effects of splanchnic nerve section and atropinization been tested, the effect might easily have been mistaken for a hypothalamic activation of splanchnic cholinergic fibres.

Mode of adrenergic fibre influence on gastric motility. As outlined in Introduction, neuro-histochemical methods suggest that there are no adrenergic neurons in the ganglionic plexa of the gastro-intestinal wall; most of these intramural neurons appear to be cholinergic. The abundance of adrenergic fibres in the gastric wall, which predominantly seem to make contact with the intramural neurons, have their cell bodies in the abdominal sympathetic ganglia outside the stomach. Very few of these adrenergic ramifications penetrate into the smooth muscle layers and most, possibly all, that do not terminate on intramural ganglionic cells, innervate blood vessels rather than the gastric smooth muscles proper (Norberg 1964, Norberg, personal communication 1967, Jacobowitz 1965, Schofield 1968).

The close approximation of the adrenergic ramifications and the intramural neurons, with few — if any — such ramifications in contact with the gastric smooth muscles, suggest that the adrenergic fibres may affect gastric motor function by modulating cholinergic ganglionic activity rather than affecting the smooth muscles directly. From the results described in III and IV it is clear that the adrenergic fibres to the stomach act *antagonistically* to cholinergic effects with respect to gastric motility. It further appears from the motility studies in III and IV that the adrenergic fibres may affect gastric motility by primarily inhibiting the intramural cholinergic ganglion cells, rather than directly affecting the gastric smooth muscles; thus, the functional studies are in good agreement with morphological findings. Adrenergic fibre stimulation had comparatively weak inhibitory effects on gastric tone in the corpus-fundus in the acutely vagotomized and atropinized animal. Such inhibitory effects were, moreover, considerably delayed (latency 10—40 sec), suggesting an indirect mode of action, in sharp contrast to the prompt (latency 3—4 sec) adrenergic inhibition of

cholinergic neuronal activity even at low frequency stimulation and the rapid (latency 3—4 sec) pronounced suppression of gastric tone produced by the vagal relaxatory fibres.

Such a long latency of nerve action is hardly compatible with the presence of a close junction between adrenergic fibres and those gastric smooth muscles which are responsible for the pronounced gastric tone described in III. Only when comparatively high frequencies of sympathetic stimulation were used, did the suppression of gastric tone become significant in size although the latency was still remarkably long. In this situation it is known that overflow of the adrenergic transmitter takes place and that considerable portions also reach the blood stream.

It can be argued that the weak, or absent, adrenergic inhibitory responses after blocking of the cholinergic intramural neurons might still be compatible with a direct adrenergic fibre influence on gastric smooth muscles. Such directly innervated muscle cells, however, may display any activity that can be inhibited adrenergically *only* if they are excited by the cholinergic intramural neurons. If so, they are certainly not identical with the smooth muscles in the stomach that are responsible for the pronounced gastric tone seen in acutely vagotomized and atropinized animals. This possibility, however, is also unlikely since gastric contractions, induced by the muscarinic effect of an intra-arterial infusion of acetylcholine, were unaffected by such adrenergic nerve activation that promptly inhibited *vagally* induced contractions of largely similar magnitude and appearance (III).

It appears difficult to harmonize these observations with any other view than the suggestion that the *major*, possibly only, site of inhibitory action of the adrenergic fibres of the stomach is localized to the intramural cholinergic neurons, at least with respect to the nervous control of the reservoir function of the stomach. It is, of course, possible that the arrangement of the nervous control might be different in other, specialized parts of the stomach, such as the sphincteric regions, which largely escape exploration in this type of study.

5. Vagally mediated gastric relaxation versus inhibition produced by adrenergic fibres

Martinson (1965 c) considered the excitatory gastric response induced by the low-threshold vagal fibres to be facilitated by the action of the vagal relaxatory fibres, a view strongly supported by the present findings. On efferent vagal stimulation with increasing intensities, pronounced, or

even enhanced, rhythmic contractions of the stomach were also recorded when the vagal relaxatory fibres were simultaneously activated. Furthermore, in animals with an intact vagal nerve supply, pronounced gastric contractions were often seen simultaneously with a considerable background discharge in the vagal relaxatory fibres (Fig. 5); as mentioned earlier, the presence of such a background discharge could easily be revealed by vagal cooling.

Lastly, when esophageo-gastric vago-vagal relaxatory reflexes were elicited, gastric contractions occurred simultaneously with the pronounced relaxatory responses. In the experiment illustrated in Fig. 6, gastric contractions not only persisted during an activation of the vago-vagal relaxatory reflex, but they even became more pronounced. There is thus no evidence of any suppressing influence from the relaxatory fibres on such gastric contractions that are dependent on the vagal cholinergic influence. The two vagal fibre sets thus appear to act jointly in promoting the changes in gastric motility associated with food intake; the reservoir becomes widened and exhibits at the same time increased rhythmic activity. This apparent lack of any direct competition between vagal excitatory and relaxatory influence in the effector organ might be explained by an action of the two sets of vagal fibres on different smooth muscle layers in the stomach wall; one with high myogenic activity (responsible for gastric tone) that is suppressed by the relaxatory fibres, and one that is excited by the cholinergic excitatory fibres.

In contrast to the facilitating effects between the two vagal fibre sets, the adrenergic fibres, exerting their main inhibitory action by suppressing the intramural cholinergic neurons, thus act *antagonistically* to the vagal excitatory influence on gastric motility.

The mode of action of the relaxatory and the adrenergic fibres and the situations when they are activated are thus completely different. The relaxatory fibres appear to form part of the feeding response and prepare the stomach for the reception and digestion of food; the adrenergic fibres appear to suppress gastro-intestinal function in general.

Summary

Extrinsic nervous activity controlling gastric motility was studied in anesthetized cats with special reference to the influence exerted by the vagal relaxatory fibres and the splanchnic adrenergic fibres.

On the basis of the observations made, the following conclusions were drawn:

1. The existence of a vago-vagal relaxatory reflex to the stomach is shown by electrical stimulation of vagal afferents at different levels. The vagal high-threshold relaxatory fibres form the efferent pathway of this reflex. These efferent vagal fibres operate by a non-adrenergic neuro--effector transmission and seem to facilitate the cholinergic influence of the vagal excitatory fibres on gastric motility. The gastric response to activation of the relaxatory fibres consists of a marked and prolonged relaxation, primarily affecting the corpus-fundus sections which can increase manifold in volume.

2. Receptor mechanisms sensitive to even slight esophageal distension are shown to reflexly activate the vagal relaxatory fibres, forming an "esophageo-gastric vago-vagal relaxatory reflex". Also in connection with pharyngeally elicited swallowing, reflex gastric relaxation is induced *via* the vagal relaxatory fibres.

These results suggest that the gastric relaxation patterns described, play a dominant role in "receptive relaxation" of the stomach during deglutition.

3. Activation of the adrenergic supply to the stomach elicits prompt gastric inhibition by counteracting the vagal excitatory influence on gastric smooth muscles. The results suggest that this type of neurogenic inhibition is due mainly to an adrenergic suppression of the cholinergic intramural neurons.

4. It is shown that even slight distension of different parts of the small intestine causes reflex activation of the adrenergic supply to the stomach. Hypothalamic sympatho-excitatory structures (the defence area) produce gastric inhibitory responses by means of an activation of the adrenergic supply to the stomach. Activation of the hypothalamic sympatho-inhibitory area suppresses prevailing adrenergic discharge to the stomach. Similar modulations of a prevailing adrenergic discharge to the stomach can be reflexly elicited *via* somatic pressor and depressor afferents, respectively.

These results suggest that the adrenergic fibres to the stomach are involved in such central and reflex patterns of sympathetic discharge that involve a generalized suppression of gastro-intestinal activity. However, it is not excluded that the adrenergic fibres might also be more directly involved *e. g.* in normal gastric emptying.

ACKNOWLEDGEMENTS

I wish to express my sincere gratitude to Professor Björn Folkow for his invaluable help and interest throughout this study. I am also very grateful to Dr Jan Martinson who directed my interest to gastrointestinal physiology and who has given me continued constructive advice. To Dr Hasse Abrahamsson and Dr Björn Lisander I render may thanks for valuable help.

The English of this summary was corrected by Miss Helen Brogren and the English of the papers by Mr L. James Brown. I wish to thank them for instructive suggestions.

For skilful technical assistance and pleasant collaboration I thank Mrs Eva Hermansson, Miss Lisbeth Larsson and Mrs Birgitta Vallander. Thanks are also due to Mrs Kerstin Andréasson for typing the final manuscript.

This work was supported by grants from the Swedish Medical Research Council (Grant B68-14X-16-04C), from AIR FORCE OFFICE OF SCIENTIFIC RESEARCH through European Office of Aerospace Research, OAR United States Air Force under Contracts AF 61 (052)-732 and F61052-68-C-0044, from Public Health Service (Grant HE-05675-06-07) and from the Faculty of Medicine, University of Göteborg.

For generous supplies of drugs I am indebted to the following companies: Merck (Atropine sulphate), CIBA (Ismelin®) and May & Baker (Flaxedil®).

GENERAL INTRODUCTION

The "final common path" for motor regulation, i. e. the α-motoneurone (Sherrington 1904) is strongly influenced from segmental reflex paths originating from various kinds of receptors (cf. Creed, Denny-Brown, Eccles, Liddell and Sherrington 1932). Of particular importance is the muscle spindle which has large afferent fibres with monosynaptic excitatory effects to motoneurones supplying its own muscle (cf. Lloyd 1943, Granit 1950). These afferents provide the afferent path for the well-known stretch reflex (Liddell and Sherrington 1924).

Onanoff's finding (1890) of an efferent nerve supply to the muscle spindle gave this receptor a unique position among muscle receptors. The subsequent analysis by Leksell (1945) and Kuffler, Hunt and Quilliam (1951) showed that the muscle spindle of the cat indeed has a motor supply of its own via nerve fibres of small calibre, the γ-efferents. The central control of the γ-motoneurones is exerted via different segmental reflex paths (Hunt 1951, Kobayashi, Oshima and Tasaki 1952) and from various supraspinal structures (Granit and Kaada 1952, Eldred, Granit and Merton 1953, Granit and Holmgren 1955); parallel effects could often be evoked in α- and γ-motoneurones but often with lower threshold in the latter. The γ-control determines the discharge rate in the muscle spindle afferents during dynamic and static conditions in the muscle and is thereby one important factor determining the excitability level of the α-motoneurones (cf. Granit 1955, 1968, Matthews 1964).

In 1962 it was shown that the γ-efferents are of two kinds (Jansen and Matthews 1962a, Matthews 1962), one type controlling mainly the dynamic sensitivity of the primary endings (Ia afferents) and the other the discharge rate, and presumably also the static sensitivity of the primary endings (Jansen and Matthews 1962a, Brown, Lawrence and Matthews 1969) and in addition the activity in secondary endings (group II afferents) (Appelberg, Bessou and Laporte 1966).

Rather selective effects on static and dynamic γ-motoneurones can be produced from different central nervous structures. Thus, stimulation of the anterior lobe of the cerebellum gives a depression of the activity mainly in dynamic γ-motoneurones (Jansen and Matthews 1962 a). A selective activation of dynamic γ-motoneurones to certain muscles can

be evoked from the mesencephalic tegmentum (Appelberg 1963, Appelberg and Emonet-Denand 1965), and from the pyramidal tract (Vedel 1966). Effects on static γ-motoneurones are obtained from the caudate nucleus (Vedel and Paillard 1965) and from certain regions of the cerebral cortex outside the motor area (Baudevin and Vedel 1967).

Certain differences between the two kinds of γ-motoneurones appear to exist also at the segmental level (Jansen 1966). Thus in the spinal cat, dynamic but not static γ-motoneurones are spontaneously active and reflexly excitable (Alnaes, Jansen and Rudjord 1965). On the other hand, after an injection of DOPA, which is assumed to liberate noradrenaline from descending noradrenergic fibres in the spinal cat, static γ-motoneurones to flexors acquire a resting discharge and can be reflexly activated (Grillner, Hongo and Lundberg 1967). The cited studies on the selective control of dynamic and static γ-motoneurones have all been obtained by indirect methods (recording of muscle spindle afferents) and it is difficult to draw conclusions regarding the synaptic linkage of various systems influencing these neurones.

The detailed investigations of the control of γ-motoneurones have been greatly handicapped by the difficulty in obtaining intracellular records or applying a monosynaptic test technique. In the present studies γ-motoneurones have been investigated by intra- or extracellular recordings in the spinal cord or by the activity in single efferents in peripheral nerve filaments and also indirectly through spindle afferents. The aim has been to elucidate some aspects of

I. The segmental control of static and dynamic γ-motoneurones via different reflex paths.

II. The descending control of static and dynamic γ-motoneurones via

a) two fast conducting descending systems from the brain stem. i. e. the vestibulospinal tract and fibres coursing in the medial longitudinal fascicle (MLF) presumably of reticular origin and

b) the "noradrenergic reticulospinal system"

METHODOLOGICAL CONSIDERATIONS

Papers I—V have been concerned with a study of γ-motoneurones supplying the left hindlimb of the cat. The detailed methodological descriptions are given in the different papers.

In papers I, III—V the control of single γ-motoneurones has been investigated and only one point of general interest will be considered here, the identification of γ-motoneurones.

In paper I the γ-motoneurones intracellularly recorded could be identified by the following criteria

1) antidromic invasion from one muscle nerve should occur without graded prepotentials,

2) the conduction velocity of the efferent responsible, should be within the range 20—45 m/sec (cf. Eccles, Eccles, Iggo and Lundberg 1960),

3) the location of the cell should be within the appropriate motor nucleus (Eccles et al. 1960, Nyberg-Hansen 1965),

4) no monosynaptic excitation should be evoked from group Ia afferents (Hunt and Paintal 1958, Eccles et al. 1960),

5) the threshold for the efferent fibre, should be several times above that for group Ia afferents or α-efferents (Leksell 1945).

A few cells were recorded when the ventral roots were cut and then the identification rested on criteria 1, 3—5. Particular attention was then paid to criterion 4, and the lack of Ia EPSP was checked by stimulation of the dorsal roots. In the extracellular material the activation of a cell with a fixed latency was taken to indicate that it was antidromically activated; criteria 2—5 could then be applied. If such a cell was later impaled it was always found to be a γ-motoneurone by the above criteria.

In papers III—V the γ-motoneurones had to be investigated for a long time and therefore the γ-efferents were recorded in peripheral nerve filaments. By stimulation of the intact ventral root(s) the number of γ-efferents in a filament could be determined; the isolation of γ-efferents did not depend on the presence of a resting discharge. The identification of an efferent as being of the "γ-type" rested on criteria 2, 4, 5. The isolation of only one, or sometimes two easily distinguished γ-efferents, was performed by making successive lesions in the ventral root until only one (two) γ-efferent was in connexion with the spinal cord.

be evoked from the mesencephalic tegmentum (Appelberg 1963, Appelberg and Emonet-Denand 1965), and from the pyramidal tract (Vedel 1966). Effects on static γ-motoneurones are obtained from the caudate nucleus (Vedel and Paillard 1965) and from certain regions of the cerebral cortex outside the motor area (Baudevin and Vedel 1967).

Certain differences between the two kinds of γ-motoneurones appear to exist also at the segmental level (Jansen 1966). Thus in the spinal cat, dynamic but *not static γ-motoneurones are spontaneously active* and reflexly excitable (Alnaes, Jansen and Rudjord 1965). On the other hand, after an injection of DOPA, which is assumed to liberate noradrenaline from descending noradrenergic fibres in the spinal cat, static γ-motoneurones to flexors acquire a resting discharge and can be reflexly activated (Grillner, Hongo and Lundberg 1967). The cited studies on the selective control of dynamic and static γ-motoneurones have all been obtained by indirect methods (recording of muscle spindle afferents) and it is difficult to draw conclusions regarding the synaptic linkage of various systems influencing these neurones.

The detailed investigations of the control of γ-motoneurones have been *greatly handicapped by the difficulty in obtaining intracellular records* or applying a monosynaptic test technique. In the present studies γ-motoneurones have been investigated by intra- or extracellular recordings in the spinal cord or by the activity in single efferents in peripheral nerve filaments and also indirectly through spindle afferents. The aim has been to elucidate some aspects of

I. The segmental control of static and dynamic γ-motoneurones via different reflex paths.

II. The descending control of static and dynamic γ-motoneurones via

a) *two fast conducting descending systems from the brain stem. i. e. the* vestibulospinal tract and fibres coursing in the medial longitudinal fascicle (MLF) presumably of reticular origin and

b) the "noradrenergic reticulospinal system"

the decerebrate cat. In a subsequent study, Hunt and Paintal (1958) could not confirm these results in the spinal cat. However, these two preparations differ in two respects: 1) static γ-motoneurones are spontaneously active in the decerebrate (Jansen and Matthews 1962 a, b) but not in the spinal preparation, in which only the dynamic have a resting discharge (Alnaes, Jansen and Rudjord 1965, paper II); 2) a tonic stretch reflex occurs in the decerebrate but not in the spinal preparation (Liddell and Sherrington 1924). The different findings on decerebrate and spinal cats would be explicable if the autogenetic inhibitory effects were exerted only on static γ-motoneurones. If the group I inhibition (paper I) is responsible, it is relevant that of four γ-motoneurones tested for descending effects, all received monosynaptic EPSPs, which suggests that they are of the static type (paper I, IV, V). It is also relevant that the group Ib afferents have a high sensitivity for active, but not for passive tension (Jansen and Rudjord 1964, Houk and Henneman 1967). The absence of autogenetic inhibition in the spinal, but its presence in the decerebrate preparation may be correlated with the fact that a stretch reflex occurs in the latter but not in the former state (Liddell and Sherrington 1924). Accordingly it may be possible to explain the findings by Hunt (1951) and Hunt and Paintal (1958) without any postulate regarding a selection in destination to static and dynamic γ-motoneurones.

B. Group II afferents

Stimulation of muscle nerves at strength of 2.5 to 8 times threshold of the most excitable fibres activates the fibres conducting in the group II range (Eccles and Lundberg 1959). At this stimulation strength excitatory effects could be evoked in flexor γ-motoneurones classified as static and dynamic (paper III) and also in gastrocnemius γ-motoneurones excitatory or inhibitory reflex effects could be revealed (paper V). These effects could be evoked from nerves to flexors and extensors working at different joints. In this unanaesthetized spinal preparation corresponding effects can occasionally be evoked in α-motoneurones (cf. paper V). Although the majority of group II fibres probably have secondary endings from the muscle spindles (cf. Hunt 1954) the presence of other fibres of this diameter has been shown by Paintal (1960) and Barker (1967). Thus the presence of "group II effects" does not necessarily imply that they are caused by secondary endings from the spindle. However, Laporte and Bessou (1959) have shown that in a spinal preparation, in which conduction in group I afferents had been blocked, inhibitory effects are evoked on muscle stretch in extensor and excitatory effects in flexor α-motoneu-

rones. Although reflex effects from smaller diameter fibres cannot be entirely excluded the most likely explanation is that these reflex effects are due to activation of secondary endings, which hence are assumed to give effects conforming to the flexor reflex pattern (Sherrington 1910). These results are in accordance with the results obtained with electrical stimulation of peripheral nerves (Laporte and Lloyd 1952, Eccles and Lundberg 1959). However, excitatory effects to extensors can also sometimes be encountered (Holmqvist and Lundberg 1961, Wilson and Kato 1965). Since the secondary endings are under efferent control and have a signal lineraly related to muscle length, these seemingly nonspecific reflex connexions (cf. Matthews 1964) to α- and presumably also γ-motoneurones are rather puzzling (cf. also page 24). However, it might be pertinent to note that the frog, which has no specific motor supply to the spindles (Katz 1949), only has one type of afferent corresponding presumably to the primary ending. The significance of the secondary endings in the cat might not be related to a delicate spinal reflex pattern but in mediating information related to muscle length and static γ-bias to supraspinal structures.

C. Cutaneous afferents and group III muscular and joint afferents

In Hunt's (1951, cf. also Kobayashi, Oshima and Tasaki 1952) original description of the reflex activation of γ-motoneurones he reported that these efferents as a rule followed the pattern of flexor-crossed extensor reflexes of α-motoneurones (Sherrington 1910). Numerous exceptions to this pattern were, however, found in a subsequent study by Hunt and Paintal (1958). Their conclusion that the reflexes to α- and γ-motoneurones differ in several respects deserves some further discussion.

In confirmation of several previous studies, γ-motoneurones to flexors (paper III) were found to receive excitation from ipsilateral nerves. All γ-efferents studied could be reflexly activated by single volleys, dynamic γ-motoneurones more effectively than static (for identification see page 17). The analysis of their reflexes was aided by the comparison of effects before and after DOPA. An injection of DOPA decreased the reflex activation of dynamic and increased the reflex activation of static γ-motoneurones (paper III). These opposite effects may be a consequence of the corresponding changes in the resting activity; an alternative possibility is that the effects were mediated by two different short latency reflex pathways (cf. Fig. 10 paper III). Reflex effects have previously only been demonstrated in a part of the extensor γ-motoneurone population (Hunt and Paintal 1958), but with the aid of DOPA it was [illegible] to demonstrate

short-latency reflex effects in all gastrocnemius γ-motoneurones investigated. Hence it is postulated that both static and dynamic γ-motoneurones can be influenced. The detailed analysis of these reflex effects is difficult since both excitatory, inhibitory and mixed effects could be evoked from ipsilateral nerves. There were some discrepancies between intra- and extracellular findings, which rather would be expected (paper I). Since ipsilateral excitatory effects were common in extensor γ-motoneurones (I, V), it can be concluded that the reflex pattern is more complex than the classical flexor-crossed extensor reflex pattern. This confirms the previous results by Eldred and Hagbarth (1954), Hunt and Paintal (1958), Alnaes, Jansen and Rudjord (1965) and Jansen and Rudjord (1965).

However, the reflex effects to α-motoneurones from these afferents also diverge from this reflex pattern (Creed, Denny-Brown, Eccles, Liddell and Sherrington 1932, Hagbarth 1952); after Hunt and Paintal's (1958) report detailed information concerning these effects have been obtained. The crossed reflex actions to α-motoneurones in the spinal unanaesthetized cat are excitatory to extensors in about 50 % of the preparations, in the remainder they are inhibitory or mixed (Holmqvist 1961). From ipsilateral high threshold muscle afferents excitatory effects can often be encountered in extensor α-motoneurones (Lundberg, personal communication, Holmqvist and Lundberg 1961, Wilson and Kato 1965). From cutaneous afferents excitatory or mixed effects are generally evoked in α-motoneurones (triceps surae) supplying fast motor units, while inhibitory effects dominate in slow motor units (Bruggencate, Burke and Jankowska, unpublished). The complex organization and the fact that there are two types of α-motoneurones with different reflex effects within the same muscle renders a conclusion regarding an α-γ-linkage in reflex effects to the gastrocnemii very difficult. Reflexes to foot muscles from the pad can also diverge from the flexor reflex pattern (Engberg 1964) in a similar way to fusimotor reflexes to these muscles (Hunt and Paintal 1958).

The analysis of reflex effects evoked from repetitive nerve stimulation at different frequencies were of particular interest because of the previous findings (with indirect methods) by Alnaes, Jansen and Rudjord (1965) that reflex activation of dynamic but not static γ-motoneurones could be obtained in the spinal cat by repetitive nerve stimulation (40 pps). γ-motoneurones with a resting discharge were further accelerated with increasing rate of stimulation. On the other hand, units with no spontaneous activity could often be discharged at low stimulation frequencies (paper

III, V), but at higher rates they were inhibited. With the frequency employed by Alnaes, Jansen and Rudjord (1965) only γ-efferents with a resting discharge were influenced and not the other group (paper III, V). These findings are relevant in relation to the problem of whether or not the short-latency reflex effects to static and dynamic γ-motoneurones are mediated by the same reflex pathway (cf. paper III), and were also an important criterion in the classification of cells as dynamic or static (cf. below).

Adequate activation of the skin and underlying tissues could, in the present low spinal preparation (paper III, V), sometimes reflexly influence γ-motoneurones from a receptive field extending from the level of the spinalization to the most caudal part of the tail (paper V) including afferents from the skin, muscle tissues (activated by pressure or pinching of the muscle), the periosteum and the bladder; thus by unspecific stimuli from a very large receptive field that is unexpected for a system dealing with motor control. Increasing evidence has, however, accumulated that the descending control of α-motoneurones from e. g. the pyramidal and the rubrospinal tract (Lundberg and Voorhoeve 1962, Hongo, Jankowska and Lundberg 1969) is exerted through a facilitation or inhibition of the interneurones of reflex arcs providing an excitatory or inhibitory impingement of the cells. The functional significance of these large receptive fields might be to provide a background for the descending control, which will "rule" through an inhibition or facilitation of the reflex paths.

It should be emphasized that even if the above explanation is correct it does not exclude the presence of specific and very delicate spinal reflex pathways to γ-motoneurones.

D. Recurrent inhibition

In four of nine extensor γ-motoneurones, tentatively classified as being of both the dynamic and the static type (paper V), recurrent inhibitory effects were revealed in confirmation of the reports of Ellaway (1968) and Brown, Lawrence and Matthews (1968 a). The important problem whether the recurrent inhibitory effects are exerted in parallel in α- and γ-motoneurones remains to be solved.

E. α—γ linkage?

What is now the position with respect to an α-γ-linkage in the organization of spinal reflex pathways? The only firmly established difference between connexions to α- and γ-motoneurones is the lack of monosynaptic

excitatory connexions from group Ia afferents in the latter (Hunt and Paintal 1958, Eccles et al. 1960). The effects from group I afferents offer a particularly interesting problem. It has not yet been established if the group I IPSPs in γ-motoneurones are evoked from muscle spindles or Golgi tendon organs. Should the latter receptor turn out to be responsible it still remains to be shown if the linkage is limited to static γ-motoneurones.

The complex reflex pattern evoked from cutaneous and high threshold muscle afferents makes it difficult to compare the detailed effects to α- and γ-motoneurones. Further investigations are required but at present there is no strong evidence to disprove the hypothesis of an α-γ-linkage of reflex effects from these afferents. The finding that short-latency reflex effects can be evoked both in dynamic and static γ-motoneurones raises the question of a linkage between α-motoneurones and both types of γ-motoneurones. Effective reflex activation of the two types of γ-motoneurones occurred under different experimental conditions. It is not known if the effects to static and dynamic γ-motoneurones are transmitted via different reflex pathways or whether the differences in reflex transmission mainly depends on a differential excitability in the two types of cells due to other factors (cf. below and paper III).

SUPRASPINAL CONTROL VIA TWO FAST DESCENDING SYSTEMS

The presence of monosynaptic connexions to lumbosacral α-motoneurones from descending fibres were demonstrated by Eide, Lundberg and Voorhoeve (1961). These fibres have subsequently been found to be largely derived from two supraspinal regions. One is the Deiters' nucleus that gives supraspinal effects to knee and ankle extensors (Lund and Pompeiano 1968, Grillner, Hongo and Lund 1969) and the other can be activated within a very limited region of the ipsilateral medial longitudinal fascicle (MLF) (Grillner and Lund 1968) by fibres that were postulated to originate in the lower pontine reticular formation. This descending system gives monosynaptic effects to knee and ankle flexors as well as hip and some toe extensors. In the analysis of the origin of these effects to α-motoneurones chronic lesion experiments were employed, as well as a correlation of the threshold for evoking the monosynaptic effects with the location of the Deiters' nucleus and MLF as indicated by the antidromic field potential evoked on stimulation of the lower thoracic ventrolateral funicle. The location of the stimulation electrode was always checked histologically.

In paper I it is shown with intracellular technique that lumbosacral γ-motoneurones also receive monosynaptic excitation from descending fibres activated at the lower thoracic level and coursing in the ipsilateral ventral quadrant. EPSPs have been considered as monosynaptic when occurring with a latency of 0.4—0.9 msec, from the peak of the positivity in the descending volley recorded at cord dorsum of the segment, to the onset of the EPSP. This peak can be assumed to signal the arrival of activity in the fastest descending fibres (Lund and Pompeiano 1968, Grillner and Lund 1968, Grillner, Hongo and Lund 1969). The "segmental latency" includes the conduction time in the arborizing terminals of the descending fibres and the actual synaptic delay.

To analyze the supraspinal origin of these effects stimulating electrodes were located in the Deiters' nucleus and the MLF respectively with the same criteria as used in the studies on α-motoneurones (cf. above). Since only the ipsilateral ventral quadrant was left intact the risk for coactivation of other descending systems is decreased; furthermore since only

monosynaptic effects evoked by fast conducting fibres (100 m/sec) were studied, the risk for trans-synaptic activation of other descending systems can be neglected. Monosynaptic EPSPs could be evoked with low threshold in lumbosacral γ-motoneurones from either of the two regions. γ-motoneurones belonging to a given motor nucleus received monosynaptic excitation with low threshold from the same region as the α-motoneurones did (paper I). In each experiment also α-motoneurones were recorded and they could be monosynaptically excited from one of the two regions with the same low threshold. Since only 13 γ-motoneurones (2 not included in paper I) with descending monosynaptic effects have been studied, great caution should be applied in interpreting these results. However, they do allow the suggestion that the two descending supraspinal systems exert parallel effects on α- and γ-motoneurones of the same motor nuclei.

Since not all γ-motoneurones received the descending monosynaptic EPSP the question was raised whether the monosynaptic control was exerted only on one type of γ-motoneurone. To test this hypothesis the γ-efferents studied in paper III and V were also tested for descending effects (IV and V) by stimulation of the ipsilateral ventrolateral funicle. These γ-efferents could be classified as static or dynamic (though less certainly to extensors, see below), and indeed monosynaptic effects were revealed in static but never in dynamic γ-motonerones. This does not necessarily imply that there is no monosynaptic effects in dynamic cells, but if so, this effect was not strong enough to discharge the cells although they were tested against a high level of background activity. Since the size of the descending monosynaptic EPSP evoked from supraspinal regions in paper I was of similar amplitude to the one obtained on stimulation of the descending fibres at lower thoracic level, the results indicate that the descending EPSPs evoked in the γ-motoneurones investigated are largely of supraspinal origin and that strong effects are exerted on static γ-motoneurones.

It is of some interest that driving of primary endings can be elicited from the "fast descending system" of Granit and Holmgren (1955). Driving seems to be an exclusive action of static γ-motoneurones (Crowe and Matthews 1964 b, Appelberg, Bessou and Laporte 1966). Although this system is activated from the contralateral tegmentum its fibres descend in the ventral quadrant of the ipsilateral side, hence this system could be identical with the systems investigated in the present study.

In Fig. 1 the descending effects to motoneurones acting at the knee joint are summarized, demonstrating the parallel effects on α- and γ-moto-

SUPRASPINAL CONTROL VIA TWO FAST DESCENDING SYSTEMS

The presence of monosynaptic connexions to lumbosacral α-motoneurones from descending fibres were demonstrated by Eide, Lundberg and Voorhoeve (1961). These fibres have subsequently been found to be largely derived from two supraspinal regions. One is the Deiters' nucleus that gives supraspinal effects to knee and ankle extensors (Lund and Pompeiano 1968, Grillner, Hongo and Lund 1969) and the other can be activated within a very limited region of the ipsilateral medial longitudinal fascicle (MLF) (Grillner and Lund 1968) by fibres that were postulated to originate in the lower pontine reticular formation. This descending system gives monosynaptic effects to knee and ankle flexors as well as hip and some toe extensors. In the analysis of the origin of these effects to α-motoneurones chronic lesion experiments were employed, as well as a correlation of the threshold for evoking the monosynaptic effects with the location of the Deiters' nucleus and MLF as indicated by the antidromic field potential evoked on stimulation of the lower thoracic ventrolateral funicle. The location of the stimulation electrode was always checked histologically.

In paper I it is shown with intracellular technique that lumbosacral γ-motoneurones also receive monosynaptic excitation from descending fibres activated at the lower thoracic level and coursing in the ipsilateral ventral quadrant. EPSPs have been considered as monosynaptic when occurring with a latency of 0.4—0.9 msec, from the peak of the positivity in the descending volley recorded at cord dorsum of the segment, to the onset of the EPSP. This peak can be assumed to signal the arrival of activity in the fastest descending fibres (Lund and Pompeiano 1968, Grillner and Lund 1968, Grillner, Hongo and Lund 1969). The "segmental latency" includes the conduction time in the arborizing terminals of the descending fibres and the actual synaptic delay.

To analyze the supraspinal origin of these effects stimulating electrodes were located in the Deiters' nucleus and the MLF respectively with the same criteria as used in the studies on α-motoneurones (cf. above). Since only the ipsilateral ventral quadrant was left intact the risk for coactivation of other descending systems is decreased; furthermore since only

THE "NORADRENERGIC RETICULOSPINAL SYSTEM"

Descending fibres in the spinal cord containing large amounts of noradrenaline were described by Carlsson, Falck, Fuxe and Hillarp (1964); subsequently Dahlström and Fuxe (1965) demonstrated that these fibres originate from cell bodies located in the reticular formation of the lower brain stem. No neurones with their cell bodies located in the spinal cord were found to contain noradrenaline (Carlsson et al. 1964). The injection of DOPA, i.e. a precursor of noradrenaline, has been postulated to cause an increased synthesis and liberation of noradrenaline from descending noradrenergic fibres (Andén, Jukes, Lundberg and Vyklicky 1966 a, Andén, Jukes and Lundberg 1966 b). The evidence relating the injection of DOPA to the formation and liberation of noradrenaline has been summarized in paper III. *On the basis of this postulate the effects of the descending noradrenergic system can be studied in the acute spinal cat after an intravenous injection of DOPA.*

The injection of DOPA causes a profound change in reflex transmission in the spinal cord. Thus the short-latency effects evoked from cutaneous, high threshold joint, group II and III muscular afferents (i.e. FRA) to α-motoneurones and ascending neurones are depressed (Andén et al. 1966 a), but, on the other hand, late reflex effects evoked with long central delay occur in α-motoneurones and in the terminals of Ia afferents (Andén, Jukes, Lundberg and Vyklicky 1966 c, Jankowska, Jukes, Lund and Lundberg 1967).

A. The resting discharge and the identification of static and dynamic γ-motoneurones

In paper III it was found that the single efferents to flexors could be subdivided in two groups, one with a resting discharge that was decreased after DOPA, the other with no resting discharge initially, but which acquired a spontaneous activity after DOPA. Identification of these two groups of γ-motoneurones in terms of dynamic and static can be made by a comparison with results obtained with indirect methods. Thus,

Alnaes, Jansen and Rudjord (1965) found evidence for a resting discharge only in dynamic γ-efferents in the spinal cat and Grillner, Hongo and Lundberg (1967) showed that static γ-motoneurones are accelerated after DOPA. For the identification it was also necessary to know whether the activity in dynamic γ-motoneurones changed after DOPA. In paper II the response of primary endings to linear stretch at different velocities was studied; the dynamic sensitivity, the peak and the mean frequencies during stretch were decreased to lower values after DOPA, although there was evidence for an increased static fusimotor bias. The possibility of a tonic slow α-activity was excluded, since there was no EMG activity in the tenuissimus muscle before DOPA. These findings can only be interpreted as a decreased dynamic γ-motor drive to the spindles after DOPA. This evidence is further supported by the previously discussed reflex effect evoked from repetitive nerve stimulation (page 11). At low frequencies neurones classified as both static and dynamic γ-motoneurones could be activated; at a stimulation frequency of 40 pps only neurones classified as dynamic were activated, which was the frequency employed by Alnaes, Jansen and Rudjord (1965) when they found reflex activation of only dynamic γ-motoneurones. Since the type of γ-motoneurones obtained during the isolation procedure is largely random it is of relevance that 7 γ-motoneurones could be classified as dynamic and 15 as static, corresponding approximately to the ratio of the numbers of dynamic and static γ-efferents, which is 1 to 3 (Bessou and Laporte 1966).

Hence the two types of γ-efferents to flexors (paper III) could be identified in terms of dynamic and static. Accordingly the noradrenergic descending system exerts a reciprocal control of dynamic and static γ-motoneurones to flexors.

γ-efferents to extensors (gastrocnemius) were almost invariably accelerated after DOPA (paper V). 4 out of 15 had a resting discharge before DOPA. The identification of these neurones in terms of dynamic and static is more difficult than was the case with flexor cells. On the basis of a comparison with the results of Alnaes, Jansen and Rudjord (1965) the tentative suggestion was made that the four neurones with a resting discharge before DOPA were of the dynamic type and those without a resting discharge were of the static type. This was again supported by the effects of repetitive nerve stimulation with the same findings as discussed above for flexors. Since all γ-efferents (except one) were accelerated after DOPA, it can be inferred, even if the above tentative identification should prove to be wrong, that both dynamic and static γ-efferents to extensors are accelerated after DOPA.

The results thus indicate that the descending noradrenergic system creates a situation with a static fusimotor activity to flexors and a dynamic and a static activity to extensors. The functional implications of this will be discussed below (cf. page 27).

The generation of the resting activity in the spinal cat is largely dependent on the activity in the dorsal roots (Hunt 1951), although some activity may persist after secion of the dorsal roots (Voorhoeve 1960, Lindsley and Eldred 1960). Also the resting activity in neurones spontaneously active after DOPA is greatly reduced after transection of the dorsal roots of the neighbouring segments (paper III, V). Thus it can be concluded that the afferent inflow in tonically discharging afferents, presumably from a large variety of receptors, maintains this activity; in this connexion it is of particular interest that the receptive fields from which the γ-motoneurones can be influenced is very large (paper V). It is likely that the resting activity in γ-motoneurones spontaneously discharging before DOPA is maintained through the short-latency reflex paths to γ-motoneurones. A more complex situation exists after DOPA when both short-latency pathways and the pathways mediating the late discharge are open. A more detailed discussion of different factors of importance is given in paper III.

B. The effect of DOPA on the reflex discharge evoked through short latency reflex paths in static and dynamic γ-motoneurones

The short-latency transmission from the flexor reflex afferents (FRA) to certain ascending pathways and to α-motoneurones is depressed after DOPA, very likely due to a depression at an interneuronal level (Andén et al. 1966 a).

The reflex discharge evoked in γ-motoneurones from the FRA has been compared before and after DOPA in flexor (paper III) and extensor γ-motoneurones (paper V). In flexor γ-motoneurones a rather consistent pattern was found. The reflex discharge in dynamic γ-motoneurones was smaller after DOPA; the resting discharge, however, also ceased. Static γ-motoneurones on the other hand are more effectively activated after DOPA, though a resting discharge appears. In extensor γ-motoneurones mixed excitatory and inhibitory effects were often elicited; furthermore the excitability in all γ-motoneurones increased after DOPA as reflected by the increased resting discharge. Whether this is due to a facilitation of short latency excitatory pathways or to other factors is not known.

Alnaes, Jansen and Rudjord (1965) found evidence for a resting discharge only in dynamic γ-efferents in the spinal cat and Grillner, Hongo and Lundberg (1967) showed that static γ-motoneurones are accelerated after DOPA. For the identification it was also necessary to know whether the activity in dynamic γ-motoneurones changed after DOPA. In paper II the response of primary endings to linear stretch at different velocities was studied; the dynamic sensitivity, the peak and the mean frequencies during stretch were decreased to lower values after DOPA, although there was evidence for an increased static fusimotor bias. The possibility of a tonic slow α-activity was excluded, since there was no EMG activity in the tenuissimus muscle before DOPA. These findings can only be interpreted as a decreased dynamic γ-motor drive to the spindles after DOPA. This evidence is further supported by the previously discussed reflex effect evoked from repetitive nerve stimulation (page 11). At low frequencies neurones classified as both static and dynamic γ-motoneurones could be activated; at a stimulation frequency of 40 pps only neurones classified as dynamic were activated, which was the frequency employed by Alnaes, Jansen and Rudjord (1965) when they found reflex activation of only dynamic γ-motoneurones. Since the type of γ-motoneurones obtained during the isolation procedure is largely random it is of relevance that 7 γ-motoneurones could be classified as dynamic and 15 as static, corresponding approximately to the ratio of the numbers of dynamic and static γ-efferents, which is 1 to 3 (Bessou and Laporte 1966).

Hence the two types of γ-efferents to flexors (paper III) could be identified in terms of dynamic and static. Accordingly the noradrenergic descending system exerts a reciprocal control of dynamic and static γ-motoneurones to flexors.

γ-efferents to extensors (gastrocnemius) were almost invariably accelerated after DOPA (paper V), 4 out of 15 had a resting discharge before DOPA. The identification of these neurones in terms of dynamic and static is more difficult than was the case with flexor cells. On the basis of a comparison with the results of Alnaes, Jansen and Rudjord (1965) the tentative suggestion was made that the four neurones with a resting discharge before DOPA were of the dynamic type and those without a resting discharge were of the static type. This was again supported by the effects of repetitive nerve stimulation with the same findings as discussed above for flexors. Since all γ-efferents (except one) were accelerated after DOPA, it can be inferred, even if the above tentative identification should prove to be wrong, that both dynamic and static γ-efferents to extensors are accelerated after DOPA.

The results thus indicate that the descending noradrenergic system creates a situation with a static fusimotor activity to flexors and a dynamic and a static activity to extensors. The functional implications of this will be discussed below (cf. page 27).

The generation of the resting activity in the spinal cat is largely dependent on the activity in the dorsal roots (Hunt 1951), although some activity may persist after secion of the dorsal roots (Voorhoeve 1960, Lindsley and Eldred 1960). Also the resting activity in neurones spontaneously active after DOPA is greatly reduced after transection of the dorsal roots of the neighbouring segments (paper III, V). Thus it can be concluded that the afferent inflow in tonically discharging afferents, presumably from a large variety of receptors, maintains this activity; in this connexion it is of particular interest that the receptive fields from which the γ-motoneurones can be influenced is very large (paper V). It is likely that the resting activity in γ-motoneurones spontaneously discharging before DOPA is maintained through the short-latency reflex paths to γ-motoneurones. A more complex situation exists after DOPA when both short-latency pathways and the pathways mediating the late discharge are open. A more detailed discussion of different factors of importance is given in paper III.

B. The effect of DOPA on the reflex discharge evoked through short latency reflex paths in static and dynamic γ-motoneurones

The short-latency transmission from the flexor reflex afferents (FRA) to certain ascending pathways and to α-motoneurones is depressed after DOPA, very likely due to a depression at an interneuronal level (Andén et al. 1966 a).

The reflex discharge evoked in γ-motoneurones from the FRA has been compared before and after DOPA in flexor (paper III) and extensor γ-motoneurones (paper V). In flexor γ-motoneurones a rather consistent pattern was found. The reflex discharge in dynamic γ-motoneurones was smaller after DOPA; the resting discharge, however, also ceased. Static γ-motoneurones on the other hand are more effectively activated after DOPA, though a resting discharge appears. In extensor γ-motoneurones mixed excitatory and inhibitory effects were often elicited; furthermore the excitability in all γ-motoneurones increased after DOPA as reflected by the increased resting discharge. Whether this is due to a facilitation of short latency excitatory pathways or to other factors is not known.

Hence it is not possible to conclude whether this change of reflex effects reflects only a modified excitability of the γ-motoneurones or if it is due to influences on the short-latency interneuronal pathway.

C. The late reflex discharge

Neuronal systems for alternate activation of the limb muscles do exist in spinal cord, since in the chronic spinal cat stepping movements can occur for long periods (Sherrington 1910). Graham Brown (1911, 1914) showed that it is essentially due to an intraspinal process. In an unanaesthetized (decerebrate) acute spinal cat with its hindlimbs intact, stepping movements can be induced by a variety of adequate stimuli after the injection of DOPA (unpublished observation). The late and longlasting reflex discharge that can be evoked from ipsilateral nerves in flexor motoneurones and from contralateral nerves in extensor motoneurones after an injection of DOPA, can give rise to alternate activation of flexors and extensors similar to "spinal stepping" (Jankowska et al. 1967, cf. paper V, Fig 1). It has been suggested that stepping can be evoked through the interneuronal network responsible for these reflex discharges not only by reflex effects from spinal afferents but also by effects in descending pathways and probably also from autochtonus interneuronal activity (Jankowska et al. 1967).

α-motoneurones and also static and dynamic γ-motoneurones participate in the late reflex discharges to extensors and flexors (paper III, V). In most instances there was a slowing of the resting discharge in extensor γ-motoneurones during the reflex discharge in flexors, which would be meaningful since it decreases the reciprocal Ia inhibition evoked in antagonists (paper V).

The results thus infer that the activation of descending noradrenergic fibres reveals a neuronal system for alternate activation of flexors and extensors. It is of considerable interest that both dynamic and static γ-motoneurones are activated with α-motoneurones in the late discharge. The functional implications of linkage will be further discussed below.

D. The stretch reflex

In the decerebrate preparation a tonic stretch reflex occurs in extensor muscles, but not in the acute spinal preparation (Liddell and Sherrington 1924). After an injection of DOPA, however, a tonic stretch reflex does

occur in the soleus muscle (paper V) as judged from an activity together with an increase of tension on extension. Also in flexor muscles a stretch reflex occurs (unpublished). This effect occurs in parallel with an appearance of a ... in static γ-motoneurones (see above). Since after DOPA change in excitability occurs in α-motoneurones in the s preparation used by Andén et al. (1966 a) with most ipsilate contralateral nerves cut, it is tempting to relate this t reflex to the occurrence of a static fusimotor activity. In a preparation there is a spontaneous activity in static γ-moto sen and Matthews 1962 a, b, Jansen 1966) but in the spin only dynamic γ-motoneurones appear to be spontaneously ac Jansen and Rudjord 1965, cf. paper II). The decerebrate pr been described as "a caricature of standing" (Creed et al. 1 spinal cat after DOPA with its hindlimbs pendent both . extensors are at rest with no sign of EMG activity (unpublished tion). One important difference between the decerebrate prepa... and the "DOPA preparation" is that in the former, practically no ...ing activity occurs in γ-motoneurones to flexors (Jansen and Rudjor ... 1965) whereas the "DOPA preparation" has a resting discharge in static γ moto-neurones to both flexors and extensors (paper III, V), which gives rise to a discharge in afferents from muscle spindles in both types of muscles; the reciprocal Ia inhibitory effects exerted in both directions between flexors and extensors might provide an explanation for the lack of tonus in the "DOPA preparation" at rest (cf. above C).

GENERAL DISCUSSION OF THE PROPERTIES OF THE γ-MOTOR SYSTEM WITH PARTICULAR REFERENCE TO THE SYSTEMS INVESTIGATED IN PAPERS I-V

Papers I—V are mainly concerned with the central control of γ-motoneurones. In an effort to understand the possible role of the γ-loop during posture and locomotion, some of its properties will be considered. The muscle spindle will be treated as a black box; some characteristics of its input-output relations will be discussed and also some quantitative aspects of data relevant to the transfer function of the different elements in the stretch reflex loop. Very little attention will be paid to the inhibitory effects evoked from Ia afferents in antagonist motor nuclei (Lloyd 1946), although it should be emphasized that these effects presumably are of great functional significance in motor control.

A. Properties of the stretch reflex loop

The different input variables are the frequency of impulses in fusimotor fibres and the muscle length and its derivative, the velocity of length change. It has been proposed (Schäfer 1967, Grüsser and Thiele 1968) and subsequently denied (Lennerstrand 1968 b) that the spindle is also sensitive to acceleration. This possibility will not be discussed below. The outputs of the spindle are the primary and the secondary endings. The loop from the primary ending will mainly be considered, i.e. primary *ending — monosynaptic excitation of certain α-motoneurones leading* to a contraction and development of tension and eventual shortening of the muscle.

The transfer functions* between both static and dynamic γ-motoneurones and the primary endings are linear, as they are from static γ-motoneurones to secondary endings within the frequency range used (¼—12 Hz) (Andersson, Lennerstrand and Thodén 1968). With length input there is a linear transfer function with amplitudes less than 100 μ (Poppele and

* A linear transfer function is here defined as one in which a given input (sinusoidal) at a certain frequency gives a response linearly related to the amplitude of the input and always having the same phase shift at a given frequency.

Terzuolo 1968, Matthews and Stein 1968). Poppele and Terzuolo (1968) have extended their analysis to the synaptic effect on the α-motoneurone (cf. also Redman Lampard and Annal 1968) and the development of tension induced in the muscle under a given γ-bias in an extensor muscle of the decerebrate cat. There is, at stretches below 100 μ, a linear transfer function for sinusoidal stretch between the length change and the induced change in tension. In the first part of the control loop there is a phase advance until the stage of the EMG activity, but in the last part, i.e. α-efferent (EMG) to tension development in the muscle there is a phase lag (Partridge 1965, Poppele and Terzuolo 1968). For these reasons the tension developed in the muscle followed the applied length changes without appreciable phase shift within the frequency range used (0.1—6.0 Hz). With applied sinusoidal stretching above 100 μ the transfer function between applied length change and tension development is not linear (cf. Lippold, Redfearn and Vuco 1958, Jansen and Rack 1966). It is of considerable interest, however, that the relation between motoneuronal activity and applied length can be linear over a wide range of length changes (Poppele and Terzuolo 1968). Since the increase in tension in the stretch reflex is not primarily due to a frequency modulation but rather to a recruitment of new motor units (Denny-Brown 1929, cf. Poppele and Terzuolo 1968), this implies that either the threshold or the synaptic input to, or the properties of different motoneurones supplying the muscle varies within quite a wide range.

It should be noted that with slow sinusoidal stretches the responses (tension developed) to each cycle are not identical if the experiment is performed on a decerebrate cat. Thus Higgins, Partridge and Glaser (1962) have shown that during the first few cycles (0.5—1.2 Hz) of large amplitude stretching (5 or 8 mm), the tension developed is phase advanced and of larger amplitude, reaching after less than 30 sec a steady state with no phase advance and smaller amplitude. These findings could be explained if the sinusoidal stretching decreased the activity in dynamic γ-motoneurones to the muscle studied. This transient response disappeared if the cerebellum was removed. It can therefore not be assumed that the γ-bias is identical during resting conditions and during sinusoidal stretching, or during vibration of the muscle tendon. Whether changes occur also directly in the α-motoneurones due to a similar mechanism is not known.

The reflex stiffness, i.e. the static gain of the stretch reflex loop of the soleus muscle in the decerebrate preparation, can vary considerably; values of 40—200 g. wt/mm have been given (Matthews 1959). When estimating the gain of the stretch reflex loop it is difficult to know how relevant

GENERAL DISCUSSION OF THE PROPERTIES OF THE γ-MOTOR SYSTEM WITH PARTICULAR REFERENCE TO THE SYSTEMS INVESTIGATED IN PAPERS I-V

Papers I—V are mainly concerned with the central control of γ-motoneurones. In an effort to understand the possible role of the γ-loop during posture and locomotion, some of its properties will be considered. The muscle spindle will be treated as a black box; some characteristics of its input-output relations will be discussed and also some quantitative aspects of data relevant to the transfer function of the different elements in the stretch reflex loop. Very little attention will be paid to the inhibitory effects evoked from Ia afferents in antagonist motor nuclei (Lloyd 1946), although it should be emphasized that these effects presumably are of great functional significance in motor control.

A. Properties of the stretch reflex loop

The different input variables are the frequency of impulses in fusimotor fibres and the muscle length and its derivative, the velocity of length change. It has been proposed (Schäfer 1967, Grüsser and Thiele 1968) and subsequently denied (Lennerstrand 1968 b) that the spindle is also sensitive to acceleration. This possibility will not be discussed below. The outputs of the spindle are the primary and the secondary endings. The loop from the primary ending will mainly be considered, i.e. primary ending — monosynaptic excitation of certain α-motoneurones leading to a contraction and development of tension and eventual shortening of the muscle.

The transfer functions* between both static and dynamic γ-motoneurones and the primary endings are linear, as they are from static γ-motoneurones to secondary endings within the frequency range used (¼—12 Hz) (Andersson, Lennerstrand and Thodén 1968). With length input there is a linear transfer function with amplitudes less than 100 μ (Poppele and

* A linear transfer function is here defined as one in which a given input (sinusoidal) at a certain frequency gives a response linearly related to the amplitude of the input and always having the same phase shift at a given frequency.

B. The functional role of the "γ-loop"

These results provide a basis for an estimate of what effects the γ-loop could exert, but they do not answer the question of what the γ-loop is actually used for. Merton (1953, cf. also Eldred, Granit and Merton 1953) in his follow up length servo hypothesis postulated that the "γ-loop" constituted an independent route for motor control. Merton (1953) clearly pointed out that the direct activation af α-motoneurones would be a disturbing factor for this kind of servo, and further that the gain of the loop needs to be high enough. Subsequent work of Granit and others has shown that in most cases α- and γ-motoneurones are coactivated although the γ-motoneurones often have lower threshold for excitation, which is why the expression α-γ-linkage was introduced (Granit 1955). The results presented on the segmental (paper I, III, V) and on the descending control provide further evidence for an α-γ-linkage as well as the results obtained during naturally elicited alternating rhythmical movements (cf. below page 27). It has also been argued that the gain of the stretch reflex loop is too low (in soleus 40—200 g. wt/mm) to allow operation of an independent follow-up-length-servo (Matthews 1967). For these reasons and since the evidence used to support Merton's (1953) hypothesis merely shows that the excitability of the α-motoneurones is dependent on activity in muscle spindle afferents (cf. Hunt and Perl 1960 and Matthews 1967), the γ-loop will in the present context not be considered as an independent route for motor excitation. However, the "γ-loop" does have servo properties (cf. Matthews 1964); the primary endings are in fact accelerated instead of decelerated during a "naturally" elicited muscular contraction (cf. below), although α- and γ-motoneurones are coactivated.

It is presumably of importance when considering the function of the "γ-loop" to differentiate between posture and locomotion. In standing there is possibly a rather stable discharge in α- and γ-motoneurones. Under these conditions the muscle spindle with its afferent supply acts to counteract any change in muscle length, i.e. as a negative feedback. These negative feedback properties can be changed considerably by the γ-motor supply, and it has to be divided into a static and a dynamic component. A primary ending extended to a given length and with a resting discharge has

1) under no γ-bias a resting discharge with high dynamic sensitivity to muscle shortening (a decreased discharge, i.e. unloading), and a certain dynamic sensitivity to lengthening (increased discharge) (B. H. C. Matthews 1933);

2) during dynamic fusimotor drive there is, compared to 1), an increased dynamic sensitivity to muscle lengthening but a decreased dynamic sensitivity to muscle shortening. There is still, however, an abrubtly decreased resting discharge on shortening (Crowe and Matthews 1964 a, b);

3) during static fusimotor drive the dynamic sensitivity to both shortening and lengthening is reduced compared to 1) and 2) and the signal will be linearly related to muscle length (Crowe and Matthews 1964 a, b);

4) during a concomitant static and dynamic fusimotor drive there is a high dynamic sensitivity to muscle lengthening but not to shortening when the discharge is proportional to length (Lennerstrand 1968 a, b).

The static fusimotor drive will set the discharge rate of the primary endings (Matthews 1962, Crowe and Matthews 1964 a) and in addition presumably also increase their static sensitivity, i.e. the increased discharge on extension in imp/sec/mm (Jansen and Matthews 1962 a, Brown, Lawrence and Matthews 1969).

1. *During posture*

If during standing there is a dynamic and a static fusimotor bias (as in extensors of the decerebrate cat) a sudden increase in load leading to lengthening will be effectively counteracted by the high dynamic sensitivity. If the static loop gain is high enough the muscle will remain at approximately the same length; if not, supraspinal structures would, during the period in which the high dynamic sensitivity is acting, have time to readjust the excitability of the motoneurones. In this connexion the very high sensitivity of the primary ending for changes in muscle length below 100 or 200 μ should be considered (decerebrate cat, Terzuolo and Poppele 1968, Matthews and Stein 1968). It is then tenfold higher than during larger amplitudes of stretch. In other words, the gain of the stretch reflex loop is much higher in this range and would detect and counteract even very small length changes. Thus, if α- and γ-motoneurones are coactivated and have brought a muscle to a certain length, the stretch reflex will act as an efficient circuit for maintaining the length (cf. Matthews and Stein 1968). It is of interest to make a comparison with the frog that has a slow and a fast (twitch) extrafusal motor system. The slow motor system that presumably is involved in postural activities increases the dynamic sensitivity of the spindle but the fast twitch system increases the static discharge of the spindles (Matthews and Westbury 1965). It should perhaps be noted that the viscoelastic properties of the muscle itself, which differs considerably in the active and passive states, also counteracts lengthening.

2. *During movement*

The muscle spindle presumably has a different role in phasic movemer The primary endings are accelerated during naturally elicited movements such as the respiratory movements (Critchlow and Euler 1963), the lo. motion that can be induced in the mesencephalic cat (Severin, Orlov and Shik 1967) and the reflexly initiated contraction of the jaw mus (Taylor and Davey 1968); efferent recordings have shown that both and γ-efferents participate (Eklund, Euler and Rutkowski 1964, Sl Orlovskii and Severin 1966). Euler and Peretti (1966) have found that dynamic and static γ-motoneurones appear to be coactivated in the respiratory movements. The alternate stepping movements might be the corollary of activity in the neuronal system mediating the late reflex discharges that can be evoked after DOPA (cf. page 20, Jankowska et al. 1967) α- and γ-motoneurones of both types participate in these reflex discharges (paper III, V). How does the fusimotor activity influence movements? The advantage of dynamic fusimotor activity is the same as during standing. However, a muscle spindle with dynamic sensitivity to muscles shortening (decreased discharge) would counteract the contraction. A coactivation of α- and static γ-motoneurones removes this effect, since the primary endings are not unloaded; indeed it has been shown that an acceleration of static γ-motoneurones during a shortening (in contrast to dynamic γ-motoneurones) is able to cause an increased discharge rate in the primary endings (Lennerstrand and Thodén 1968). This would not only compensate for the unloading but also add excitation to the α-motoneurones through the γ-loop, the amount of excitation being dependent on the actual length of the muscle. Thus it can be concluded from the above findings that a static γ-α-linkage indeed occurs under natural conditions and that the activation of static γ-motoneurones gives servo properties to the γ-loop.

3. *What is the functional role of the resting discharge in γ-motoneurones?*

In the spinal state there is a resting discharge mainly in dynamic γ-motoneurones (Alnaes, Jansen and Rudjord 1965, paper II); the preparation is then counteracting any changes of length with its dynamic sensitivity to lengthening and shortening, the overall effect being a general damping of movement in the system (cf. Alnaes, Jansen and Rudjord 1965). After DOPA, i.e. under influence from descending noradrenergic fibres, the resting discharge of γ-motoneurones changes; flexor γ-motoneurones of the static type acquire a resting discharge but the dynamic are depressed; to extensors on the other hand the resting discharge of both types of

γ-motoneurones is increased. The functional significance of this change of the resting discharge is obscure. However, if the very speculative assumptions are made that 1) the descending noradrenergic system activated by DOPA is one functional entity and not several separate descending systems provided with the same transmitter and 2) that the injection of DOPA reveals the neuronal pools employed during stepping (Jankowska et al. 1967, see above), it is relevant to ask if the change of γ-bias to flexors and extensors induced by the noradrenergic system would be purposeful for the act of stepping, i. e. if the adjustment of γ-bias can be looked upon as a preparatory state for locomotion.

During stepping, rapid forceful alternate contractions of flexors and extensors are required. The damping properties, i.e. the dynamic sensitivity to lengthening and shortening is probably not particularly important for flexors, since their function in locomotion is to rapidly flex and bring forward the leg and not to counteract the lengthening. With a γ-bias of only the static type, the spindle has its lowest dynamic sensitivity to both lengthening and shortening. During the late discharge there is a concomitant activation of all three types of motoneurones, including dynamic γ-motoneurones, but since during contraction the discharge of the primary ending is entirely influenced by the discharge in static γ-efferents this does not essentially change the condition. The situation in the extensors during locomotion differs considerably from that of flexors since then the contraction will lead not only to an extension of the leg resulting in the propulsive force for the body but will also support the body, i.e. being antigravitatory. The resting discharge in static and dynamic γ-motoneurones thus provides a situation with no dynamic sensitivity during the contraction, but an eventual lengthening would be counteracted by the dynamic sensitivity to lengthening provided by the discharge in dynamic γ-motoneurones.

Hence it seems as if an activation of the descending noradrenergic system changes the resting discharge in static and dynamic γ-motoneurones towards a γ-bias that would give an appropriate background discharge during locomotion on which the phasic activation of α- and γ-motoneurones can be superimposed.

ACKNOWLEDGEMENTS

For the guidance and the valuable discussions throughout these investigations I would like sincerely to express my gratitude to my teacher Anders Lundberg.

I also wish to thank Joseph Bergmans, Toshinori Hongo and Staffan Lund for a very stimulating collaboration.

Thanks are also due to Erling Eide with collaborators and Yngve Källström for invaluable technical constructions; Rauni Larsson, Eva-Britt Gordon and Tomas Palm for skilled technical assistance.

Last but by no means least I would like to thank Berit Nilsson for typing the various versions of these papers and John Manson for scrutinizing the English text.

γ-motoneurones is increased. The functional significance of
of the resting discharge is obscure. However, if the very
assumptions are made that 1) the descending noradrenergic
vated by DOPA is one functional entity and not several separ
ing systems provided with the same transmitter and 2) that
of DOPA reveals the neuronal pools employed during ste
kowska et al. 1967, see above), it is relevant to ask if th
γ-bias to flexors and extensors induced by the noradrenergic s
be purposeful for the act of stepping, i. e. if the adjustment
be looked upon as a preparatory state for locomotion.

During stepping, rapid forceful alternate contractions of
extensors are required. The damping properties, i.e. the dynam
to lengthening and shortening is probably not particularly i
flexors, since their function in locomotion is to rapidly fl
forward the leg and not to counteract the lengthening. Wit

INTRODUCTION

Physical training increases the body's performance capactiy. This is a well established fact, which is easily confirmed with a measuring-tape and a stop watch. However, a closer analysis of the physiological effect of training has mainly been based on cross-sectional studies where different individuals at different stages of training have been compared. The advantages offered by this method are the great intra- individual disparities in the variables studied. The method has, however, its shortcomings. For instance, it leaves unanswered the question as to what degree the measured differences betwen the untrained and the trained individual are the consequence of the training and to what degree they arise from dissimilar constitutional—that is genetic—backgrounds. Furthermore the amount and quality of training and the age at which training was first started may vary greatly. For these reasons longitudinal studies are necessary, in which the same individual is studied before and after training, thereby constituting his own control.

In the present research project the object has been to study:

1. the oxygen transport system of very successful athletes in endurance sports. By studying these individuals extreme values for human performance capacity are obtained and it can be analyzed how these extreme values are accomplished.
2. the effect of training on the oxygen transport system by way of longitudinal studies.

Chapter 1 refers to well-trained athletes (study III). Chapter 2 and 3 deal with the effect of training on previously untrained 20 year-old men (studies II and V). Chapter 4 is concerned with the effect of training on individuals during the years of adolescent growth (study V).

It may be emphasized that in this paper no attempts have been made to elucidate the general regulatory mechanism behind the circulatory adjustment to exercise. For this topic see review articles of Asmussen and Nielsen (1955), Rushmer and Smith (1959) and Bevegård and Shepherd (1967).

METHODS

Detailed descriptions of the methods used are reported on in the separate papers and are therefore only briefly summarized here.

In order to study the effect of training standardized exercise methods were used. Exercise was carried out on either a motor-driven treadmill, of which the speed and degree of inclination can be varied or on an electrically braked Krogh bicycle ergometer.

Oxygen uptake was determined with the Douglas bag technique. Heart rate was calculated from electrocardiographic (ECG)-recordings. Blood lactate concentration was determined in samples, taken from arterial blood in the experiments with determination of the cardiac output and otherwise in blood taken from a prewarmed finger tip. Cardiac output was measured with the dye dilution technique, using Cardio Green as indicator. Brachial intraarterial blood pressures were recorded with an Elema-Schönander pressure transducer.

Current statistical methods were used. Student's t-test was applied to analyze the significance of differences. The probability level of significance used was $p < 0.05$.

Comments

Oxygen uptake: The error of the method for determination of the oxygen uptake at submaximal work (6—8 min) was calculated from the difference between two consecutive determinations for bicycle (study II) and treadmill (study III) exercise. The error of the method for determination of the maximal oxygen uptake, which includes both methodological errors and biological variations, was calculated from two determinations of the maximal oxygen uptake, made on separate days within a week of each other (study II and V). Only values on maximal oxygen uptake obtained in experiments without catheters have been used. The results are given in TABLE 1.

There was no systematic difference between the first and the second determination of oxygen uptake on either submaximal or maximal level of exercise. The error in the methods are of the same order as reported earlier (Taylor et al. 1955, Mitchell et al. 1958, Åstrand 1960, Åstrand and Saltin 1961).

Oxygen uptake measured at about the 5th min on each work load increases

TABLE 1. Error of the method for a single determination of oxygen uptake and cardiac during submaximal and maximal bicycle and treadmill exercise.

	n	Oxygen uptake liters/min	Error of the method %	n	Cardiac output liters/min	Error of the method %
			Submaximal work			
Bicycle	54	1.95	2.5	14	11.1	3.0
				47	17.1	3.2
				63	21.1	3.5
Treadmill	30	3.38	1.5	26	26.5	5.1
			Maximal work			
Bicycle	19	4.13	2.1	43	23.1	3.3
Treadmill				14	32.0	3.9

with progressively heavier work loads up to a level beyond which any subsequent raising of the work load will not induce any further increase in oxygen uptake ("levelling off") (Herbst 1928). In the present publication this "levelling off" of oxygen in relation to work load and/or a high blood lactate concentration was used as criterion that maximal oxygen uptake was attained.

This "levelling off" of oxygen uptake in relation to work load raises the question of the definition of maximal work. Maximal oxygen uptake can be obtained on several different work loads from point A (in Fig. 1)—this is the point of "levelling off"—to point B. The work load at the point of "levelling off" is the lowest load, which still gives maximal oxygen uptake. This load is here defined as $WLmaxO_2$. Work loads above $WLmaxO_2$ (for instace at point B) are "supermaximal" in regard to the maximal aerobic power.

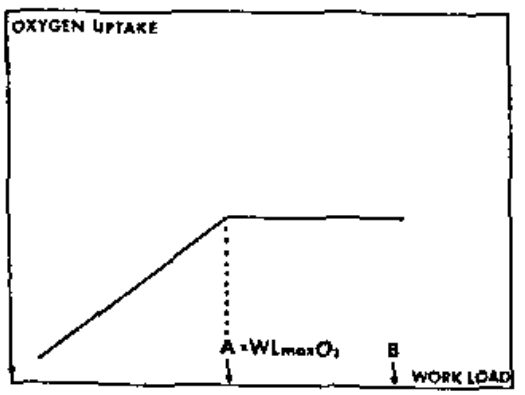

Fig 1. Oxygen uptake in relation to work load. Point A represents the point of "levelling off" defined as $WLmaxO_2$, which is the lowest work load that still gives maximal oxygen uptake To assure that point A represents point of "levelling off", work time should be at least 4 min and blood lactate at least 8 mM. Work loads above this point (for instance point B) are "supermaximal" in regard to maximal aerobic power.

The higher the work load above $WL\text{max}O_2$ the shorter will the work time be, and—as shown in study I—there is a risk that the oxygen uptake at work loads much higher than $WL\text{max}O_2$ is somewhat lower than those obtained at $WL\text{max}O_2$. Furthermore in a recent study from this laboratory (to be published) where heart rate and cardiac output were measured during exhaustive exercise at different work loads all requiring maximal oxygen uptake, it was found that in order to ensure maximal values on heart rate and cardiac output, the work load should be selected so that the work time exceeds 4 min. For these reasons the work loads for the circulatory studies in this publication were chosen from the first part of the plateau just to the right of the point of "levelling off" ($WL\text{max}O_2$) in order to allow for a work time above 4 min.

Cardiac output: The error of the method for the determination of cardiac output during submaximal and maximal exercise on bicycle (study II and V) and treadmil (study III) has been calculated from double determinations in the same experiment. The results are given in TABLE 1. These errors of the method are of the same order—or 3 to 5 per cent—as reported earlier fro mthis and other laboratories (Asmussen and Nielsen 1952, Saltin 1964a., Stenberg 1966).

PROCEDURES

Experimental procedures: A detailed description of the experimental procedure can be found in each individual paper.

The first time the subjects came to the laboratory they familiarized themselves with the test methods used by performing submaximal and maximal work. The data from these very first experiments are not included in the results. In experiments with and without catheters the experimental procedure for submaximal and maximal work of short duration was identical.

When cardiac output was determined the subjects came to the laboratory at 8 a. m. after a light, fat-free breakfast. Two catheters were inserted, one in the brachial artery and one in a deep cubital vein, according to the Seldinger technique (Bernéus et al. 1954). Thereafter the subjects rested for at least 1 hour in supine position, before the exercise was started.

Unless otherwise indicated exercise at submaximal work loads was carried out for 6—8 min. The heart rate was recorded each minute of exercise. The blood pressures were recorded at the 3rd min in the experiments with catheters inserted. Simultaneous determinations of oxygen uptake and cardiac output were made after the 5 th min. Blood samples for determination of lactic acid concentration, hematocrit, hemoglobin and oxygen saturation were taken during the collection of expired air.

All maximal work loads were preceded by a 3 min warming-up spell of work, which loaded the oxygen transport system to about 50 per cent of it's maximum. Immediately thereafter, work at maximal load started and was carried out for 4 to 6 min (see METHODS). The ECG was recorded for 10—15 sec each min of exercise and continuously during the collection of expired air. The blood pressures were recorded at the 2nd min. All other measurements started 2.5 to 3 min after the beginning of the maximal work. At least two simultaneous determinations of oxygen uptake and cardiac output were made.

Training procedure: The same principles for training were applied in all studies, whereas the training volume and pace was adapted to the training status of the individual. Both dash-, interval- and endurance training have been included in the programme.

Dash training consists of full speed preferably uphill running during 30—60 sec and repeated 5—10 times with 2—3 min periods of low activity between each dash. Blood lactate concentration after such a period of exercise exceeds 10 mM and values up to 28—30 mM have been recorded (Ekblom et al. 1967, Karlsson et al. 1967).

In interval training the running speed is chosen so that the running time is about 10 per cent lower than the individual's best time for a given distance (for explanation, see study I). The running time should last 3 to 7 min. Depending on the individual's state of fitness, the intervals are repeated 3 to 7 times with low activity periods of up to 6 to 8 min in between each interval.

Distance training consists of running mostly at submaximal speed for 45 to 75 min. During short periods of increased speed or when running uphill, maximal values for heart rate and oxygen uptake might have been obtained.

The number of training periods per week is specified in each study. The training dealt with in studies IV and V was supervised, but in the remaining cases the subjects conducted their own training according to a predetermined programme.

Comments

Experimental procedure: When performing the same exercise with and without catheters inserted the heart rate did not vary more than what could be expected from day to day variations without catheters indwelled. At the submaximal level, therefore, the catheters do not appear to have caused any specific changes in the circulatory response. This agrees with earlier findings reported (Rowell 1962, Saltin et al. 1968). On the other hand, the maximal oxygen uptake of a number of subjects was lower in the experiments with catheters inserted (in 3 subjects the differences were greater than 10 per cent). The reason for this is not quite clear. It should be mentioned that in connection with these experiments the blood loss in no case was more than 150 to 200 ml.

Training procedure: As was stated under the heading of "METHODS", exhaustive exercise can infer different degrees of load from $\dot{V}O_2max$ and

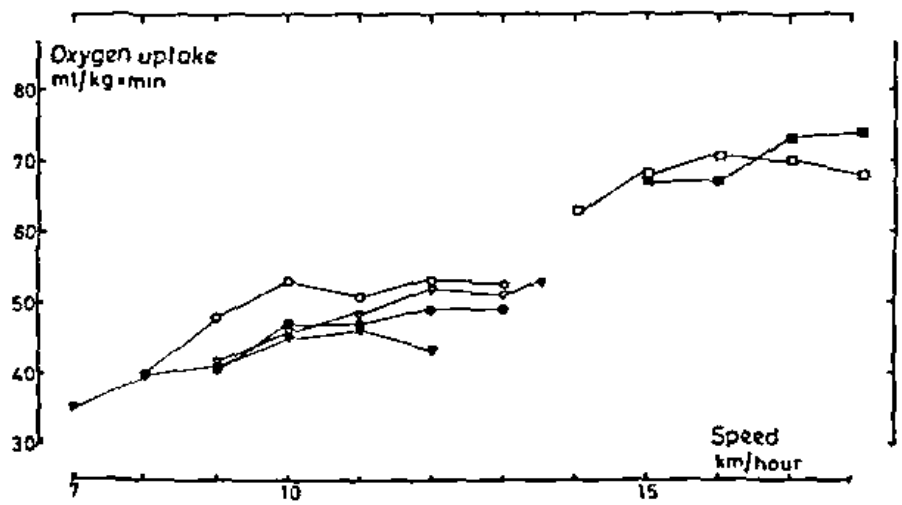

Fig. 2. Oxygen uptake in relation to speed (angle 3°) in 4 untrained and 2 well-trained subjects (PS filled and BE unfilled squares).

higher. This has bearing on the training programme. What speed is sufficient for the attainment of maximal oxygen uptake?

In study I five subjects were studied during submaximal and maximal exercise on the treadmill. Oxygen uptake, heart rate and blood lactate concentration were measured. Firstly tests were made in order to determine the highest speed which the subject could stand for 4 min. Thereafter on different days the subject was tested at speeds slightly below the one which had thereby been established. The duration of the exercise period was regulated so that the same total distance would be covered for each exercise period. The results (Fig. 2) show that the plateau for the "levelling-off" of oxygen uptake in relation to increased speed varied in length for the various individuals. The longest plateau was attained by subject *BE*, i.e. from 15 to 18 km/hour with an inclination of the treadmill of 3° and the shortest by subject *PS*, i.e. from 17 to 18 km/hour with the same inclination. It is worth mentioning that in these two well-trained subjects maximal oxygen uptake was obtained also at 19 and 20 km/hour (with the work time correspondingly shortened). Accordingly, the total plateau for "levelling-off" for subject *BE* was from 15 to 20 km/hour, if the work spells were reduced below 4 min.

As for bicycle exercise the length of the plateau for "levelling-off" (work time $>$ 4 min) is often somewhat shorter than that for treadmill exercise in the same individual. This might depend on that the muscle mass engaged is less in maximal bicycle work than in maximal running; that the proportion of static muscular work is higher during maximal bicycle exercise; that the muscle pump is more effective during running etc.

The indications to which the main results of this investigation point may be summarized by stating that in order to attain maximal oxygen uptake during interval training (work time 3 to 7 min) it is not necessary to maintain the maximal running speed for a given distance. This could indicate that a decrease in speed of 10 per cent may not reduce the training effect of the maximal aerobic power. However, it is still unproved if this reduced speed represents the same training stimulus on the maximal aerobic power, as the training at maximal speed ("supermaximal work"), i.e. if "intensity" can be replaced by "duration". On the other hand the higher the speed the fewer bursts of activity in a given period of time can be performed, since the recovery time is prolonged. For that reason it is highly recommendable to make use of both training methods.

SUBJECTS

Detailed information about the subjects used for this research project are found in each individual study. Since some confusion of definition exists as regards the classification of different subjects with regard to their habitual amount of training, an attempt is made below to establish such categories.

Very inactive—Individuals who for certain reasons, as for instance bed rest, physical or psychic handicaps, were forced to be extremely inactive.

Sedentary—Healthy individuals in occupations which impose no physical demands, who had never taken part in physical training previously, or who had once trained moderately, but not in recent years. Examples—subjects in studies II and V before they started training.

Moderately active.—Individuals who exercise regularly (1—4 times a week) but do not take part in contests. This group also includes individuals in occupations involving heavy manual work or individuals who take part in compulsory exercise during military service or at school. The physical education student belongs to a special sub-group among the moderately active, since the student in physical education trains regularly every day during the term for 2 years in Sweden. However, the intensity of the training cannot be compared with that of the athlete.

Athlete—Individuals who have trained for contests practically every day over the course of several years. Training, for instance in the case of an athlete in endurance events, consists of dash-, interval- and endurance training (for definitions see under heading "METHODS"). The athlete category should be divided into two sub-groups,

1. Top athletes, prominent in international and national events, such as group 1 in study III.
2. Athletes, who in contests cannot be compared with group 1. Examples, group 2 in study III.

In the case of the categories moderately active and athletes information should also be included on the subject's state of training at the time the study was undertaken.

CHAPTER 1

THE OXYGEN TRANSPORT SYSTEM IN ATHLETES

a) Previous investigations

Oxygen uptake during heavy muscular work was measured as far back as in the 1910 decade, but it was not until 1937 that Robinson, Edwards and Dill could present more acceptable data on maximal oxygen uptake in athletes (5.35 liters/min for D. Lash—the world record holder for 2 English miles). Christensen and Högberg (1950) and Åstrand (1955) could confirm these high values for maximal oxygen uptake, and since then many investigations have been reported on maximal oxygen uptake measurements in athletes representing various kinds of sports (Mellerowics and Hansen 1965, and others). In one of the most recent papers Saltin and Åstrand (1967) present the highest measured values heretofore given for maximal oxygen uptake for top athletes in endurance events (highest values 6.17 liters/min and 85.1 ml/kg per min).

In addition to a high maximal oxygen uptake athletes are also characterized by a low heart rate on submaximal loads (Christensen 1931) and large dimensions for the oxygen transporting organs, such as heart volume, total hemoglobin, blood volume and vital capacity (Kjellberg et al. 1949, Roskamm et al. 1966, among others).

In order to throw light on how the large oxygen transport capacity of athletes is coped with, measurements on the cardiac output are of great importance. Rowell (1962), Saltin (1964b) and Åstrand et al. (1964) have presented data on maximal cardiac output (28 to 32 liters/min) maximal stroke volume (150 to 170 ml) and maximal arterio-venous oxygen difference (150 to 190 ml/liter) for subjects with a high maximal oxygen uptake (4.8 to 5.4 liters/min). In addition stroke volumes in the order of 150 to 170 ml have also been measured during submaximal work (Bevegård et al. 1963).

At a submaximal level athletes have a higher oxygen pulse than habitually sedentaries. This is caused to a high degree by a greater stroke volume. There has been some discussion as to whether the well-trained athlete's cardiac output for a given submaximal oxygen uptake is larger, the same or less than that for an untrained person (Bevegård et al. 1963, Hanson and Tabakin 1965). There has also been a lively debate on the size of the change in the athlete's stroke volume when shifting from rest to different degrees of exercise (Rushmer 1959, Bevegård 1962a). Musshof et al. could in 1959 report that the stroke volume increased relatively more in the case of athletes than in non-athletes, whereas

neither Rowell (1962) nor Bevegård et al. (1963) could find any difference between athletes and non-athletes in that respect.

b) Present investigation (study III)

Group 1 consisted of 7 very well-trained top athletes with a very high maximal oxygen uptake— in each case over 70 ml/kg per min. Group 2 comprised 5 athletes who were also well-trained having carried out regular training for many years, but never attained the high maximal oxygen uptake levels which were recorded for the top athletes in group 1.

During maximal exercise the top athletes in group 1 attained an average maximal oxygen uptake of 5.57 liters/min—corresponding to 73.9 ml/kg per min. The highest individual values were 6.24 liters/min and 81.1 ml/kg per min respectively. Average maximal heart rate was 192 beats/min. The cardiac output averaged 36.0 liters/min, the highest individual value being 42.3 liters/min. (Fig 3). The

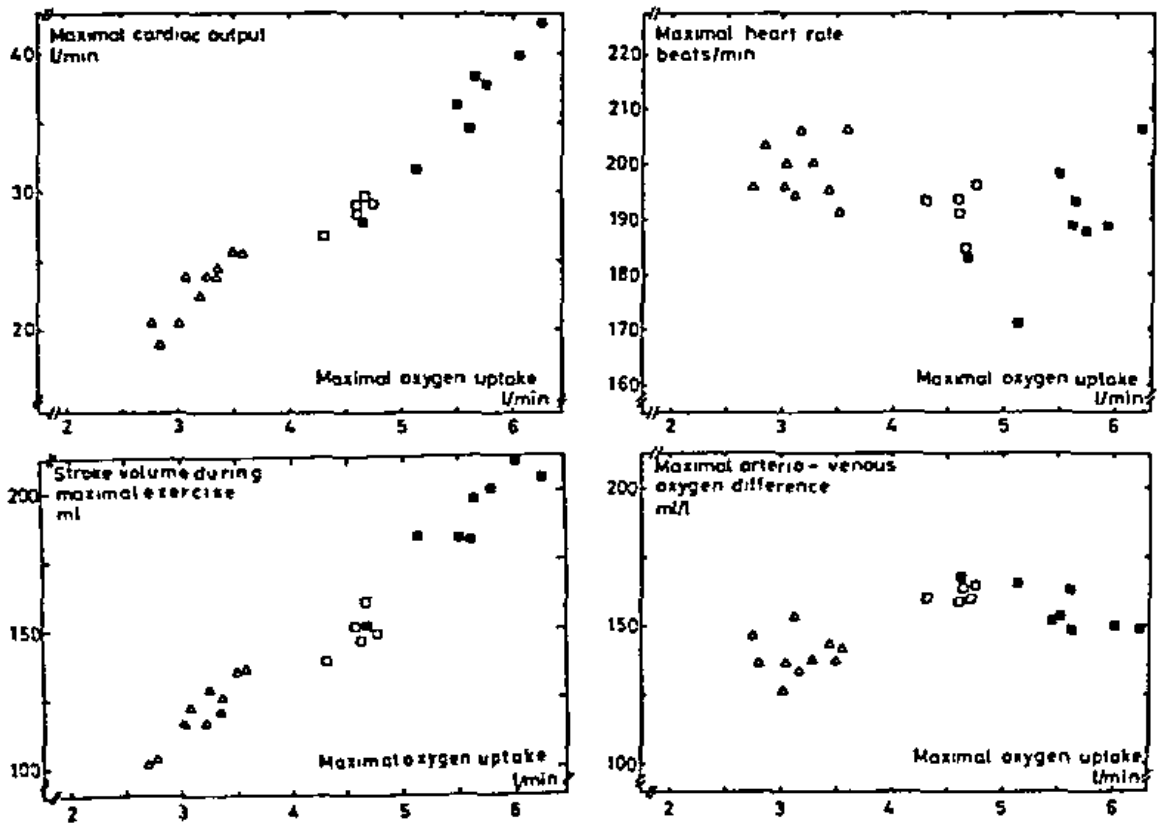

Fig. 3. Heart rate, cardiac output, arterio-venous oxygen difference and stroke volume during maximal exercise in relation to maximal oxygen uptake in top athletes from group 1 (filled squares), athletes from group 2 (unfilled squares) and sedentary from study II (unfilled triangles).

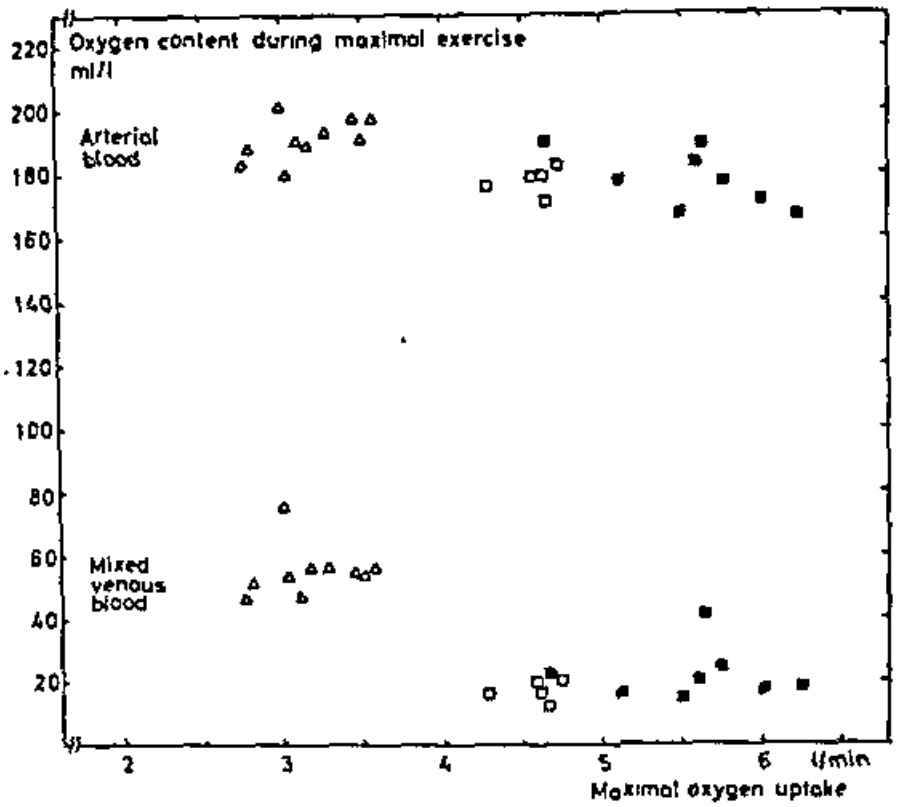

Fig. 4. Oxygen content in arterial blood (measured) and in mixed venous blood (calculated) in relation to oxygen uptake during maximal exercise. Symbols as in Fig 3.

stroke volume during work with the maximal load was on an average 189 ml, the highest individual values being 212, 205 and 201 ml respectively. Maximal arterio-venous oxygen difference was on an average 156 ml/liter. Since the oxygen content of the arterial blood during maximal exercise was on an average 181 ml/liter, the calculated oxygen content of the mixed venous blood was 25 ml/liter

In group 2 the mean maximal oxygen uptake during the time the cardiac output was measured was 4.58 liters/min—corresponding to 64.2 ml/kg per min —the mean maximal heart rate was 191 beats/min and the mean maximal cardiac output 28.4 liters/min with a highest value of 29.4 liters/min (Fig. 3). The mean stroke volume during exercise at maximal load was 149 ml and the mean maximal arterio-venous oxygen difference was 161 ml/liter. The calculated oxygen content of the mixed venous blood was then 20 ml/liter (Fig. 4).

The cardiac output for a given oxygen uptake was the same for the two groups of athletes. The equation for the regression line between cardiac output and oxygen uptake was: $\dot{Q}=4.1+6.09\ \dot{V}o_2$. The mean heart rate for a given submaximal oxygen uptake was lower for the top athletes in group 1 than for the athletes in group 2, which means that the stroke volume was greater for the former group.

The stroke volume of both groups rose as the work was stepwise increased from the lightest loads (c. 30 per cent of maximal oxygen uptake) to a load corre-

sponding to c. 70 per cent of maximal oxygen uptake, after which on the whole it was unchanged up to maximum. (In 9 out of 13 athletes maximal stroke volume was actually measured at the same time as the maximal cardiac output was recorded.)

Discussion

The high maximal oxygen uptake which was observed for the top athletes was made possible by a high cardiac output, whereas the maximal arterio-venous oxygen difference due to the low arterial oxygen content (low Hb concentration), was not greater than 156 ml/liter. The high maximal cardiac output was effected by a very high stroke volume which for most of the subjects was at maximal level even when exercising maximally.

Top athletes in group 1 were distinguished from athletes in group 2 by a higher maximal oxygen uptake. They had a greater cardiac output due to a greater stroke volume, since the maximal heart rate was the same for both groups (Fig. 3). The calculated oxygen content of the mixed venous blood during exercise at maximal load was roughly the same for both groups (Fig. 4). In comparison with habitually sedentaries from study II well-trained athletes have a higher maximal oxygen uptake, partly explained by a higher cardiac output (i.e. the stroke volume) and partly to a more complete extraction of oxygen from the arterial blood, resulting in a lower content of oxygen in the mixed venous blood. It should be pointed out that because of a relatively low hemoglobin concentration in athletes the arterio-venous oxygen difference is not necessarily higher among athletes than among sedentaries.

The body height and weight was 3 cm and 4 kg greater, respectively, for the elite athletes in group 1 than for athletes in group 2. However, this does not explain the differences found in heart volume and red cell volume between the two groups. (For discussion regarding dimensional differences between individuals of different body height, see Chapter III). A difference in the mentioned dimensions of c. 5 per cent could be expected between the groups on the basis of the differences in body height (Asmussen and Heeböll-Nielsen 1955).

The difference actually found in the vital capacity was about 6 per cent, thus corresponding to predicted value. The heart volume and the red cell volume differed, however, much more between the two groups and averaged 19 per cent and 14 per cent, respectively, which was higher than predicted. It should be borne in mind that the individual variation is wide and these static dimensions cannot, therefore, be used for prediction of maximal oxygen uptake. On the other hand, the large dimensions are a precondition for high maximal aerobic power.

CHAPTER 2

EFFECT OF PHYSICAL TRAINING ON CIRCULATION DURING SUBMAXIMAL AND MAXIMAL EXERCISE OF SHORT DURATION IN PREVIOUSLY UNTRAINED MALE ADULTS

a) Previous investigations

Christensen's classical studies in 1931 showed that when heavy muscular exercise was performed over a period of several weeks or months the heart rate decreased at a given load, indicating an improved cardiovascular function. The increase in the maximal oxygen uptake by training in fairly untrained individuals was, however, first demonstrated by Robinson and Harmon (1941) and by Knehr et al. (1942). It was not until about 1960 that an analysis was made of how the increased oxygen uptake in connection with maximal exercise came about. Rowell (1962) established that an increase in the maximal oxygen uptake from 3.47 liters/min to 3.93 liters/min (15 per cent) was a consequence equally of an increase in the cardiac output, where the stroke volume was the factor which increased, and a widening of the arterio-venous oxygen difference. A subsequent study by Saltin et al. (1968) where the maximal oxygen uptake increased up to 43 per cent after 55 days of training performed by 3 previously untrained subjects, agreed as a whole with the findings of Rowell's investigation.

Circulatory adaptation to submaximal work after training has been the subject of several investigations (for reference see Åstrand 1956). A reduced heart rate for a given submaximal load following training has been shown in many studies to depend on an improved mechanical efficiency (Gemmill et al. 1930, Robinson and Harmon 1941, Cotes and Meade 1959). Common to all these investigations has been that also the O_2 pulse has increased during training. It is an open question whether the cardiac output for a given submaximal oxygen uptake is modified by training and in this regard varying assumptions have been presented.

The training effect on the different static dimensions has varied from study to study. The roentgenological heart volume may increase with training, as also the blood volume and the total hemoglobin (Holmgren et al. 1960, Roskamm et el. 1966). Most observers agree (see Åstrand 1965) that the vital capacity remains unchanged in adults (for adolescents, see Chapter III).

b) Present investigation (study II)

In this investigation 8 subjects were studied before and after 16 weeks of physical training. The oxygen uptake, heart rate and cardiac output during sub-

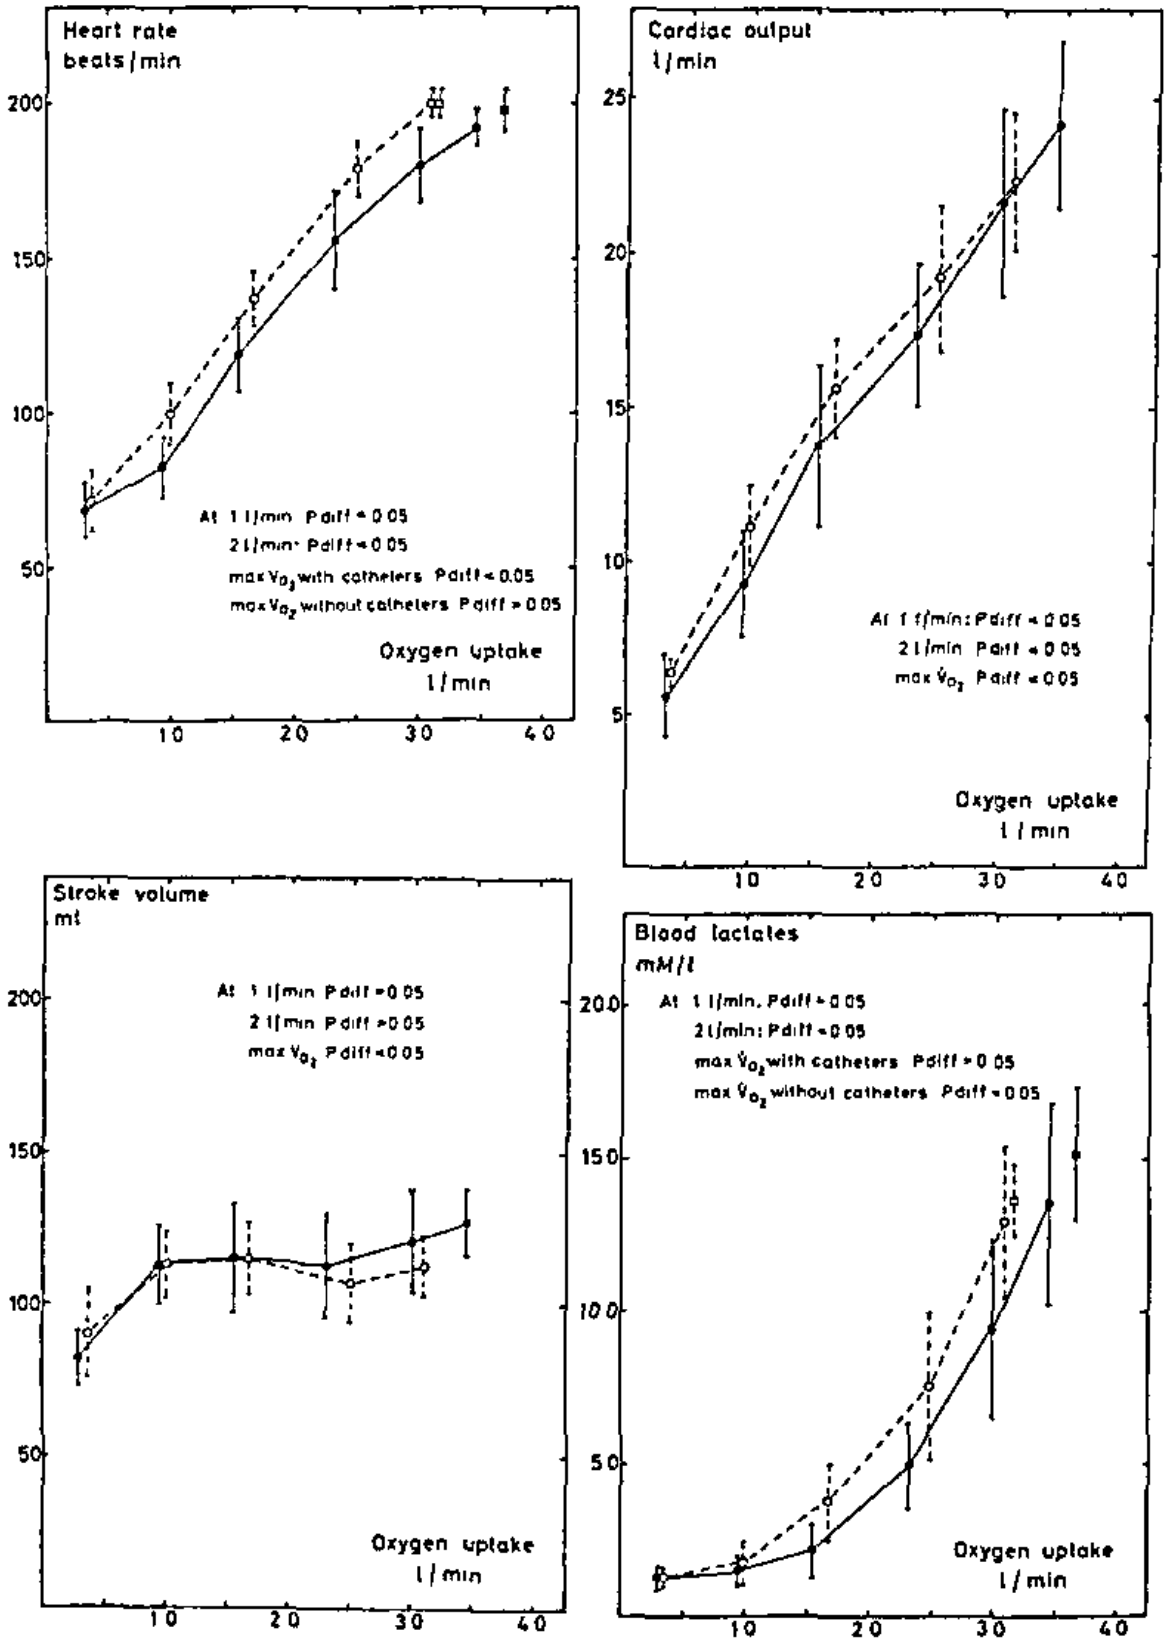

Fig. 5. Mean values (n=8) of heart rate, cardiac output, stroke volume and blood lactates in relation to oxygen uptake during submaximal and maximal exercise before (dotted line) and after (solid line) 16 weeks of training. Squares indiciate values obtained without catheters indwelled. *Pdiff* refers to the difference in ordinate values before and after training at a given abscissa value

maximal and maximal cycling were measured. For details, see study II. Some results are illustrated in Fig. 5.

The maximal oxygen uptake rose from 3.15 liters/min to 3.68 liters/min (16 per cent). The maximal heart rate and the heart volume remained unchanged during the training period. The greater maximal oxygen uptake was accomplished partly by a higher cardiac output—i.e. an increase from 22.4 liters/min to 24.2 liters/min, the stroke volume accounting entirely for the increase (from 112 ml to 127 ml)—and partly by a wider arterio-venous oxygen difference.

For a given submaximal load the heart rate was some 25 beats/min lower after training. This depended partly on an improved mechanical effiency ($p < 0.05$) and partly on a widened arterio-venous oxygen difference ($p < 0.05$) (hemoglobin concentration unchanged). The stroke volume did not change with training at the lower submaximal levels, but was somewhat higher after training at the highest submaximal levels.

The arterial blood pressure tended to be higher during submaximal exercise after training, but the differences were not significant. However, with maximal exercise the average intra-arterial diastolic, mean and systolic blood pressures were higher ($p < 0.05$) after the subject had trained.

The concentration of blood lactate was lower during exercise with a given oxygen uptake. At maximal work loads the blood lactate concentration was significantly higher, however, after training.

At regular intervals after that this study was finished (16 weeks) the subjects were re-examined (a complete report thereon will be published elsewhere). Two

subjects, *LM* and *IS*, had continued with intensive training, and at certain periods they have trained up to 7 days a week. Some circulatory data obtained during submaximal and maximal work are given in TABLE 2 and Figs. 6, 7 and 8.

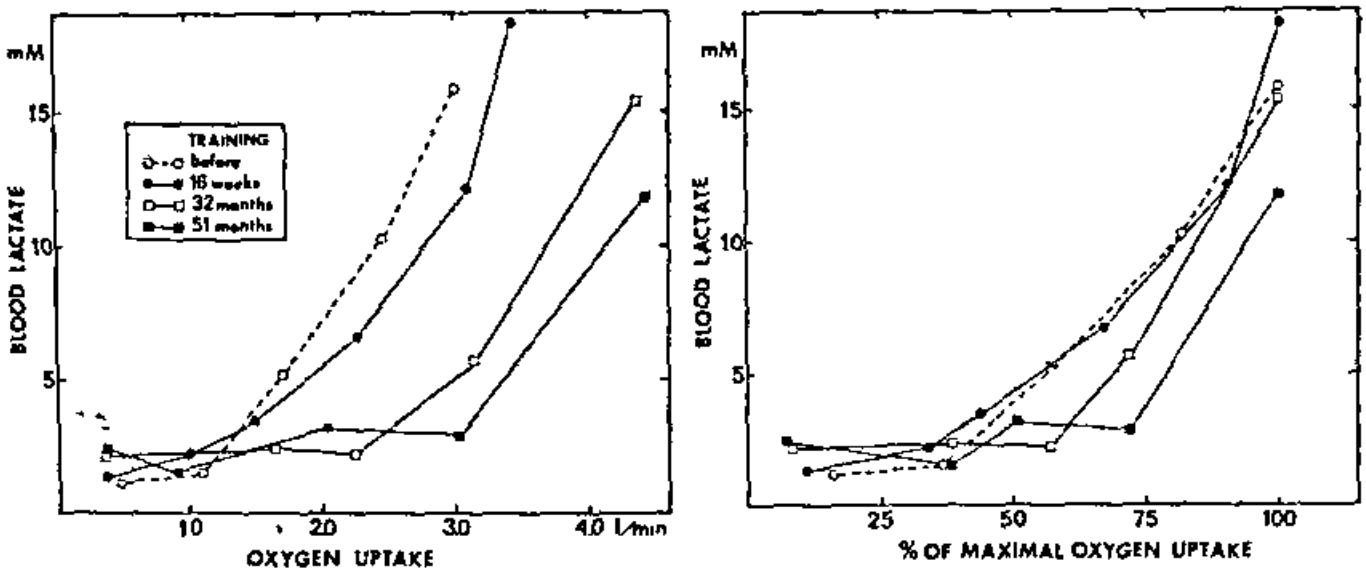

Fig. 8. Blood lactate concentration in relation to absolute values of oxygen uptake (left) and to oxygen uptake in per cent of maximal oxygen uptake (right) in subject *IS*. Symbols as in Fig. 6.

For subject IS the maximal oxygen uptake increased from 3.07 liters/min at the onset of the training to 4.41 liters/min after 51 months of training (total increase 44 per cent). This improvement was ascribable partly to an increase in the cardiac output from 23.9 liters/min to 26.6 liters/min (11 per cent) and partly to an increased extraction of oxygen from the blood (from 126 ml/liter to 166 ml/liter = 32 per cent). The maximal heart rate fell as training continued from 205 beats/min before training to 186 beats/min after 51 months of training. The greater maximal cardiac output was therefore accomplished by a rise in the stroke volume from 122 ml to 146 ml.

The heart rate at a given submaximal work load decreased for subject IS in accordance to the length of training (Fig. 6). As already mentioned the cardiac output for a given submaximal oxygen uptake was lower after 16 weeks of training. However, in the case of the following determinations, recorded after 32 and 51 months of training, respectively, the cardiac output at a given submaximal oxygen uptake was the same as it was before the training started. With an oxygen uptake of 2 liters/min the heart rate fell c. 40 beats/min, and thus the stroke volume correspondingly increased. The highest stroke volume measured during exercise rose from 122 ml before training to 150 ml after 51 months of training. At the same time the heart volume at rest rose from 920 ml prior to training to 1060 ml after 51 months of training.

The concentration of blood lactate when this person exercised at increasing loads is presented in Fig. 8. Both at an absolute and at a relative submaximal oxygen uptake level the concentration of blood lactate was lower after 51 months of training than it was before training commenced.

The mean blood pressure for a given submaximal oxygen uptake was higher after 16 weeks of training than before training started, but after 51 months of training the lower pre-training values were again obtained. However, at maximal exercise the mean blood pressure was higher, but also the cardiac output was as mentioned above higher.

Discussion

The increased capacity for oxygen transportation after 16 weeks of training was partly due to an elevated stroke volume (from 112 ml to 127 ml—or 13 per cent), giving a higher cardiac output during maximal exercise, and partly to a more complete extraction of oxygen from the blood. The reduced blood lactate at a given submaximal load may be taken as a criterion of a more effective regulation of the muscle blood flow. More pronounced vasoconstriction in non-active tissues may explain the rise noted in blood pressure.

As for the long-term physical training, (more than ½ year) which brought to light an asymptotic elevation of the maximal oxygen uptake, the mechanism for the increased capacity for oxygen transportation was the same as for the short-term training. *In both subjects (LM and IS) there was a further increase in stroke* volume, giving a higher maximal cardiac output, and a further widening of the arterio-venous oxygen difference.

The increase in blood lactate concentration for a given submaximal oxygen uptake became less pronounced throughout the training period. A similar change at a relative load was obviously manifested somewhat later. In other words the reduction in blood lactate concentration at a relative oxygen uptake (e.g. 75 per cent of maximal) did not manifest itself after 16 weeks of training, in spite of the fact that maximal oxygen uptake rose about 25 per cent (subject *LM* and *IS*).

EFFECT OF PHYSICAL TRAINING ON CIRCULATION DURING PROLONGED SEVERE EXERCISE IN PREVIOUSLY UNTRAINED MALE ADULTS

a) Previous investigations

Little knowledge is at hand on the effect of physical training on circulation during prolonged hard muscular exercise for more than 30 min. It is a recognized fact (Christensen 1931, Astrand 1960, Saltin and Stenberg 1964, Ekelund and Holmgren 1964) that the heart rate progressively increases during prolonged hard muscular exercise in sedentary as well as in well-trained individuals. Concomitantly stroke volume declines, giving an unchanged cardiac output throughout the work period. This decrease in stroke volume which may be interpreted as a consequence of impaired cardiac function was noticed even during supine work (Saltin and Stenberg 1964, Ekelund 1966).

b) Present investigation (study V)

Seven sedentary subjects were studied before and after 22 weeks of physical training. They cycled for one hour with a load demanding an oxygen uptake of 75 per cent of the individual maximal oxygen uptake. This standard test was performed both before and after the training. The heart rate, oxygen uptake and cardiac output were measured. For details see study V.

In experiments without catheters indwelled the maximal oxygen uptake rose from 3.41 liters/min prior to training to 3.64 liters/min subsequent to training. The maximal heart rate fell from 201 beats/min to 194 beats/min ($p < 0.05$) during this period. The heart volume remained unchanged.

The actual work load in the pre-training test was in average 1010 kpm/min, and in the post-training test 1170 kpm/min. The demand was in both cases 75 per cent of the maximal aerobic power. The explanation to the different work outputs was partly the higher maximal oxygen uptake attained after training and partly a gradually improved mechanical efficiency.

During the early phase of exercise (the 5 and 15 min values) the heart rate was the same prior to and following training. The cardiac output after training was 2.6 liters/min ($p < 0.05$) greater, while the oxygen uptake was 0.1 liters/min higher. The arterio-venous oxygen difference was 127 ml/liter prior to training and 123 ml/liter ($p > 0.05$) afterwards. The stroke volume was significantly larger after training than before—namely 130 and 115 ml, respectively.

From the 5th min up to the 60th min the heart rate gradually increased, but this elevation was equally high prior to and after the training. During this period of time the cardiac output remained virtually unchanged both in the pre-training and the post-training experiment, and therefore the stroke volume fell. Before training this drop was from 116 ml to 111 ml and after training from 132 ml to 123 ml. Mean blood pressure measured at the 5th min was higher after training ($p < 0.05$) and it dropped gradually during exercise both prior to training and afterwards.

The blood lactate content was unchanged prior to training from the 5th min onwards through the entire one hour of exercise (c. 6.8 mM), whereas after training it reached at the 5th min the same value as before training but thereafter it fell successively.

Discussion

The effect of the physical training on the maximal oxygen uptake in this group of subjects was fairly low (c. 8 per cent increase). However, considering that the pre-training mean value was rather high (48 ml/kg per min), the improvement is within the "normal" limits for the increase in maximal aerobic power after short-term physical training in previously untrained young male adults (see Fig. 12).

The combined effect of improved mechanical efficiency and increased maximal oxygen uptake resulted in a much higher work output during the one hour test after training. The total amount of kilopondmeters, that could be performed during the 1 hour test at the same relative load was thus increased from 60,100 kpm before to 70,000 kpm after the training (16 per cent difference). In addition, many subjects spontaneously stated that the prolonged exercise was subjectively felt much easier after training than beforehand. This may partly be explained by an improved local circulation, since the blood lactate content, which prior to training was unchanged throughout the period of exercise after training fell successively during the course of exercise after the initial elevation.

The oxygen pulse was higher after as compared with before the training, depending only on an increased stroke volume. This did not, however, change the circulatory pattern during the prolonged severe exercise, since heart rate rose and stroke volume decreased equally much in the two tests. Thus, whatever the causes may be for the gradual elevation of heart rate and reduction in stroke volume during prolonged exercise, these causes were not affected by training for 22 weeks.

CHAPTER 4

EFFECT OF PHYSICAL TRAINING ON OXYGEN TRANSPORT SYSTEM OF ADOLESCENTS

a) Previous investigations

Relatively little information is available concerning the effect of physical training in individuals in puberty. In the cross-sectional study by Åstrand et al. (1963) on Swedish girl swimmers in the age groups 10—17 years it was definitely shown that various dynamic functions (e.g. maximal oxygen uptake) and static dimensions (e.g. heart volume, vital capacity) in the oxygen transport chain were greater among girl swimmers than among moderately active girls of a corresponding age. Nevertheless, it is impossible on the basis of these results to isolate the effect of training from the effect of constitutional factors.

Few longitudinal studies exist which deal with the effect of training on the organism in adolescence. One complication in this type of studies is to establish a control group of untrained subjects. In most schools a certain degree of physical activity is compulsory and furthermore, young boys and girls are spontaneously very active in leisure hours.

Sprynarova (personal communication) measured maximal oxygen uptake in 90 Czech boys who were 11 years of age, and studied them at intervals for 4—5 years. She noted that the increase in maximal oxygen uptake became more pronounced in the most active boys, when comparing with the ones who were least active. However, no difference in the development of the body dimensions were revealed between the most active and least active of the boys (Pariskova 1967). On the other hand Schwartz et al. (1928) as reviewed by Schneider (1939) studied 68 boys in puberty who were undergoing 4 months of special training. These boys demonstrated a greater increase in body height (significant) and vital capacity (not significant) than a control group of 50 boys of the same age, who were not in special training. For other physiological changes during adolescent growth the reader is referred to the fundamental works of Tanner (1955).

b) Present investigation (study IV)

The present investigation was carried out in order to study the effect of prolonged strenuous physical training during puberty. The maximal oxygen uptake, heart volume and vital capacity of 6 boys—all of them 11 years of age at the start of the investigation—were measured at the onset (T1) and after 6 months of training (T2) and in 5 of these boys again after a further 26 months of

training (T3). A parallel study was made of a "control group" which did not participate in special training. After 6 months of training maximal oxygen uptake had risen from 2.15 liters/min to 2.48 liters/min (15 per cent) for the group in training. The values of the control group were unchanged. The increase in body weight, heart volume and vital capacity during this time was the same in the two groups.

After 32 months of training the maximal oxygen uptake of the training group (5 subjects) rose from 2.22 liters/min to 3.45 liters/min (55 per cent) which corresponded to an increase from 54.3 ml/kg per min to 58.1 ml/kg per min. Moreover the heart volume rose by 43 per cent and vital capacity by 54 per cent. In the control group (4 subjects) the maximal oxygen uptake increased over the

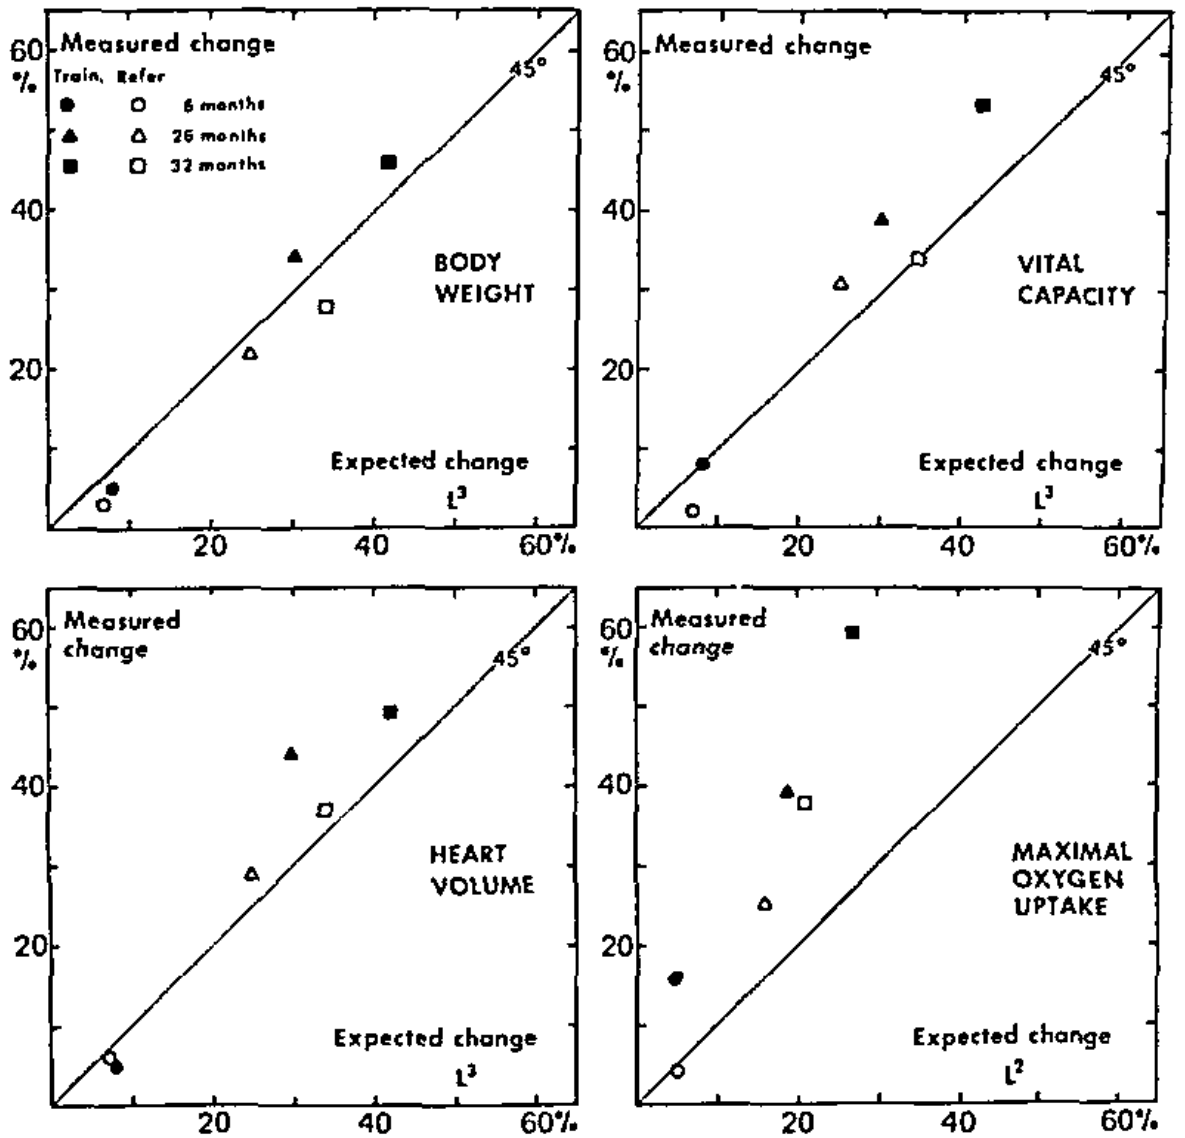

Fig. 9. Group means of measured change in body weight, vital capacity, heart volume and maximal oxygen uptake after 6, 26 and 32 months observation compared with corresponding expected change, as predicted from the relation body height after to body height before, raised to 2.0 (L^2) and 3.0 (L^3).

corresponding period from 1.85 liter/min to 2.54 liter/min (37 per cent), corresponding to 50.3 ml/kg per min and 53.9 ml/kg per min, respectively, while the heart volume rose by 36 per cent and vital capacity by 34 per cent. For four of the training subjects (*AH, HN, JA, LAT*) an increase in growth rate was noted, whereas in the control group none of the subjects exhibited such an accelerated rate of growth (Fig. 11).

Discussion

In order to evaluate the effect of physical training on the oxygen transport system of adults data obtained prior to training can be directly compared with similar data taken after a period of training. With adolescent subjects it is not possible to use this direct method of comparison, since in the case of these individuals—apart from physical training—an age-dependent growth of different static and dynamic functions must be taken into consideration. Neither—in view of individual variations etc.—can one merely make a comparison between the training group and the control group as regards differences in the increase of the parameters which have been selected.

However, theoretically it can be expected that with a specific development in body height certain volumes, such as heart volume and vital capacity should increase in line with the third power of this growth (Asmussen and Heeböll-Nielsen 1955). In this way it is possible to establish a predictable growth for various static and functional dimensions, such as heart volume, vital capacity etc. If there is a descrepancy between the predicted and measured increase, other aspects than purely geometric factors are involved. It will be seen from Fig. 9 that the predicted and measured increase for heart volume and vital capacity agrees in respect of the control group and as regards body weight for both groups. In other measurements the increases noted are greater than expected. As for the heart volume and vital capacity of the training group, the physical training is the probable reason for this difference.

In regard to the maximal oxygen uptake a sharper increase than foreseen occurred in both groups. Von Döbeln (1956) has earlier demonstrated that the theoretically expected difference in maximal oxygen uptake between individuals of different body height should be related to the ratio between the body heights raised to 2.0. However, if this theory is applied on Astrand's investigation on Swedish school children (1952) it will be found that the difference between the divergent ages as regards maximal oxygen uptake corresponded to the difference in body height, raised to 3.3. Thus, other factors than geometrical aspects, such as the effect of hormones, for instance, have played a part in the development of the maximal oxygen uptake. This observation has been confirmed in this longitudinal study. Training has further accentuated the difference between the predictable and attained value.

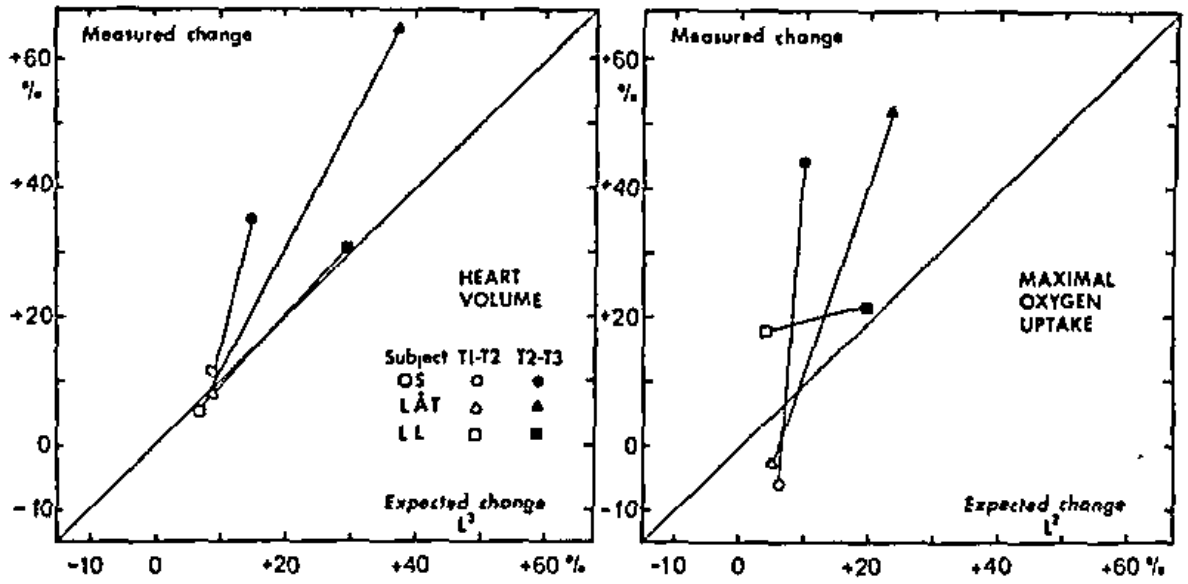

Fig. 10. Measured change in heart volume and maximal oxygen uptake in relation to corresponding expected change, predicted as in Fig. 9, between T1 and T2 (6 months) and T2 and T3 (26 months). Subject *LL* stopped and subject *OS* and *LÅT* started training after T2.

Subject LL from the original training group withdraw from the training after 6 months (at T2). Subject *OS* and *LÅT* from the original reference group started training at T2. *Fig. 10* presents the measured and expected increase in maximal oxygen uptake and heart volume at T2 and T3 for these 3 subjects. During the first 6 months of this study the maximal oxygen uptake in subject *LL* improved about 18 per cent. The heart volume remained on the whole unchanged. During the period between T2 and T3, when he was not in special training, the maximal oxygen uptake increased far less than expected. So when comparing the T1 and T3 values in this subject the measured increase in maximal oxygen uptake (and also heart volume) was identical with an expected value. On the other hand in subject *OS* and *LÅT* maximal oxygen uptake and heart *volume were on the whole unchanged during the first 6 months* (T1 and T2), when they were not in special training, whereas during the hard physical training *during the following 26 months (T2 to T3) their dimensions increased far more* than expected.

For the explanation of all these findings, some recent studies might be of interest. Goldberg and Goodman (1969) have shown that both growth hormone and physical work can induce growth of muscular mass. Concomitently, Sutton (1969) found an elevated concentration of growth hormone in blood, following severe physical exercise. It is likely, therefore, that the rate of growth can be accelerated by physical training during puberty—a period when the individual is evidently sensitive to the action of the growth hormone. This would mean that the *individual would grow more rapidly during a period of physical training than*

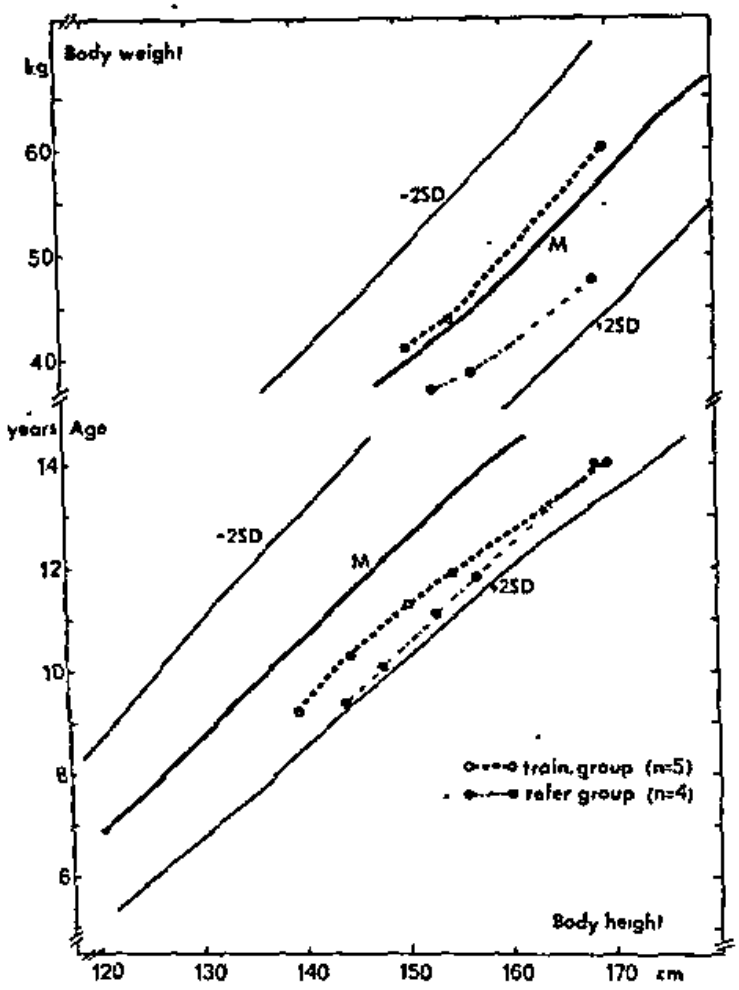

Fig. 11. Group means for body weight and body height for the 5 subjects, who have trained for 32 months (from 11 years) and corresponding non-training reference group of 4 subjects in a Karlberg-Iggbom growth chart (1959).

could be predicted from the body height development as estimated from growth charts. In other words, the individual would deviate from his pre-training age/height percentile in the growth chart, and would instead come into a "higher" percentile grade. This was the case in the present study, as seen in Fig. 11. At 11 years (T1) the body height of the "2 months" training group differed in average + 1.1 SD from the mean value of the diagram but at 14 years (T3) it differed by + 1.6 SD. These data also confirm the earlier study by Schwartz et al. (1928) in which physically active boys increased more in body height than controls.

General discussion

The effect of training on the oxygen transport system of the previously untrained adult can probably be enhanced in different ways at different phases of training. The results of the present as well as of earlier reported studies on training provide the background for the following hypothesis. 1) During the first phase of training a rapid increase in maximal oxygen uptake occurs. This is presumably the outcome of a changed circulatory regulation without any noticable difference in static dimensions. The individual can make better use of existing dimensions. During this first phase an improvement in technique or in mechanical efficiency may also play an important role for the higher work capacity after training; the individual makes better use of the available oxygen. 2) Thereafter, when training has progressed for half a year or so changes in static dimensions, for instance the heart and red cell volume, can occur, but experience points to the fact that these increases in static dimensions are—if they occur at all—relatively moderate. 3) Continued long-term hard training for years does not seem to increase the maximal oxygen uptake any further, whereas on the other hand the heart rate at fixed submaximal loads can continue to decline—indicating an additional improvement in the effectiveness of the oxygen transport system.

The greater maximal oxygen uptake after a short period of training (studies II and V) was brought about by an increase of the maximal cardiac output and a widened maximal arterio-venous oxygen difference. Since the maximal heart rate after training was unchanged (study II) or lower (study V) the entire increase in cardiac output was accounted for by a greater stroke volume. Hence the higher maximal oxygen pulse depended on an increase of both the stroke volume and of the arterio-venous oxygen difference.

In studies II and V the stroke volume increased without any observed change in the heart volume. This may indicate that after training the heart functions with less systolic residual blood volume perhaps because of a greater contractive power. Furthermore, the higher maximal arterio-venous oxygen difference after training indicates a more efficient distribution of the oxygen available in the arterial blood. In connection with long-term training ($> \frac{1}{2}$ year), it clearly emerges that the further increase in maximal oxygen uptake is accomplished by a further elevation of both the stroke volume and the arterio-venous oxygen difference.

It is an interesting observation that in subject *IS* from study II the heart volume increased, and at the same time the maximal heart rate decreased after long-term training. The question arises whether his reduction of the maximal heart rate

from 205 beats/min at the start of training to 186 beats/min after 51 months of training, can be explained by the change in heart volume.

In geometrically similar and qualitatively identical individuals all frequences (like maximal heart rate) should be expected to be inversely proportional to the length scale (von Döbeln 1956) and alla areas and volumes to be proportional to the second third power, respectively, of the length scale (Asmussen and Heeböll-Nielsen 1955). An increased heart volume can be regarded either as A) uniform, i.e. muscle cross-section area and vessel widths increases in proportion to the second and heart volume to the third power of the length scale, or as B) not uniform i.e. caused only by an increased heart blood quantity without changes in the muscle cross-section area and vessel widhts. Regarding these two marginal explanations to an increased heart volume, the maximal heart rate after 51 months training should be expected to be, according to A) $205 \times \sqrt[3]{\frac{920}{1060}} = 196$ beats/min and according to B) $205 \times \frac{920}{1060} = 178$ beats/min. This would signify that the observed change in the maximal heart rate in connection with subject *IS*'s long-term training does not require any other explanation than the change in heart volume.

In a cross-sectional investigation Holmgren and Åstrand (1966) found that the correlation between maximal heart rate and heart volume was low ($r = -0.488$) but it was significant. On the other hand, the maximal heart rate as noted for the athletes in study III, averaged about 190 beats/min, which is not significantly different from the maximal heart rate of untrained persons of the same age, although the heart volume is far greater.

Subject *IS* is still training regularly, but it is not likely that he can increase his maximal oxygen uptake up to the values which are reported for top athletes. In the case of individuals who have trained for many years, hard and intensive training does not seem to increase the maximal oxygen uptake any further. For exemple, the well-trained athletes in group 2 in study III, have not attained maximal oxygen uptake levels comparable with those manifested by top athletes. Saltin and Astrand (1967) also reported that LL, a skier who from 1955 to 1963 trained intensively and participated in World Championships, Olympic Games etc. did only raise his maximal oxygen uptake from 5.49 liters/min to 5.60 liters/min. The present writer has trained intensively for "orienteering" since 1955 (Swedish champion 1964). In 1960 the value noted for maximal oxygen uptake was 4.91 liters/min and for maximal heart rate 191 beats/min. Although severe "athletic" training (see METHODS) has been carried out 5 times a week since then, the maximal oxygen uptake and maximal heart rate have remained unchanged up to 1968. Regular measurements of the heart volume during this time have

shown variations from the mean value on the order of ±5 per cent. However, the heart rate noted at submaximal exercise has fallen from c. 155 beats/min at 1500 kpm/min (c. 250 watts) in 1960 to 130 beats/min at the same load in 1968. Corresponding observations were made on subject *AH*, see below. This decreasee in heart rate at a given submaximal work load, without a corresponding increase in maximal oxygen uptake or heart volume might be caused by an increased stroke volume.

Subject *AH* mentioned in study III, who was a top athlete in cross-country skiing and long distance running, is an interesting case in respect of the effect of prolonged hard training. Cardiac output was measured twice with a 5-year interval. Although he continued to train very hard during this time, the maximal oxygen uptake did not change, whereas the maximal cardiac output had risen from 28.8 liters/min (1962) to 34.4 liters/min (1967). Concurrently the arterial oxygen content during maximal exercise was—because of a low Hb-concentration —lower in 1967 than in 1962, a circumstance which provides an explanation for the lower maximal arterio-venous oxygen difference in 1967 and for an unchanged maximal oxygen uptake. The maximal heart rate was 8 beats/min lower in 1967 than in 1962, which means that the stroke volume during maximal work was about 50 ml higher in 1967 than in 1962. It is remarkable that at the same time the heart volume was unchanged. It can not be excluded that part of the explanation for the higher stroke volume in the 1967-study was the lower hemoglobin concentration and thus lower blood viscosity. This was also the case for the majority of the well-trained athletes, who have maximal stroke volumes greater than would be anticipated on the basis of the heart volume, as judged from data on sedentary and moderately active individuals.

Many extremely well-trained athletes have a low Hb-concentration (Grimby and Saltin 1966, study III). The cause for this is not known. Is it due to a physiological adjustment to hard physical training, or does it arise from an increased breaking down of red blood cells during training? Anyhow it should be observed that a reduction of the Hb-concentration in connection with physical training may not be an indication of iron deficiency.

The circumstance that there are possibly different phases in the changes of maximal oxygen uptake by training can be the explanation for the conflicting results which are reported in various studies on training.

When evaluating the physiological effects of training one must concider differences in the duration and intensity of the training, the subject's physical condition before training started, etc. and also the possible existence of considerable individual disparities in the response to a given amount of physical training, (see for example subject *JA* compared with the other subjects in study IV). Some studies of training may have recorded changes during the regulatory stage i.e. phase 1 (Holmgren et al. 1960, study II and V) and others with changes between

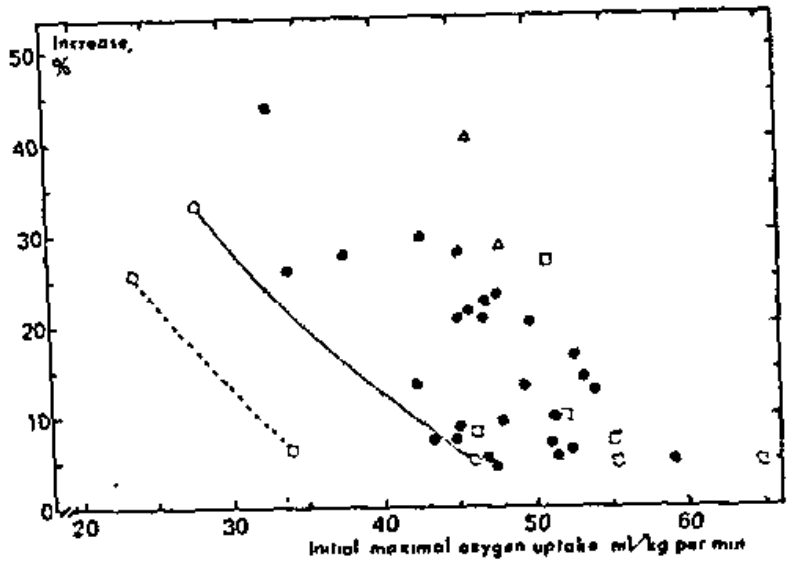

Fig. 12. The per cent increase in maximal oxygen uptake after short-term training (except triangles, see below) in relation to the pre-training maximal oxygen uptake in previously untrained individuals. Unfilled squares refer to adoloescent boys (study IV) and filled circles to young males (Rowell 1962, Saltin et. el. 1968, study II and V). Solid and dotted line refer to the mean value for middle-aged (35 to 50 years) and old (50 to 63 years) men, respectively, (Saltin et al. 1969). Triangles refer to the increase in maximal oxygen uptake in subject *LM* and *IS* from study II after 18 and 51 months of training, respectively.

phase 1 and phase 2 (Saltin et al. 1968). Douglas and Bachlake (1968) have studied the effect of training on individuals who had already undergone thorough training and who had probably reached the most advanced stage (phase 3) when the observations were conducted.

The magnitude of the increase in maximal oxygen uptake depends upon many factors, and some of interest are illustrated in Fig. 12. This diagram clearly illustrates that the expectation of an increase in maximal oxygen uptake after a short period of training (less than half a year) is greatest for subjects with the lowest level of pretraining maximal oxygen uptake. At a given level of pretraining maximal oxygen uptake the improvement seems less pronounced for individuals of 35 to 50 years and 50—63 years of age than for men of 20 to 30 years of age. Where adolescents are involved their improvements lie at the upper limit for adult men of 20 to 30 years of age. The importance of the duration of training is revealed by the data on subjects *LM* and *IS* from study II, whose maximal oxygen uptake increased far more than that of any person with approximately the same pretraining maximal aerobic power, who participated in short-term training.

Athletes represent a selected group of individuals with very special preconditions for outstanding physical performances. In addition they have trained hard for many years. These athletes provide insight on the upper performance limit for the human circulation. The differences in the maximal oxygen uptake between athletes and habitually sedentaries are connected with disparities partly in the stroke volume and partly in the arterio-venous oxygen difference. Differences between athletes in endurence events with different maximal aerobic power depend mainly in the magnitude of the stroke volume, since during maximal work

the oxygen content in the mixed venous blood for almost all had the lowest conceivable value taking into account the necessary circulation in the inactive organs.

After puberty the possibility to increase the maximal oxygen uptake by means of developing the static dimensions seems to be limited. The training of the adolescent boys gave data which tends to support the assumption that long-term—as opposed to short-term—training results in a more pronounced development of *certain dimensions, such as heart volume and vital capacity, than would have been* expected from the standpoint of age-dependent increase. On the basis of these observations it may be concluded that rational training during adolescent growth would yield the best results. Thereafter a previously sedentary person may well have forfeited his chance of developing his dimensions to a higher degree.

In all the longitudinal studies the common pattern for circulatory response to submaximal work levels has been that the heart rate and the blood lactate concentration *at a given submaximal load has been lower after training than before* In some cases the lower heart rate has been brought about by the improved *mechanical efficiency and consequently a lower oxygen uptake (studies II, IV* and V) but for almost all subjects a higher oxygen pulse has been a common finding. This might be wholly or partly attributable to a higher stroke volume (studies II and V) since the arterio-venous oxygen difference did not change regularly. However, after the long-term training (see Chapter 2) where a reduction in heart rate of 30—40 beats/min was recorded for a given submaximal oxygen uptake the higher oxygen pulse depended solely on the raised stroke *volume, whereas the cardiac output was at the same level as at the pretraining* stage. When comparing athletes (study III) with sedentaries (study II) the stroke volume for a given submaximal oxygen uptake was definitely higher for athletes, whereas the arterio-venous oxygen difference was on a whole similar for both groups.

The above mentioned changes in heart function following training raises the question, whether the reduction of heart rate or the increase in stroke volume is *the primary factor. This is not known. However, if the heart rate at a given* oxygen uptake is increased by using a pacemaker (Bevegård 1962) or at atrial flutter (Åstrand et al 1963), the stroke volume is correspondingly decreased so that the cardiac output is unchanged. Thus, in such cases stroke volume is secondary to heart rate. Whether the low heart rate and thus high stroke volume, characteristic for the trained state mainly depend on in improved myocardial function or on a reduced sympathetic and/or increased parasympathetic effect on *the myocardium, is still unsettled.*

The above mentioned changes in the circulatory adaptation to submaximal exercise indicate a better adjustment after training, i.e. the changes in the body's homeostasis between rest and work are less pronounced. Theses changes are

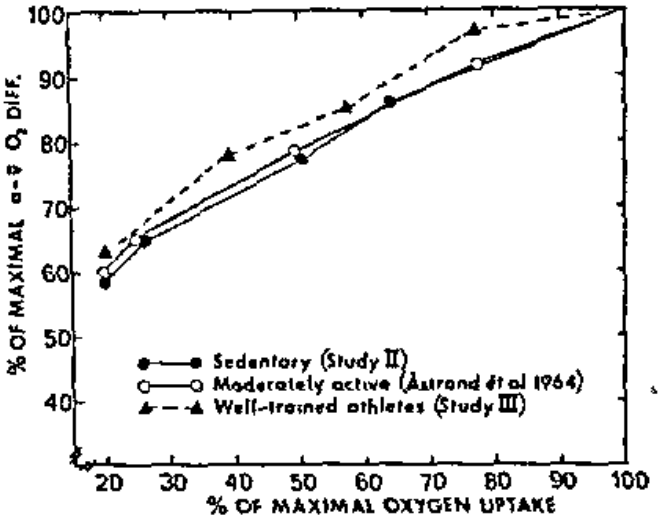

Fig. 13. Mean values of arterio-venous oxygen difference in per cent of maximal in relation to oxygen uptake in per cent of maximal in three groups of subjects.

possible to bring about by an improved peripheral blood distribution within a relatively short span of time. The developments which would occur over a somewhat longer time might be increased muscular capillary density (Petrén et al. 1936), greater concentration in the muscular cells of ATP and creatine phosphate (Yakovlev 1958), myoglobin (Wipple 1926) and mitochondria activtivy (Holloszy 1967).

From the neurophysiological standpoint it has been postulated that with a gradually increasing muscular contraction emanating from a certain motor pool, first the "red" ("aerobic") muscle fibres are brought into action and then, as the load becomes heavier, also the "white" ("anaerobic") fibres (Romanul 1964, Dawson and Romanul 1964, Kugelberg and Edström 1968). Hence it could be assumed that after training the muscle involved in order to perform a given submaximal load could be distributed on a larger motor pool, and that the relative share of the exertion borne by the "red" muscle fibers is greater after training than before.

An assumption along these lines does also provide part of the explanation for the fact that during extended (long-term) hard physical training the blood lactate concentration declines not only for a given absolute but also for a given relative oxygen uptake (see Fig. 8). Furthermore, if sedentary (study II) and moderately active (Åstrand et al. 1964) individuals are compared with the well-trained athletes (study III) it will be found, that athletes have a higher relative arteriovenous oxygen difference at a given relative oxygen uptake (see Fig. 13). .However, since the arterial oxygen content may vary highly (see study III), an even better variable, reflecting the efficiency of the peripheral circulation may be the oxygen content of the mixed venous blood. As seen in Fig. 14, well trained athletes have a definitely lower oxygen content in the mixed venous blood at a given load that non-athletes. It should be observed that a well-trained athlete and a cardiac patient may have the same low oxygen content in the mixed venous

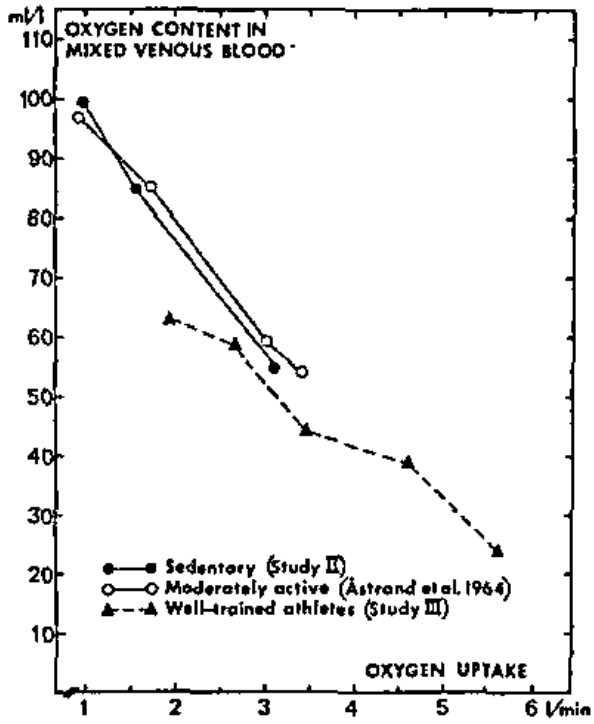

Fig. 14. Mean values of calculated oxygen content in mixed venous blood in relation to oxygen uptake during subamaximal and maximal exercise. Same subjects as in Fig. 13.

blood at the same submaximal oxygen uptake, but the causes for this are different. As for the athlete it depends on an effective distribution of offered oxygen from the heart, while the circulation in the cardiac patient may be hypokinetic due to some myocardial or other reason.

Acknowledgements

The work which is reported on in this paper was carried out during the years 1964 to 1968 at the Department om Physiology Gymnastik och Idrottshögskolan, Stockholm. I tender my grateful acknowledgement to Associate Professor *Per-Olof Åstrand* for his unfailing encourgement and guidance. I am also greatly indebted to Professor *Erik Hohwü Christensen,* Head of the Department and to Associate Professor *Bengt Saltin* for their interest, valuable advice and support during the course of the investigation.

To Dr. *Jesper Stenberg,* Dr. *Lars Hermansen,* Gym. dir. *Brittmari Wallström* and Fil. Lic. *Jan Karlsson* I express my sincere thanks for their pleasant collaboration.

Associate Professor *Wilhelm von Döbeln* gave me valuable help in making the statistical analyses.

I am also under a deep obligation to the entere staff af the laboratory for their untiring efforts and the very stimulating working environment of the laboratory.

To all the individuals who participated in the different investigations as subjects I wish to express my warmest gratitude.

This research project was suppported by financial grants from The Swedish Sports Federation, The Swedish Association against Heart and Chest Diseases, The Swedish Medical Research Council and its Defence Medical Section, and the special grant from The Karolinska Institute for the furtherance of the work of undergraduates of scientific faculties (number 18206).

Stockholm in March 1969.

PREFACE

The present work was carried out in 1967—1969 in the Department of Anatomy, University of Helsinki, under the supervision of the Head of the Department, Professor Olavi Eränkö, M. D., Ph. D. He suggested to me the subject of this investigation, which forms a part of the neurohistochemical project now in progress in this Department. I am deeply indebted to him for his valuable advice and for his unsparing help and guidance.

I also wish to thank Docent Arto Palkama, M. D., for reading the manuscript and for his advice and criticism.

My sincere thanks are due to numerous colleagues in the Department of Anatomy: especially to Dr. Aulikki Kokko, M. D., with whom I had the advantage and pleasure to co-operate in the field of histochemistry; to Mrs. Liisa Eränkö, Phil. Mag., Docent Martti Kormano, M. D., Dr. Antti Penttilä, M. D., Phil. Cand., Dr. Heikki Terävainen, M. D. for many stimulating discussions.

I should like to thank the members of the staff of the Department of Anatomy for their friendly and always helpful attitude; especially Mrs. Tuula Stjernvall, Miss Laila Hänninen and Mrs. Liisa Kangasvuo for preparing the specimens; Miss Helmi Palomäki, Librarian, for collecting the literature, and Mrs. Helmi Savolainen for the typing of manuscript.

The English text was checked by Miss Aino Wuolle, Phil. Mag., which I wish to acknowledge here.

The Department of Electron Microscopy, University of Helsinki, placed at my disposal the facilities for electron microscopy. I am very grateful to Professor Antti Telkkä, M. D., Head of that Department, and to Mr. Mauri Nyholm, Phil. Mag., for much help on practical matters. The Institute of Photography, University of Helsinki, prepared part of the prints, and I take this opportunity to thank its staff for their helpful co-operation.

Last but not least, I owe thanks to my family, especially my husband Tapani, for their constant encouragement during this study.

Helsinki, April 1969

Leena Rechardt

INTRODUCTION

A century ago Meynert (1869) described a paired hypothalamic group of nerve cells, which he called »basale Opticus-ganglion». Lenhossék (1887) introduced the term nucleus supraopticus (SON), and this term is now generally accepted.

In the mammals, the SON is formed by closely packed, large nerve cells laterocaudally to the optic chiasma. In the rat, some diffusely scattered large nerve cells form an accessory SON above the main SON (Scharrer and Scharrer 1954).

These nerve cells show several peculiar features which suggest functions other than impulse conduction. On the basis of the pioneer work of Scharrer and Scharrer (1945, 1954) and further studies by Bargmann (1949) and Bargmann *et al.* (1950), it was established that the SON nerve cells were secretory. With various basic stains, *e.g.* chrom-alum haematoxylin (Gomori 1941a), aldehyde fuchsin (Gomori 1950), Alcian blue (Adams and Sloper 1955), and paraldehyde thionin (Huber 1963), it was possible to reveal typical material in the supraoptic nerve cells. This was subsequently called »Gomori-positive material» or neurosecretory material (NSM). With these staining techniques it was possible to demonstrate a nervous pathway from the SON to the neurohypophysis. The nerve terminals, which also showed NSM in their interior, ended in the pericapillary spaces of the neurohypophysis. Some axons were reported to terminate in the capillary loops of the portal system (Arko and Kivalo 1958).

In 1924 Abel reported the existence of two hormone-like substances in the mammalian hypothalamus and in the neurohypophysis, and the production of vasopressin and oxytocin has since been related to these neurons. An extensive literature is available on the morphology, bio- and histochemistry of the SON (*e.g.* Heller and Clark 1962, Stutinsky 1967).

Comprehensive light and electron microscopic studies by Eneström (1967) and Streefkerk (1967) dealing with the rat SON contributed to elucidate mainly the morphological correlations of the neurosecretory cells in normal and experimental conditions. Nerve terminals, capillaries and glial elements of the SON area have aroused minor interest (Zambrano 1968). In the present study, some aspects dealing with those structures and especially the innervation of the neurosecretory cells and adjacent nerve fibres will be examined.

Although the enzyme histochemistry of the SON has been widely studied by light microscopy in normal rats and in rats subjected to various experimental conditions (Eränkö 1951a, Pepler and Pearse 1957, Kivalo *et al.* 1958, Uemura 1965, Pilgrim 1967), no ultrastructural histochemical studies on rat SON are available, except for one dealing with acid phosphatase activity in normal rat SON (Osinchak 1964a). There are, however, biochemical observations on several enzymes in the SONs of osmotically stressed rats (Kobayashi *et al.* 1962, Jongkind

1967, 1969, Ferreyra Moyano 1967). Light microscopic and biochemical findings on the enzyme activities have been controversial to some extent.

The development of new perfusion fixation methods for electron microscopy of brain tissue (Palay *et al.* 1962, González Aguilar and De Robertis 1963) and advances in histochemistry (*e.g.* Wood and Barrnett 1964, Adams 1965) have made possible the demonstration of several enzymes or enzyme groups in nervous tissue. Therefore it appeared likely that useful information might be obtained by studying the electron microscopic histochemistry of the neurosecretory cells under normal and experimental conditions. The present study was undertaken to find such information on some of those enzymes which can be demonstrated electron microscopically with the methods currently available.

I. ULTRASTRUCTURE OF THE SUPRAOPTIC NUCLEUS OF NORMAL AND DEHYDRATED RATS

REVIEW OF THE LITERATURE

LIGHT MICROSCOPIC OBSERVATIONS

Structural peculiarities of the cells in the SON suggesting that these cells are not ordinary nerve cells were first observed by Collin (1931), Scharrer and Gaupp (1933), Scharrer and Scharrer (1940), Scharrer *et al.* (1945). They assumed the multipolar nerve cells of the SON to be secretory and introduced the term neurosecretion, previously used by some other authors (see Scharrer and Scharrer 1940) to explain the presence of certain granules in other nerve cells.

Early efforts to find signs of neurosecretion in the SON of the rat often failed until methods were developed by which the secretory granules could be more selectively demonstrated. The cells of the rat SON were studied with such methods by Ortmann (1951), Eränkö (1951b), Stutinsky (1952) and later by many others (see *e.g.* Diepen 1962 a, Enestrom 1967, Streefkerk 1967). Eränkö (1951b) found two different types of nerve cells: light and dark cells. The dark cells were smaller and stained more intensely with basic dyes. Later Zambrano and Mordoh (1966) confirmed this finding and related it to the secretory rhythm of the cells. Enestrom (1967) described A-cells and B-cells on the basis of their staining qualities and electron microscopic appearance.

The neuronal character of the cells of the SON was determined at the light microscopic level by the existence of neurofilaments, Nissl substance and axon cylinders leading to the neurohypophysis (*e.g.* Scharrer and Scharrer 1954, Diepen 1962b).

Release of antidiuretic hormone can be induced by depriving the animals of water or by injecting hypertonic solutions. Several reports deal with the structural changes thus caused in the SON: increase in the cellular, nuclear and nucleolar volumes, increase in the ribosomal content and loss of neurosecretory material was demonstrated light microscopically by Hillarp (1949), Ortmann (1951), Eichner (1952), Edström and Eichner (1958), Ifft and Berkowitz (1965), whereas a loss of Nissl substance was reported by Bargmann (1954), Scharrer and Scharrer (1954) and Bachrach (1957).

ELECTRON MICROSCOPIC OBSERVATIONS

Ultrastructural studies of the SON were made possible by the development of suitable methods for the fixation of brain tissue. In 1960 Palay described in detail the ultrastructure of the preoptic nucleus of the gold fish. He used an OsO_4 perfusion technique for fixing the tissue. Since then the homologous nuclei have been studied in amphibia (Murakami 1964), in reptiles (Murakami 1961), and in birds (Nishioka 1967). The SON was described in the mouse by Murakami (1962), in the dog by Sloper and Bateson (1965) and Zambrano and De Robertis (1967), and in the rat by Duncan and Alexander (1961), Osinchak (1964b), Nemetschek-Gansler (1965), Sloper and Bateson (1965), Zambrano and De Robertis (1966), Enestrom (1967) and Streefkerk (1967). In these studies, the various cytoplasmic organelles were the targets of main interest, above all the so-called »neurosecretory elementary granules» and their possible site of formation.

Peterson (1965) called attention to the synapses between the neurosecretory cells and nerve terminals in the rat SON and found relatively few terminals. Polenov and Senchik (1966) were the first to report the presence of agranular and granular synaptic vesicles in the axo-somatic synapses of the mouse SON (Polenov and Senchik 1966). Enestrom and Svalander (1967) and Zambrano (1968) recently reported observations on synapses in the rat SON.

Nemetschek-Gansler (1965), Zambrano and De Robertis (1966), Enestrom (1967) and Streefkerk (1967) described ultrastructural changes in neurosecretory cells after dehydration. Proliferation and vacuolation of the endoplasmic reticulum, together with an increase in the amount of ribosomes, was found in all these studies. Observations concerning the disappearance and reappearance of neurosecretory elementary granules during and after dehydration were controversial to some extent (see Zambrano and De Robertis 1966, Streefkerk 1967).

MATERIAL AND METDODS

For this part of the present study, 55 adult male rats of the albino Sprague-Dawley strain, weighing about 300 g, were used. The studies were carried out between September and June. The rats were kept in the daytime under artificial illumination. The control rats received dried food and water *ad libitum*. The rats to be dehydrated for 3, 5 or 7 days were given only dry food. The rats were weighed before dehydration and before being sacrificed.

Perfusion-fixation was carried out under Nembutal (50 mg/kg body weight i.p.) anaesthesia. Several fixation fluids at room temperature were used: (a) 3.5 % formaldehyde *pro analysi* grade (E. Merck AG., Darmstadt) in 0.075 M phosphate-buffered 0.3 M sucrose, (b) 2.5 % glutaraldehyde (Taab Laboratories, Emmer Green. Reading. England) in 0.1 M phosphate buffer, (c) 2.5 % glutaraldehyde and 1 % formaldehyde in 0.1 M phosphate buffer, a modification of Karnovsky's (1965) fixative and (d) 2 % potassium permanganate in 0.1 M phosphate buffer, a modification of Richardson's (1964) fixative. The pH of all these fixatives was adjusted to 6.9, and the respective approximate osmolalities were (a) 1300, (b) 470, (c) 700 and (d) 350 mOsM, determined by osmometer.

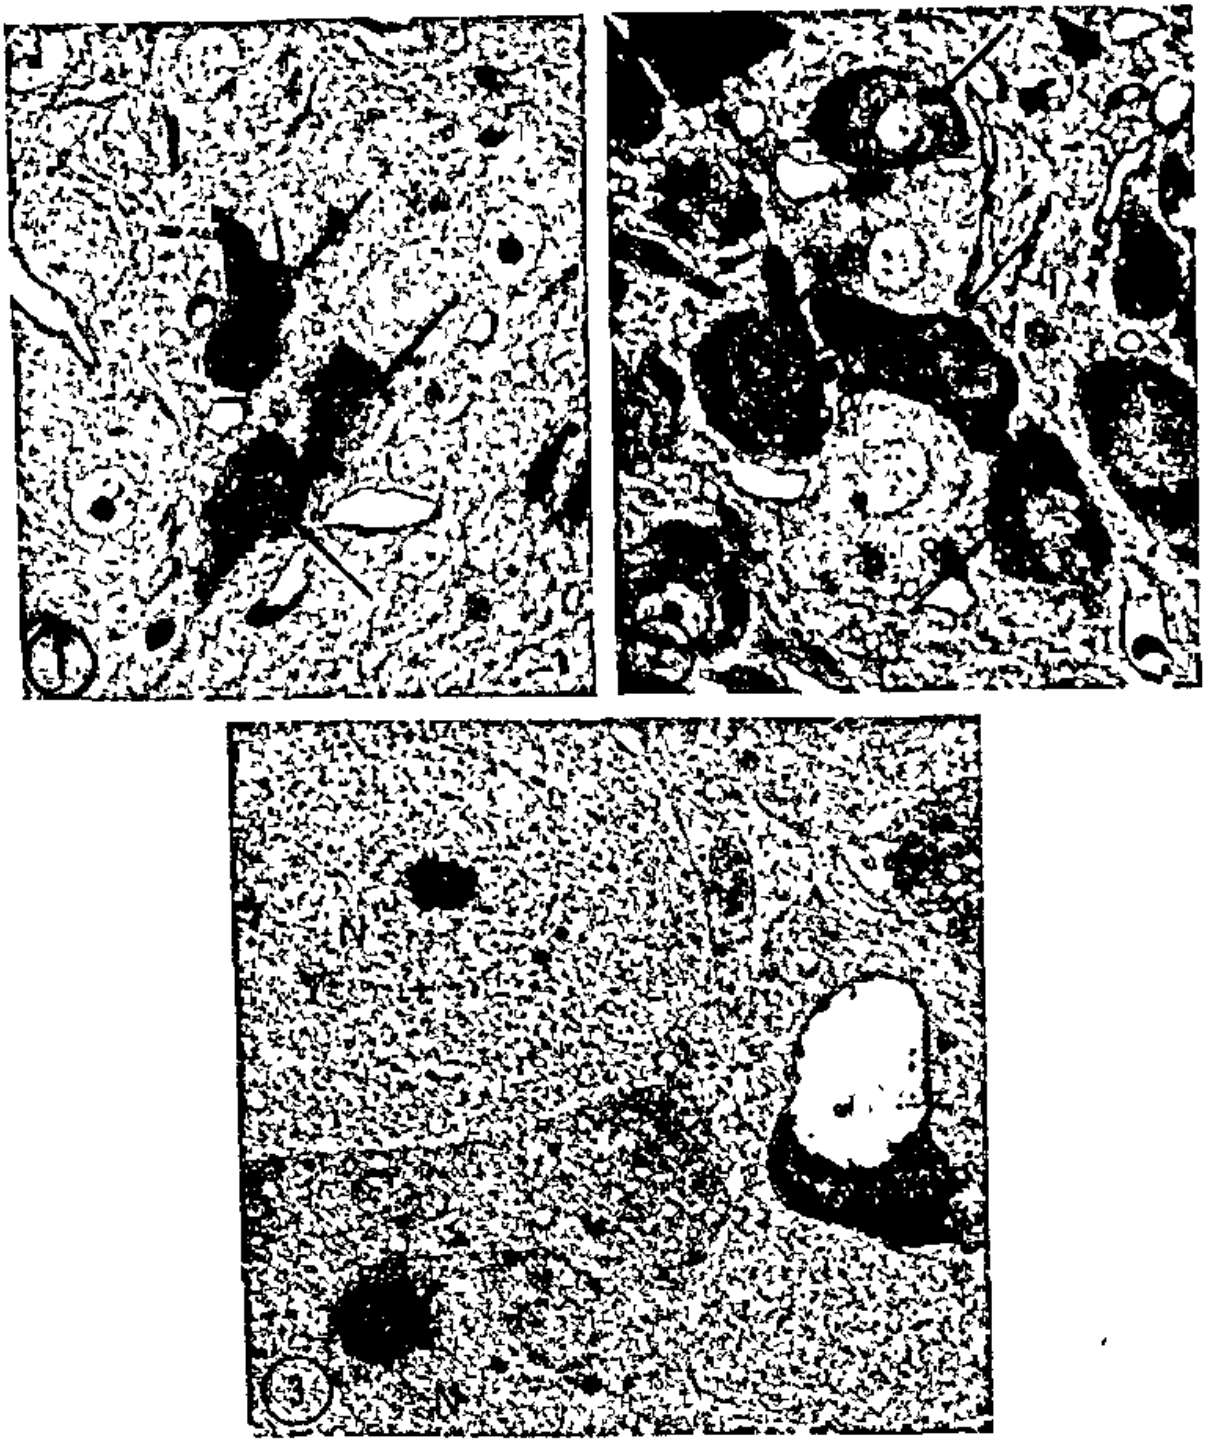

Fig. 1 Light microscopic view of the neurosecretory cells in control rat SON. Three fusiform dark neurosecretory cells, pointed by arrows, are seen among the light neurosecretory cells. Specimen perfused with Karnovsky's fixative and refixed with OsO_4 Toluidine blue stained Epon section × 750

Fig. 2 Light microscopic view of the neurosecretory cells in rat SON after 7 days' dehydration. Several dark neurons, pointed by arrows, surround two light nerve cell bodies. Note enlarged size of the cells. Specimen processed as in Fig. 1. × 750

Fig 3 Two types of neurosecretory cells in control rat SON. The neurosecretory cells are interconnected with a thin glial sheet. Note the different shade of the nucleus in the dark cell compared to the nucleus in the light cell above. Specimen glutaraldehyde perfusion fixed and refixed with OsO_4. Poststained with uranyl acetate and lead citrate × 3000

A simple blood transfusion apparatus consisting of a bottle, drop-enlargement and clamped tube was used in the perfusion procedure. The bottle was raised to obtain a hydrostatic pressure of 115 cm of the perfusion fluid, and perfusion speed was about 20 drops per minute. The perfusion was performed either *via* the abdominal aorta or intracardially *via* the left ventricle without any artificial respiration. Both external jugular veins were opened just before the perfusion was started. The abdominal aorta was clamped if intracardial perfusion was used. When glutaraldehyde or potassium permanganate was used, a prewash perfusion with 20 cc physiological saline at 39°C was administered. Perfusion time was 15 minutes. The brain was dissected out immediately after perfusion.

Thin slices of the hypothalamus containing both supraoptic nuclei were cut with a razor blade. Fixation was further prolonged by immersion of these slices for 3 hours at 4°C in the same fixative as used for perfusion. Pieces were then dissected out under a stereo-microscope containing only the SON and the optic chiasma, and these pieces were further fixed for one hour in ice-cold OsO_4 fixative as described by Rhodin and Zetterquist (Rhodin 1954). This postfixation step was omitted in potassium permanganate-fixed specimens.

After a short dehydration procedure, described in detail by Kokko and Rechardt (1968), the pieces were embedded in Epon epoxy resin (Luft 1961) and sectioned with an LKB Ultrotome. The SONs of two rats were cut serially into 1 μ sections, stained with toluidine blue, and studied under a light microscope. The resin block was further trimmed so that a small part of the optic chiasma was left in every block. Silver or grey sections were cut with an LKB Ultrotome and stained on grids with uranyl acetate and lead citrate (Watson 1958), or with lead citrate alone (Reynolds 1963). The sections were viewed and photographed with Siemens Elmiskop I and Philips EM 200 operated at 80 kV.

RESULTS

The mean weights of the rats dehydrated for 3, 5 or 7 days were reduced to 85, 81 or 68 per cent of the original, respectively. After 7 days' dehydration the rats were ataetic, soporific and cachectic.

ELECTRON MICROSCOPIC OBSERVATIONS

Techniques

Perfusion fixation proved to be essential for good structural preservation of the SON. In preliminary studies, in which only immersion fixation was used, an enlarged extracellular space, swollen mitochondria and loose myelin layers were observed. A comparison of aortic and intracardial perfusion techniques showed no differences in the fine structure of the SON, using the neurosecretory elementary granules and the granular synaptic vesicles as criteria. Preperfusion with physiological saline was necessary before glutaraldehyde or potassium permanganate. If omitted, red blood cells were found in the capillaries, and the ultrastructure was inferior.

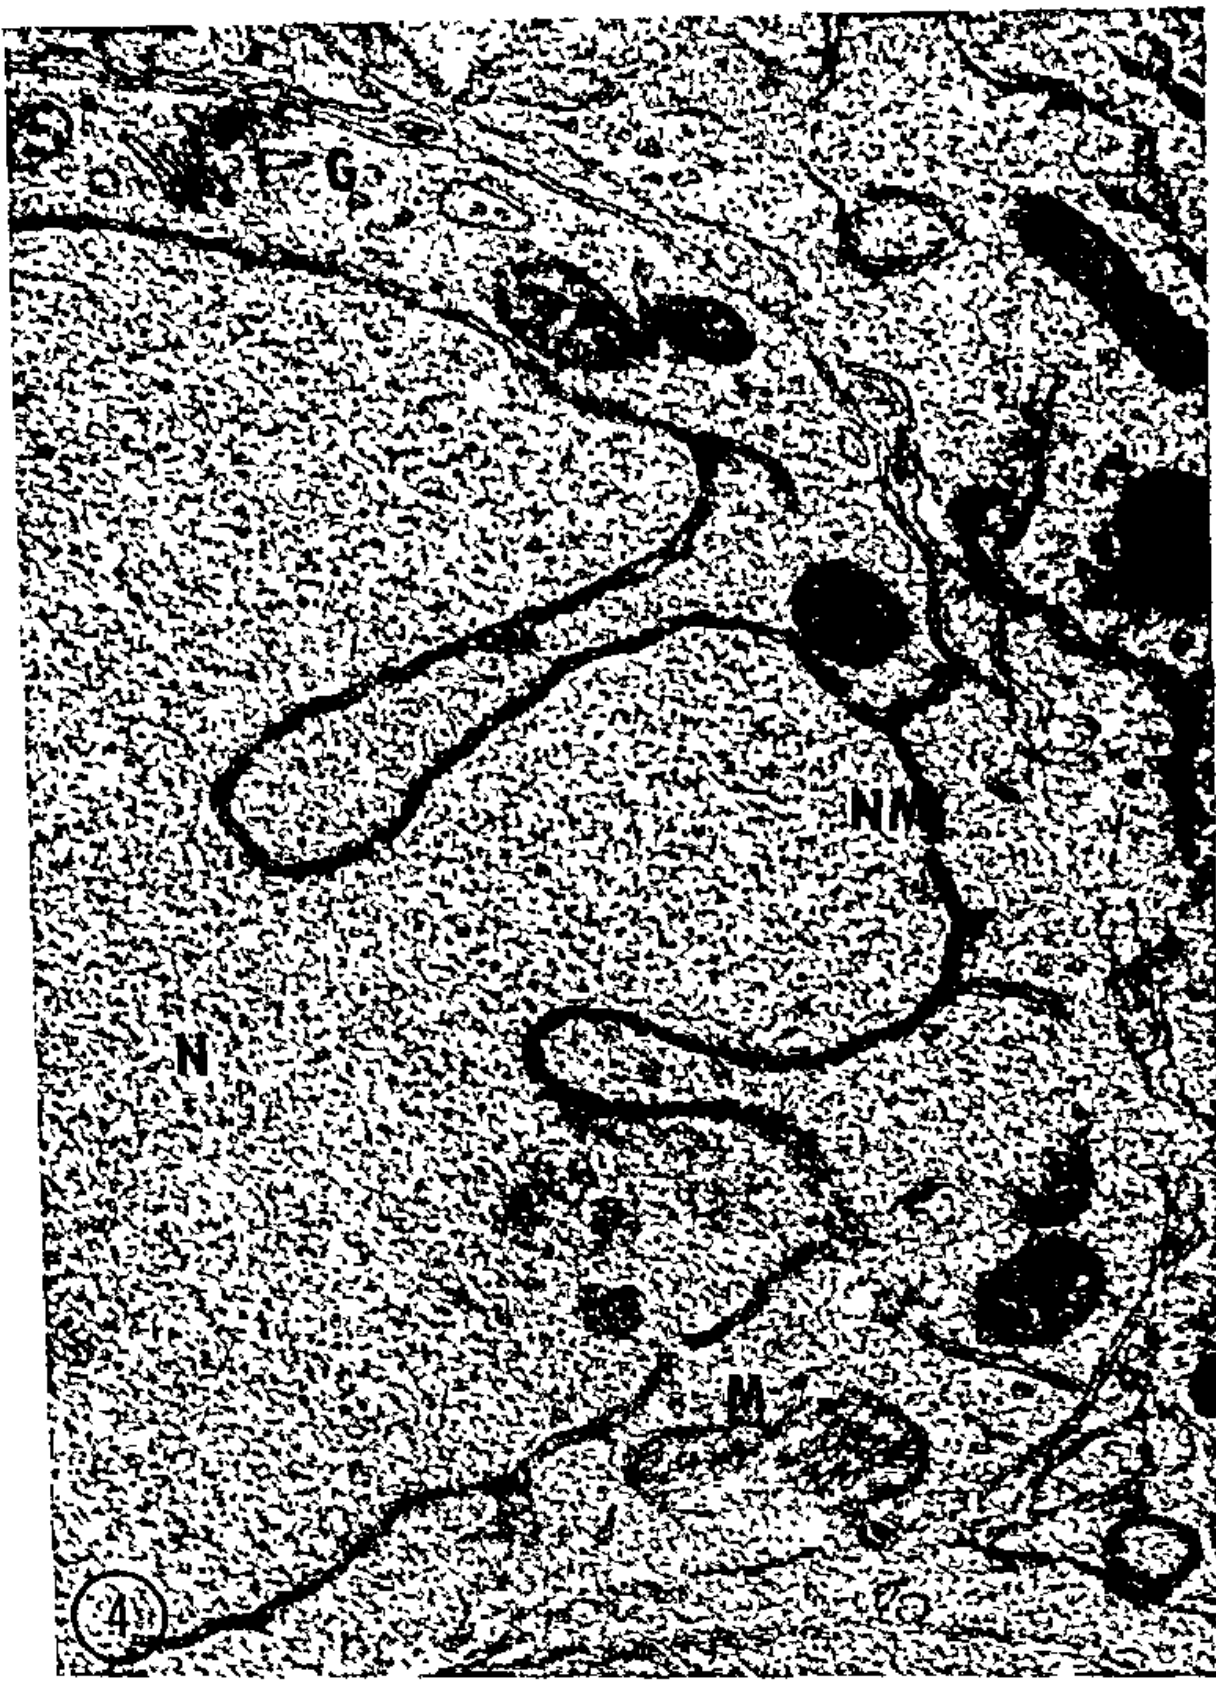

Fig. 4 A view of the nuclear membrane of neurosecretory cell in control rat SON. Nuclear indentations, pores and budding of the endoplasmic reticulum from the nuclear membrane are demonstrated in this potassium permanganate-fixed specimen. Poststained with lead citrate. × 28 000

The neurosecretory cells

When formaldehyde- and glutaraldehyde-containing primary fixatives were employed, two types of neurosecretory cells were found, light and dark cells (Figs. 1 and 3). (a) The light cells were larger and circular or oval in shape. The nuclei of these cells were large, pale and eccentrically placed.

(b) Only a few dark cells were found. These were randomly scattered amongst the light cells. The dark cells were smaller and fusiform. The nuclei were smaller than those of the light cells and their electron density was more homogeneous.

The main criterion between light and dark cells was the relative number of free ribosomes. When potassium permanganate was used as a fixative, no difference was observed in the density of the cell cytoplasm.

After dehydration the size of both light and dark cells increased considerably (Fig. 2). This seemed to be due to the proliferation of the endoplasmic reticulum, which showed dilatation of cisternae and increase in the number of free ribosomes (Fig. 8). The increase of cell size was already observed after 3 days' dehydration, and it appeared about equal to that noticed after 7 days. Numerous intercellular contacts were seen. Disappearance of glial elements between the cells was noticeable. The space between the neurosecretory cells and the capillaries was, however, wider, and the glial elements in this space were more voluminous than in the control sections, as seen in Figs. 10 and 19.

The nuclei of normal control cells often showed several infoldings and protrusions, especially in potassium permanganate-fixed specimens. Nuclear pores and the budding of endoplasmic reticulum of the nuclear membrane is clearly seen in Fig. 4.

After dehydration, the relative size of nuclei appeared to increase. The nuclei became rounded and lost their indentations (Figs. 8 and 9). These changes were observed after 3, 5 or 7 days' dehydration. The nucleolus became prominent and its size increased (Fig. 9).

Endoplasmic reticulum

The endoplasmic reticulum was mainly granular and it was situated at the periphery of the cells, forming parallel cisternae. In the dark cells, free ribosomes were especially abundant and the cisternae appeared more dilated than those in the light cells (Fig. 5). In potassium permanganate-fixed tissues a parallel arrangement of the cisternae was seldom seen. Instead, the cisternae were dilated in all cells, ribosomes were not visible using this fixative (Fig. 12).

After 3 days' dehydration the endoplasmic cisternae of the light cells appeared vacuolated and the number of free ribosomes appeared increased (Fig. 11). In the dark cells the endoplasmic reticulum was essentially unchanged even after 5 days' dehydration. After 7 days' dehydration there was an abundance of free ribosomes between the cisternae and the electron-dense material inside them, and this made the dark cells appear even darker than in the control rats (Figs. 8 and 3).

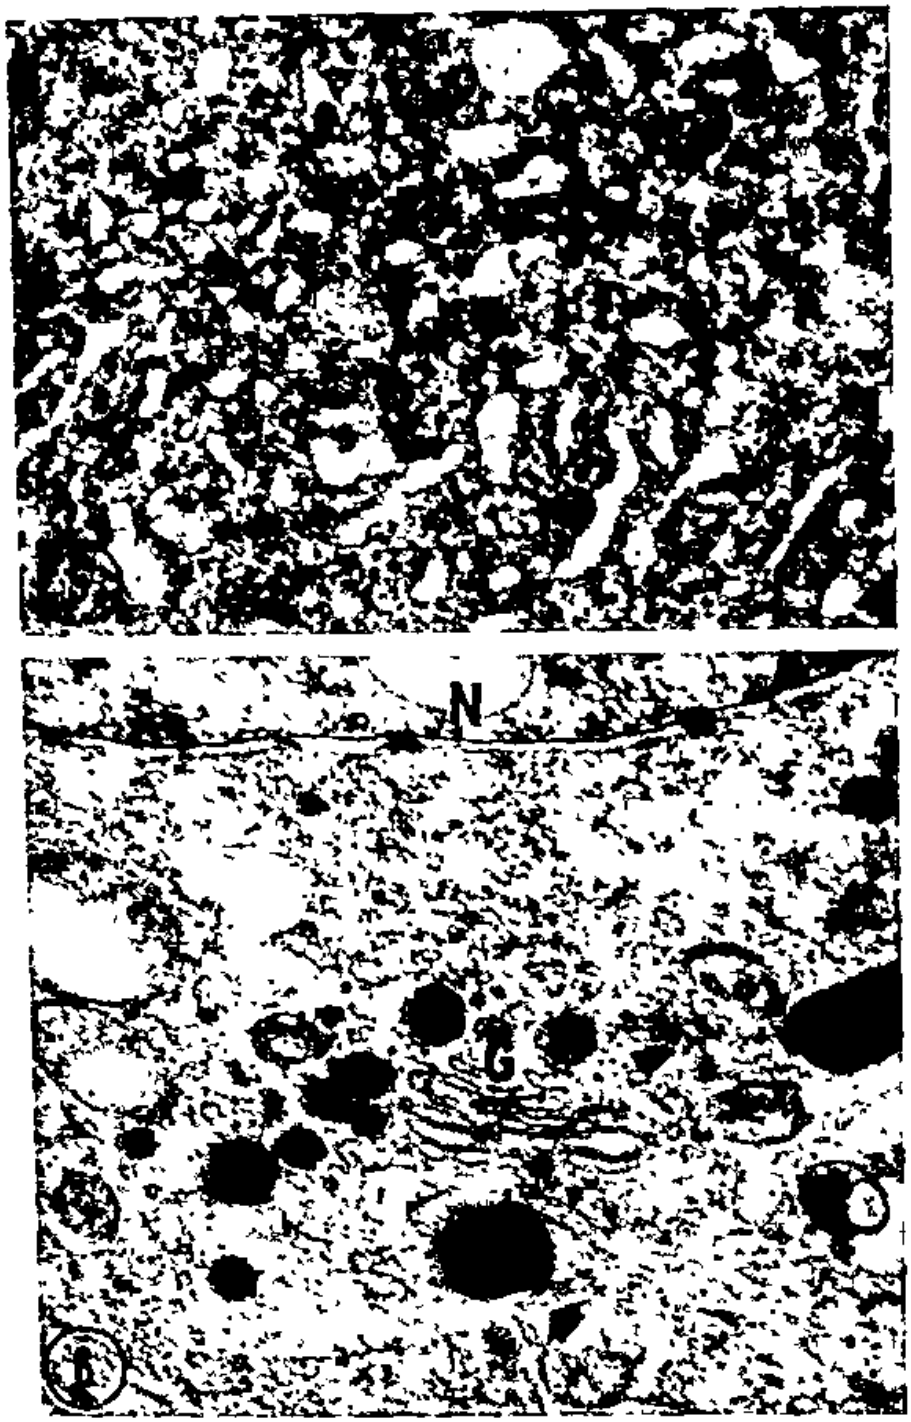

Fig. 5 A higher magnification from the periphery of a dark neurosecretory cell in control rat SON.
The endoplasmic cisternae are dilated and between them there are a great number of numerous rosettes formed by free ribosomes. Specimen processed as in Fig. 3. × 25 500

Fig. 6 Small inclusion bodies in proximity to the Golgi apparatus in a light neurosecretory cell of control rat SON.
The small inclusion bodies, about 1100 Å in diameter, have central cores which show different osmiophility. The arrow indicates a large inclusion body of type I. Specimen processed as in Fig. 3. × 39 900

The Golgi apparatus

The Golgi apparatus consisted of flattened cisternae with associated small vesicles. There were only a few large vesicles in association with the Golgi apparatus (Fig. 6). In potassium permanganate-fixed tissues, the Golgi apparatus was very prominent.

Compared with the controls, flattened vesicles were more numerous even after three days' dehydration in both types of neurosecretory cells. Empty vesicles were observed in the vicinity of the Golgi cisternae, as seen in Fig. 11.

Mitochondria

Most mitochondria were oval and varied in length from 0.3 μ to 1.0 μ. The light and dark cells were not found to differ in number or appearance of the mitochondria. The cristae were generally arranged transversally (Fig. 7); only occasionally there were longitudinally arranged cristae. Preservation of mitochondria was equally good using both formaldehyde and potassium permanganate fixatives, as seen in Figs. 7 and 4. In glutaraldehyde-fixed tissue it was usual to find swollen mitochondria (Fig. 6) with reduced number of cristae.

The shape,size and number of mitochondria did not change after dehydration.

Inclusion bodies

a) *Large bodies.* — Two types of large inclusion bodies were demonstrated. *Type I* bodies were very electron-dense and oval bodies with homogeneous contents and surrounded by a single unit membrane (Fig. 7). The size of these bodies varied from 0.5 μ to 1.0 μ.

Type II bodies were round, approximately 1.0 μ in diameter and vacuolated. They were surrounded by a single membrane and contained 1—5 vacuoles (Fig. 7). This type was rare.

The number of large inclusion bodies appeared to be unchanged in both light and dark cells after 3, 5 and 7 days' dehydration.

b) *Small bodies.* — Round or slightly oval small inclusion bodies were observed in the light and dark cells. They were mostly scattered round the nucleus or in the neighbourhood of the Golgi apparatus. These small bodies were approximately 1100 Å in diameter and were surrounded by a unit membrane. Inside this membrane there was a clear zone of 150Å. The central cores were of variable electron density, and small inclusion bodies of different shades were usually seen in the cell, as illustrated in Fig. 6.

In potassium-permanganate-fixed tissue only empty vesicles, all of the same size, about 700 Å, were found in the area of the Golgi apparatus. When formaldehyde- and glutaraldehyde-fixed tissue was compared, no outstanding difference was found in appearance, shade or size of the small inclusion bodies.

After 3 days' dehydration a distinct decrease was observed in the number of small inclusion bodies. Empty vesicles of the same size were found instead at the ends of the flattened Golgi vesicles, as seen in Fig. 11. The disappearance of small bodies was almost complete after 5 or 7 days' dehydration (Figs. 9 and 8).

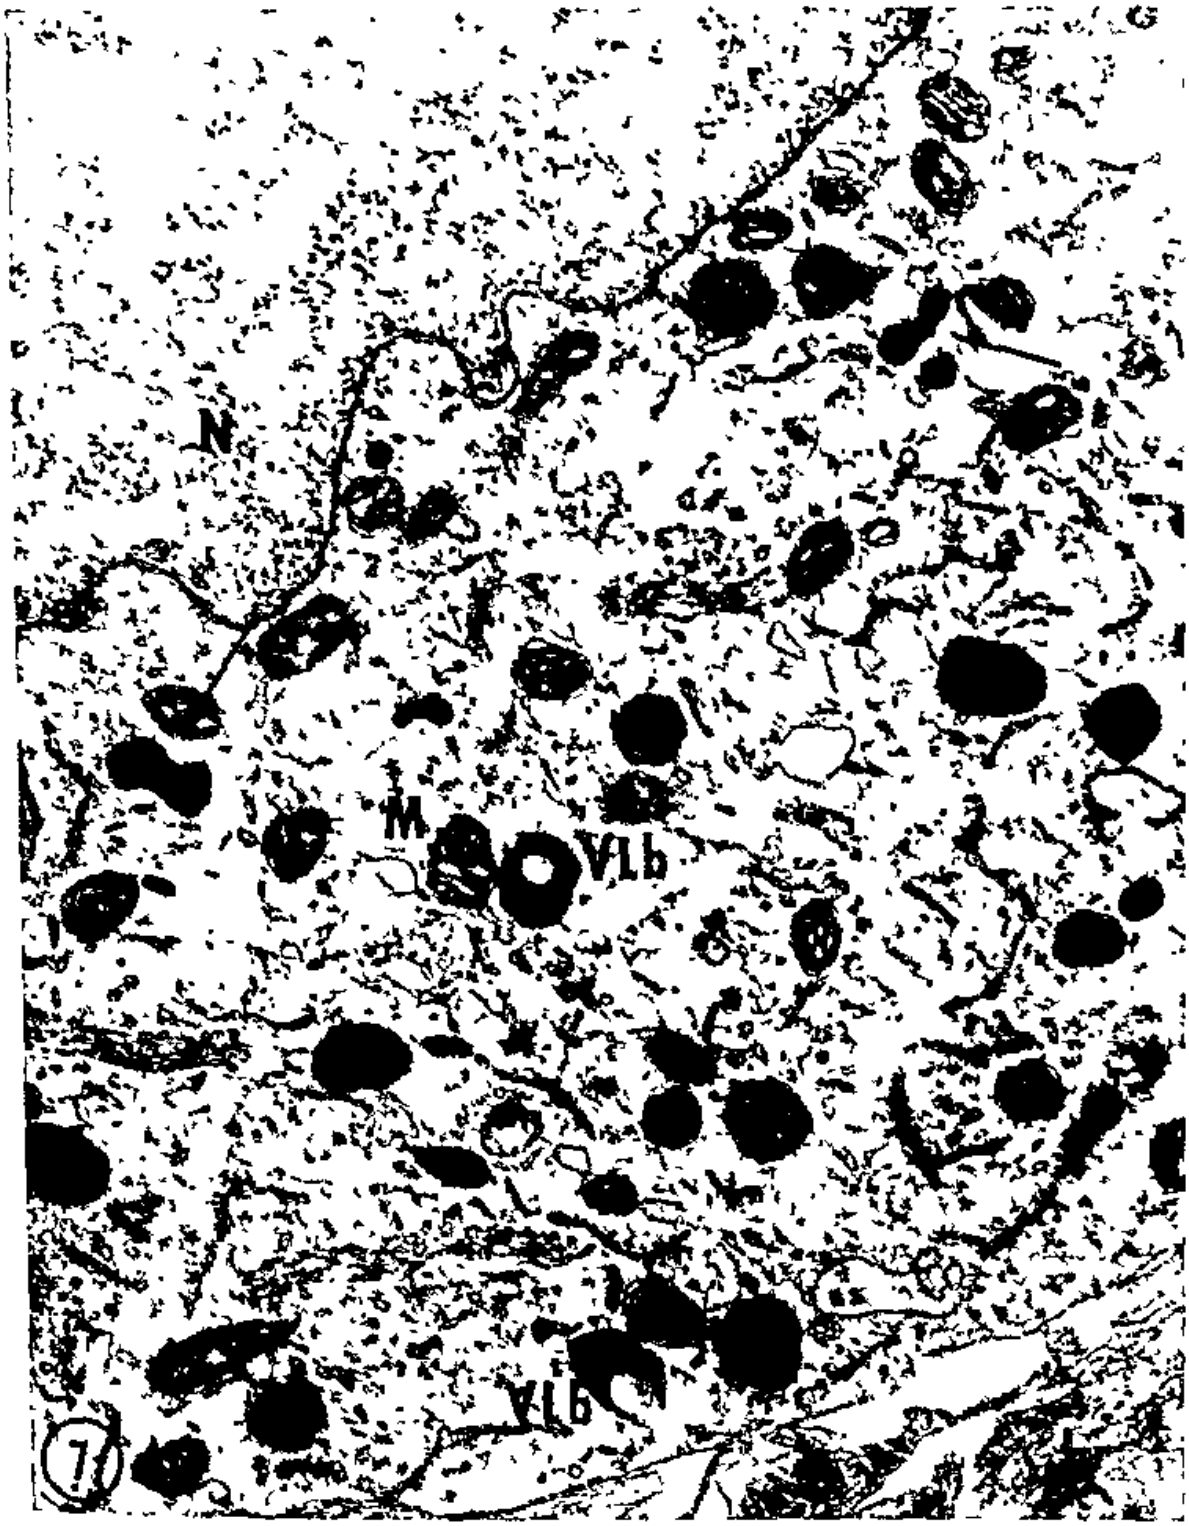

Fig. 7 Various cell organelles in the light neurosecretory cell of control rat SON. Several large inclusion bodies are scattered in the cytoplasm, two large bodies of type II are seen (VLb). The mitochondria have transversal cristae. The arrows point to budding inclusion bodies, probably of larger type. Specimen was formaldehyde perfusion fixed and refixed with OsO_4. Poststained with lead citrate. × 18 800

The nerve fibres

Neurosecretory cells and numerous capillaries occupied the bulk of the SON, the nerve fibres and glial elements being only minor constituents.

Axons and dendrites leaving the cell body were seldom present. However, Fig. 12 shows a neurosecretory cell with an axon branching off from it.

The axons of the SON neurosecretory cells were unmyelinated. Large axonal swellings, so-called Herring bodies, were often seen near capillaries. These contained round granules of different size and electron opacity (Figs. 16 and 17). These granules were larger than the small inclusion bodies in the neurosecretory cells and the large granulated vesicles in the synaptic endings. They were 1000—1750 Å in diameter. Neurotubules of 300 Å diameter, vesicles of various sizes, mitochondria and ribosomes were other components of the axonal swellings.

The dendrites showed a regular inner structure with neurotubules, long and slender mitochondria, vesicular membraneous structures and fragments of the endoplasmic reticulum (Fig. 15). The dendrites were densely covered by synapses.

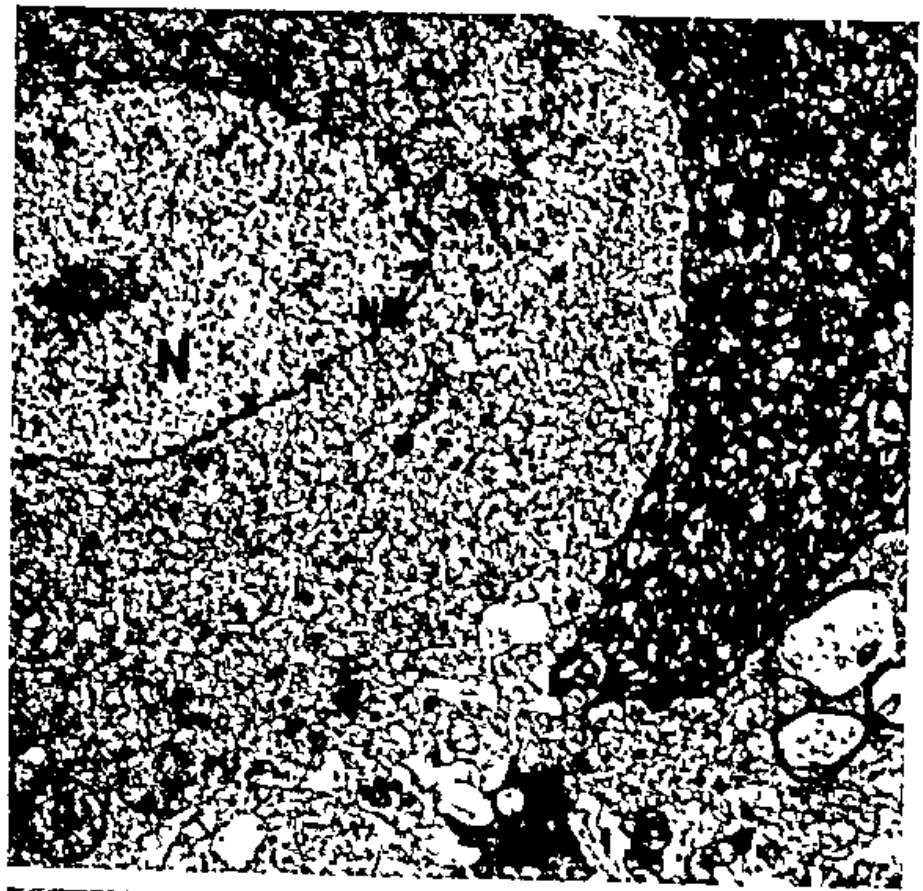
After 3, 5 or 7 days' dehydration, the large granules in the axonal swellings were larger (about 2000 Å) than in the control sections. Empty vesicles of the same size were abundantly present in the axonal swellings (Fig. 10).

Synapses

Three types of synapses were found in the SON: axo-somatic, axo-dendritic and axo-axonal synapses. In all these types three different kinds of vesicles were observed in axon terminals depending on the fixative employed.

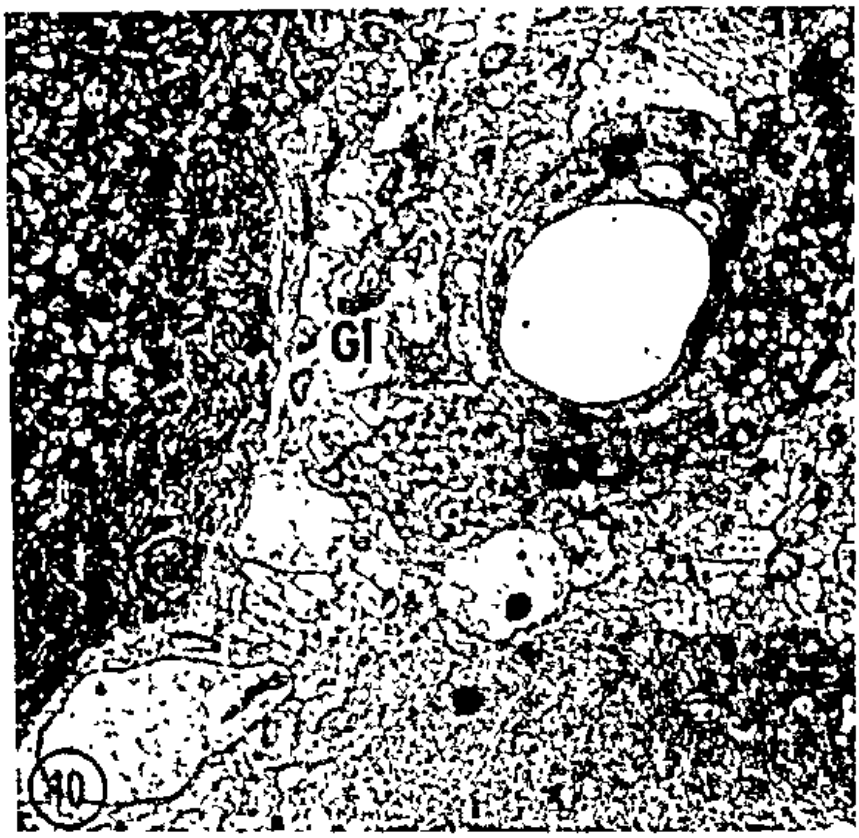
No distinct changes were observed in the synapses after dehydration, when compared to those in the control specimens.

Synaptic vesicles



The main part of axon terminals contained only agranular vesicles. In specimens fixed with formaldehyde and glutaraldehyde their size was 300—450 Å. In specimens fixed with potassium permanganate the diameter was 250—280 Å.

Large granular vesicles were demonstrated with all the fixatives used and their size varied between 800 and 1200 Å; when fixed with potassium permanganate it was 600—750 Å. Only two or three such vesicles were seen amongst the agranular vesicles in each axon terminal. The centrally located granule was about 600 Å in diameter (Figs. 14 and 15). The electron opacity of these granules varied greatly even inside one and the same axon.



Small granular vesicles were observed only in specimens fixed by potassium permanganate perfusion. They varied in diameter between 250 and 300 Å and occurred amongst the agranular vesicles (Figs. 12 and 13).

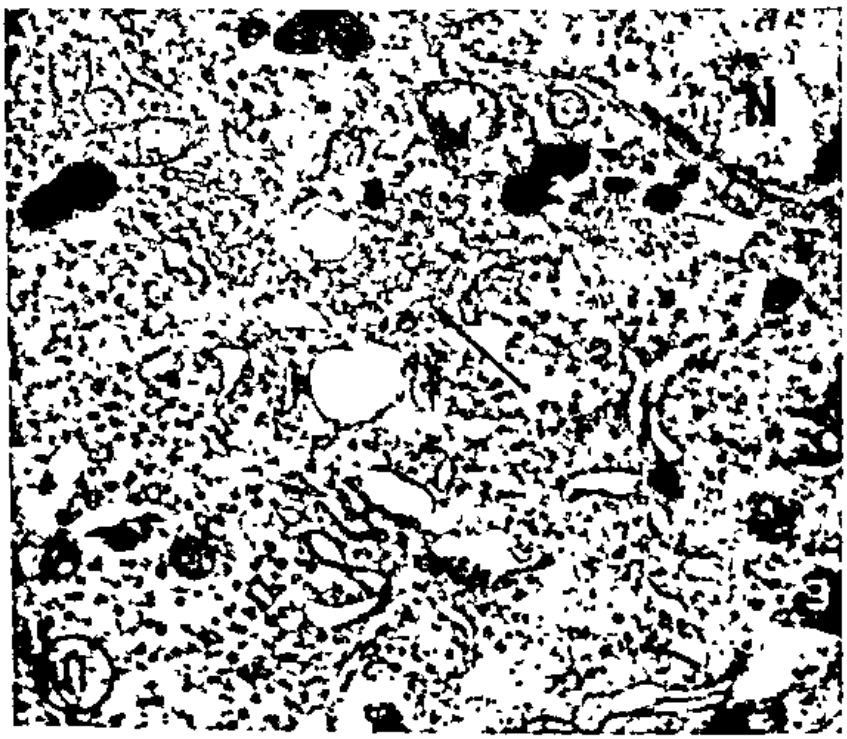


Fig. 8 A light and a dark neurosecretory cell in rat SON after 7 days' dehydration. Glial elements have disappeared between the neurosecretory cells and they lie in close contact with each other. The nuclear membrane has lost its indentations. Large inclusion bodies are seen in both of the cells, but small ones are almost completely abolished. The endoplasmic cisternae in the dark cell in the right side are filled with amorphous material. Specimen processed as in Fig. 3. × 5 100

Fig. 9 Nucleus and nucleolus in rat SON after 5 days' dehydration. The nucleus has become rounded. Note the very prominent nucleolus in this light neurosecretory cell. Only few small inclusion bodies are visible in these two light cells. Specimen processed as in Fig. 3 × 5 100

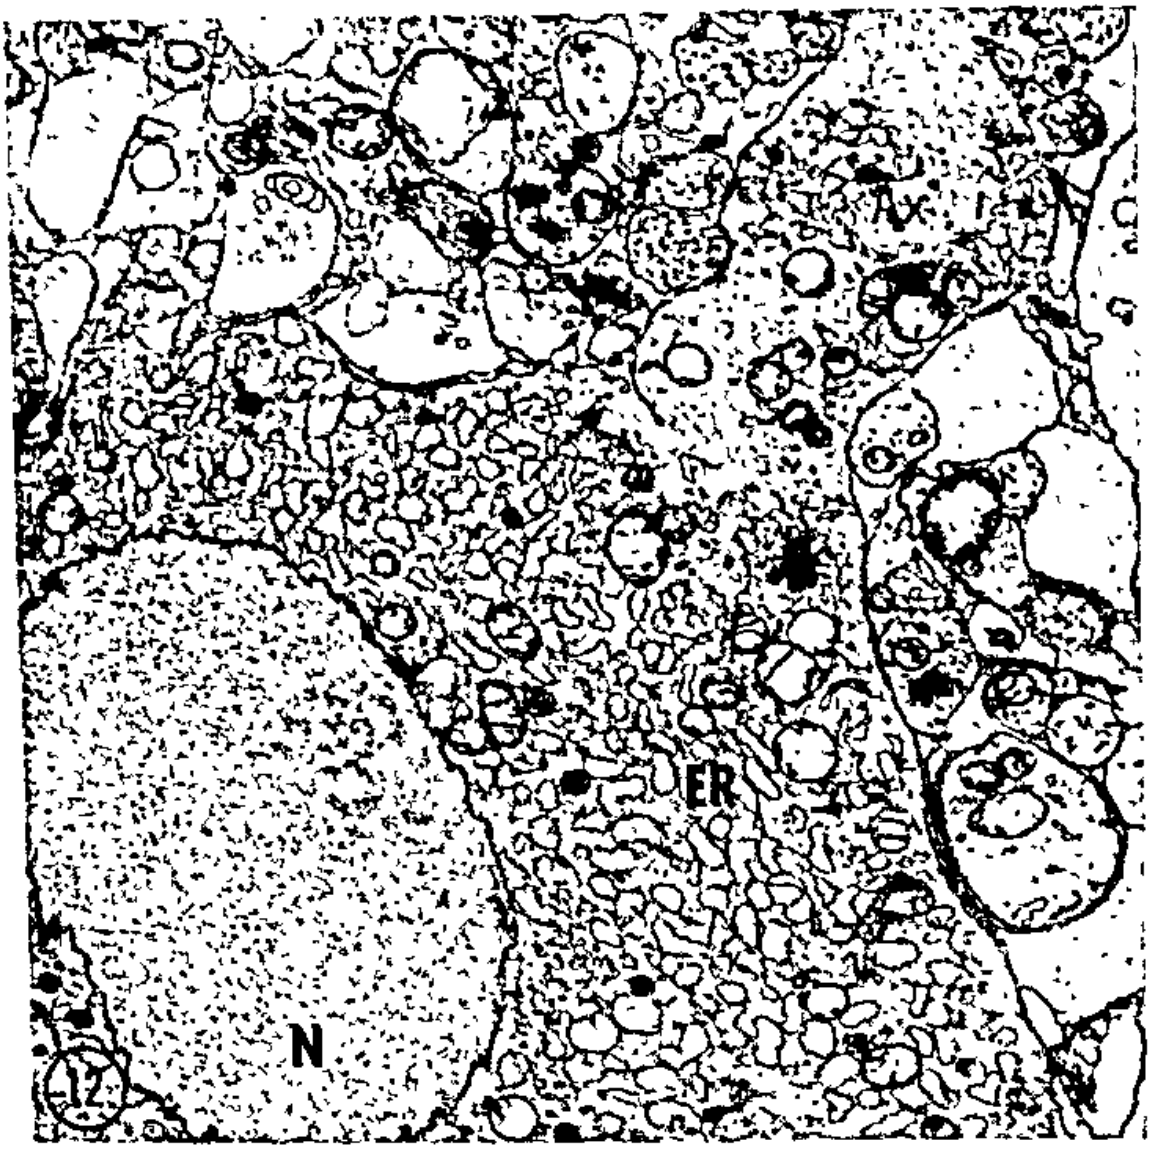

Fig. 10 General view of a capillary, glial tissue and two neurosecretory cells in rat SON after 7 days' dehydration.
Glial processes are increased round the capillary. They look pale and swollen. On the right and below the capillary an axon (Ax) is seen. It is filled with osmiophilic granules and empty vesicles of the same size. Specimen processed as in Fig. 3. × 5 100

Fig. 11 A view of a light neurosecretory cell in rat SON after 3 days' dehydration.
The amount of free ribosomes is increased and the endoplasmic cisternae, which look empty, are dilated. There are some small inclusion bodies, but in the proximity of the Golgi apparatus small empty vesicles are found (arrow). Specimen processed as in Fig. 3. × 25 000

Fig. 12 Neurosecretory cell with a branching nerve fibre. A thick nerve process is leaving the cell body. This is probably an axon with abundant endoplasmic cisternae. Several synaptic terminals are seen. Note the various vesicles inside them. Potassium permanganate perfusion and immersion fixed. No poststaining. × 13 600

Axo-somatic synapses

Only a small area of the neurosecretory cell surfaces was covered by synapses. These axo-somatic synapses contained only agranular vesicles or both small and large granular vesicles, as shown in Figs. 12 and 14. There was no difference in the number of synapses or in the proportion of the different vesicle types in the synapses ending on the light and dark cells.

Axo-dendritic synapses

The dendrites appeared to be covered very densely with synapses. Cross-sectioned dendrites showed several synapses containing all types of vesicles or only agranular ones. Typical axo-dendritic synaptic contacts are seen in Figs. 13 and 15.

Axo-axonal synapses

Synapses of this type were rare. When present, they were always located near a capillary (Fig. 16).

Capillaries

The fine structure of the capillary walls was found to be similar irrespective of the fixative used. However, the endothelial cells were more swollen after perfusion with glutaraldehyde or potassium permanganate than after perfusion with formaldehyde.

No fenestrations could be demonstrated in the endothelial cells, which showed but few pinocytotic vesicles. The basal lamina was about 400 Å thick and sometimes formed fingerlike indentations between the glial elements. When the specimen was adequately perfused, no perivascular space was noticed round the basal lamina. Some direct contacts between the neurosecretory cells and the capillaries were seen, although there were usually some glial end feet. The glial end feet were always situated between synapses and capillary walls. Axonal swellings with various granules were often found in the vicinity of the capillaries. They were not in direct contact with capillary walls (Fig. 17).

A pericyte sometimes surrounded the capillary wall, especially in the larger capillaries. Its nucleus stained intensely in the periphery, when glutaraldehyde fixation was used (Fig. 18). This type of glial cell was probably a protoplasmic astrocyte (Hartmann 1958, Palay 1958).

After 3, 5 or 7 days' dehydration the capillaries were narrowed and the endothelial cells became swollen. The basal lamina varied in thickness between 500 and 600 Å, *i.e.*, it was thicker than that in the controls. The glial elements round the capillaries appeared to be hypertrophied, swollen and pale (Figs. 10 and 19).

Glial cells

The glial cells occurred in perineuronal or pericapillary sites in the SON area. The predominant glial cell type was the protoplasmic astrocyte, as judged by

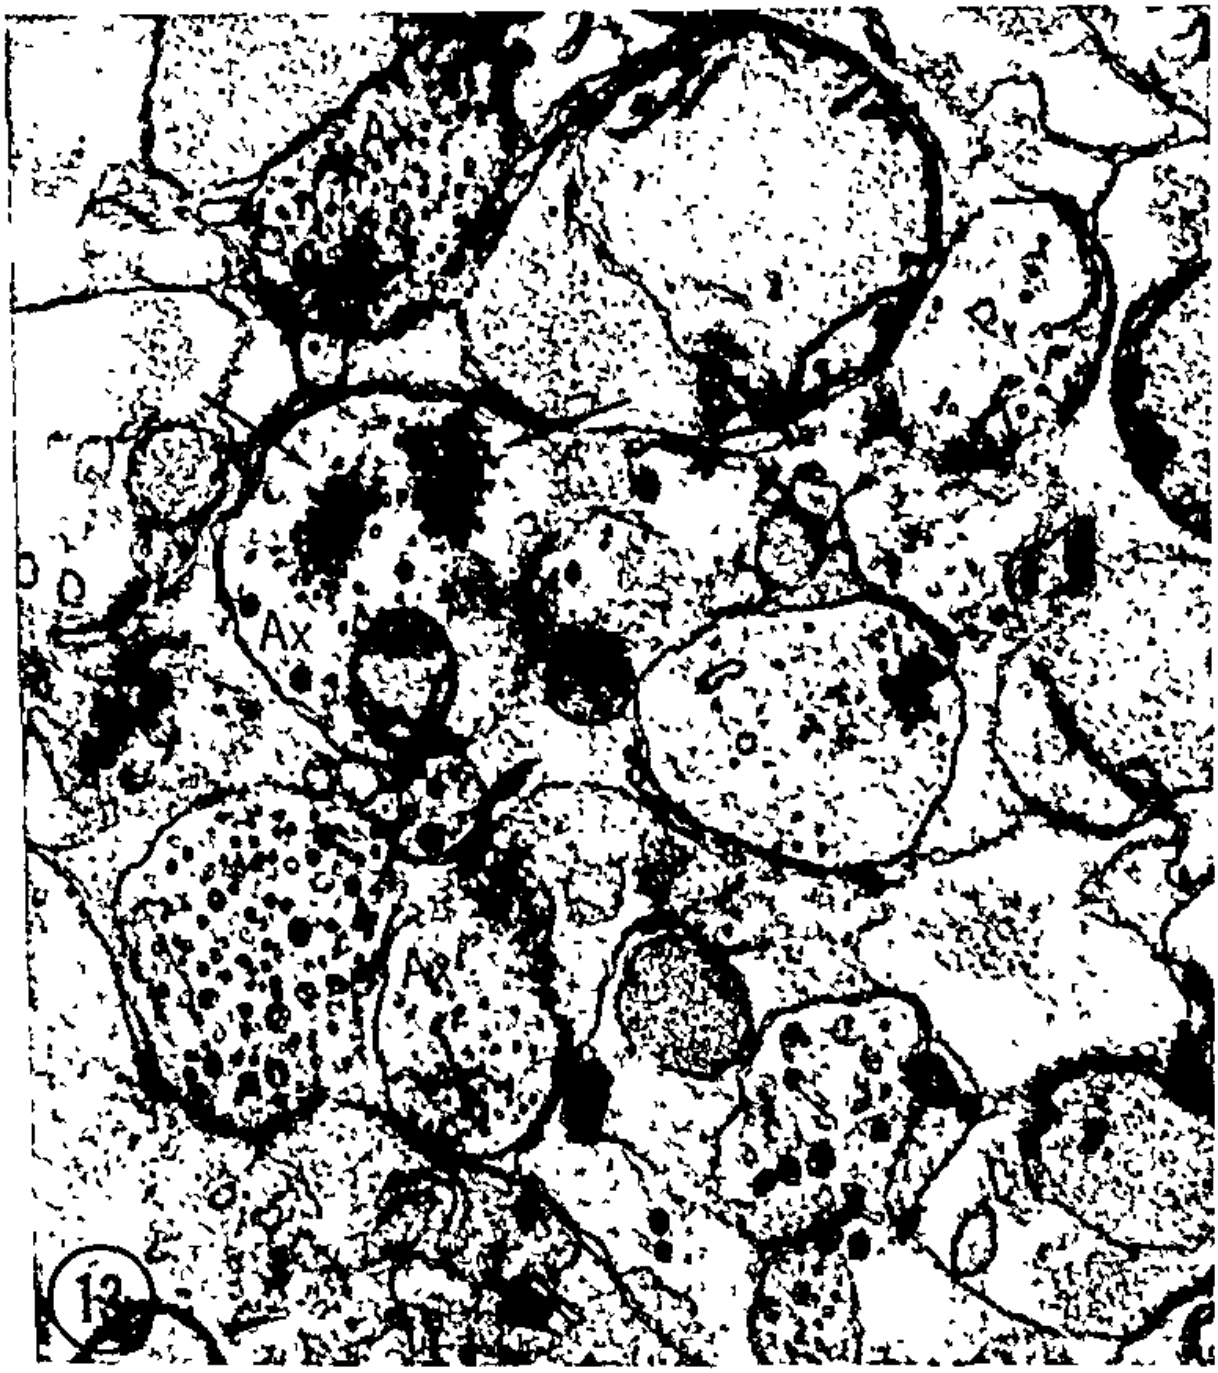

Fig. 13 Axo-dendritic synapses after potassium permanganate fixation. Among the agranular and large granular vesicles there are small electron dense vesicles. Sometimes these latter occur in groups, as indicated by the arrows. Specimen processed as in Fig. 12. × 42 500

electron microscopic criteria, which are not absolutely accurate (Hartmann 1958, Palay 1958). The scanty cytoplasm of these astrocytes consisted of endoplasmic reticulum, Golgi apparatus, a few mitochondria and lysosomes (Fig. 18).

In the vicinity of the optic chiasma, oligodendrocytes were sometimes found. No microglial cells were observed.

After dehydration, the number of glial cells was not found to be increased. The glial processes were, however, more numerous and appeared swollen and pale round the capillaries (Fig. 19). Between the neurosecretory cells the glial processes were narrow and tightly packed between the hypertrophic neurosecretory cells.

DISCUSSION

In the present study, fixation by perfusion was found to be clearly superior to immersion fixation, which was used by Enestrom (1967) and Streefkerk (1967). Indeed, perfusion fixation of nervous tissue has been strongly recommended by several authors (Palay 1960, Gonzáles Aguilar and De Robertis 1963 and Karlsson and Schultz 1965) as giving reliable and reproducible results. The perfusion technique was easy using a blood-transfusion apparatus described in the present study. All the fixatives were hyperosmolar compared to the osmolarity of the blood plasma. Potassium permanganate was used here for the first time as a perfusion fixative. Earlier it has been used exclusively as an immersion fixative (Luft 1956, Richardson 1966 and Hökfelt 1968).

Two types of neurosecretory cells were demonstrated both by light microscopy in toluidine-blue-stained epoxy resin sections and by electron microscopy. The existence of dark cells has been a matter of dispute. The dark cells have been ascribed to poor tissue preservation or to trauma due to tissue manipulation before immersion fixation (Mugnaini 1965, Wood 1967). There have been controversial reports concerning the heterogeneity of the neurosecretory cells in the rat SON. Zambrano and De Robertis (1966) found two different types of cells in formaldehyde perfused rat's SON. On the other hand, Nemetschek-Gansler (1965) did not find any difference between the cells in glutaraldehyde perfused SON. Only osmotically stressed rats' neurosecretory cells showed some variety. Enestrom (1967) described two types of cells in glutaraldehyde immersion fixed material, but Streefkerk (1967) found only one type of neurosecretory cells in SON immersion fixed in glutaraldehyde. Enestrom's (1967) A-cells are probably identical with the type II cells of Zambrano and De Robertis (1966) and with the dark cells described in the present study, in which the cell types were observed with all fixatives with the exception of potassium permanganate, which is known to dissolve proteins (Hake 1965).

A large amount of ribosomes was characteristic of the dark cells. Free ribosomes increased after 3, 5 or 7 days' dehydration. In the light cells a similar response was observed after 3 and 5 days' dehydration, but a decrease of ribosomes was noticed after 7 days' dehydration. This might reflect a failure of these cells in producing protein, or perhaps neurosecretory production occurs at this functional stage at the expence of the Nissl substance or endoplasmic reticulum (Bargmann

Fig. 14

1949, 1954, Nemetschek-Gansler 1965, and Zambrano and De Robertis 1966). No decrease of ribosomes was noticed in the dark cells. This is in agreement with the findings of Nemetschek-Gansler (1965).

Swollen mitochondria were sometimes found after primary glutaraldehyde fixation. These are probably attributable to the fixative itself and do not represent any special functional stages in contrast to what was proposed by Streefkerk (1967). With other fixatives the preservation of mitochondria was uniform. The size and shape of mitochodria did not change after dehydration. This is in agreement with the studies of Eneström and Hamberger (1968).

The large inclusion bodies found in the present study in both the light and the dark cells are possibly lysosomes, and the type II large inclusion bodies would fit into the category of multivesicular bodies (Palay 1960, Osinchak 1964a, Zambrano and De Robertis 1966). The function of lysosomes will be further discussed in Part IV.

The small inclusion bodies are interpreted as neurosecretory elementary granules by several authors (Palay 1960, Bern *et al.* 1961; see *e.g.* Streefkerk 1967). In the present study, these granules were often seen budding off from the flattened Golgi cisternae. This observation favours the theory that the neurosecretory granules, at least during the final steps, are processed by the Golgi apparatus, as suggested by Zambrano and De Robertis (1966).

The almost complete disappearance of the elementary granules here obtained after 5 or 7 days' dehydration of the rats is in agreement with the findings of Streefkerk (1967). After 3 days' dehydration of the rats the amount of the elementary granules decreased considerably. At this stage of dehydration, Zambrano and De Robertis (1966) reported an increase and dispersion of the elementary granules in the neurosecretory cells.

All three types of synapses were of Gray's type I or II (Gray 1959). No spine apparatuses were noticed. The existence of both agranular and granular vesicles in the axonal synaptic terminals is suggestive of both cholinergic and adrenergic mechanisms in neuronal transmission of the SON of the rat (De Robertis 1959, Koelle 1962, Pellegrino De Iraldi *et al.* 1963, Hökfelt 1968). Especially the small granulated vesicles, demonstrated only with potassium permanganate fixation, are highly suggestive of catecholamine-containing nerve terminals in the SON (Hökfelt 1968). The possible stimulating and inhibitory roles of these two transmitter types are discussed in detail in chapters II and III.

The axo-axonal synapses were also described by Klein et al. (1968). Although the main branch of the neurosecretory cell is functionally considered an axon, it has an inner structure of a dendrite, as already pointed out by Palay (1960).

The ultrastructure of the capillaries in the rat SON was essentially similar to that of the capillaries of other brain areas (Bloom and Fawcett 1968). No pericapillary space was found, such as was described by Streefkerk (1967) after immersion fixation. Glial processes in most cases separated the neurosecretory cells and axonal swellings from the capillaries. The glial processes obviously play an important role in the osmoreceptory functions between the capillaries, axons and the neurosecretory cells.

After 5 or 7 days' dehydration, when the nerve cell bodies were greatly hypertrophic, the glial elements between the cells appeared narrow. On the other hand, the distance between the capillaries and the neurosecretory cells increased and

Fig. 19 Capillary wall and glial processes after 7 days' dehydration. Note the increased distance between the capillary wall and the dark neurosecretory cell beneath. The basal lamina appears thicker than in the control capillaries. An arrow points to an axo-dendritic synapsis. Specimen processed as in Fig. 3. × 10 200

the glial elements appeared hypertrophied and swollen. This observation is entirely different from that made by Enestrom (1967), who used immersion fixation. According to him, all the glial elements were reduced after dehydration stress. The disparity between our observations might be due to the different fixation procedures. The present writer's observation agrees with that of Murray (1968), who reported a distinct proliferation of neuroglial cells in the rat SON after salt loading. It is of interest in this context that the number of pituicytes is known to increase after dehydration (Ortmann 1951).

II. EFFECT OF SYMPATHECTOMY, RESERPINE AND OXYPERTIN ON THE NEUROSECTORY CELLS AND NERVE ENDINGS IN THE RAT SUPRAOPTIC NUCLEUS

REVIEW OF THE LITERATURE

SYMPATHECTOMY

The localization of brain monoamines was studied with formaldehyde-induced fluorescence by Carlsson *et al.* (1962). The nerve cells in the rat SON were surrounded by fine varicose fibres, which emitted greenish fluorescence. Bilateral cervical sympathectomy had no effect on the fluorescence of these fibres.

So far there have been no reports of electron microscopic observations on the SON after cervical sympathectomy.

EFFECT OF RESERPINE

It is generally agreed that reserpine depletes noradrenaline, dopamine and serotonin from the nervous tissue by blocking the uptake and storage mechanism of the granules (Brodie *et al.* 1957, Shore *et al.* 1957 and Bertler 1961).

The fluorescent varicose fibres round the non-fluorescent nerve cells in the rat SON have been reported to disappear completely after a single dose of reserpine as low as 0.5 mg/kg i.p. (Carlsson *et al.* 1962).

There is division of opinion as regards the fate of the large granular vesicles in brain tissue after reserpine treatment. A marked decrease in the number of these vesicles in the anterior hypothalamus of the rabbit was reported by Shimizu and Ishii (1964). Pellegrino De Iraldi and De Robertis (1961) described a complete disappearance of granulated vesicles from the pineal body of the rat after reserpinization. On the contrary, Fuxe *et al.* (1965, 1966) and Bloom and Aghajanian (1967, 1968) found that reserpine treatment had only little, if any effect on the rat hypothalamus.

The SON of the rat was not examined at all in any of the above-mentioned studies.

EFFECT OF OXYPERTIN

Oxypertin, also called Win 18501-2, or 1- [(5.6-dimethoxy-2-methyl-3-indole)-ethyl]-4-phenylpiperazine has been reported to deplete catecholamines from the adrenergic nerve terminals.

The number of noradrenaline-containing granular vesicles decreased without any notable effect on 5-HT (Spector *et al.* 1962) and dopamine (Matsuoka *et al.* 1965) containing granular vesicles. However, the concentration of biochemically determined dopamine in hypothalamus has been found to be increased (Matsuoka *et al.* 1965). Fuxe *et al.* (1967) reported that after a relatively high dosis of Oxypertin all these amines were affected. However, the noradrenaline content of the rat whole brain was biochemically most affected, being reduced to 12 per cent of the control level, while dopamine was reduced to 51 per cent and 5-HT to 54 per cent, respectively.

The disappearance of fluorescent fibres after Oxypertin treatment does not occur with equal ease in all brain areas. In the rat hypothalamus a considerable number of nerve fibres with weak or medium fluorescence were still demonstrated after a relatively large dosage of Oxypertin (Fuxe *et al.* 1967).

MATERIAL AND METHODS

Fifty-seven adult, male rats of about 300 g weight were used in this part of the study. Bilateral cervical sympathectomy was performed on ten rats. They were sacrificed 5 days after operation.

Twelve rats received reserpine (Serpasil^{R}, Ciba AG) 3 mg/kg i.p. on four consecutive days before killing. Twelve further rats received Oxypertin (Winthrop, London) 25 mg/kg, 50 mg/kg and 75 mg/kg i.p. Oxypertin was dissolved in lactic acid diluted with distilled water and injected immediately after preparing the solution. The rats were killed 3 hours after the injection. Sympathectomy controls received no treatment. Drug controls were injected with physiological saline i.p.

For fluorescence microscopy, the rats were decapitated under Nembutal anaesthesia. About 2 mm thick hypothalamic slices including the SON areas were frozen, immediately after removal, in isopentane and liquid nitrogen. The tissue pieces were freeze-dried for seven days *in vacuo* at —35°C, according to the method described by Eränkö (1961, 1967). The frozen-dried tissue blocks were treated for one hour at 80°C with formaldehyde gas prepared from paraformaldehyde equilibrated with 60 % humidity; infiltrated with paraffin *in vacuo* and cut at 5 μ. Sections were mounted in xylene, examined, and the fluorescence was photographed with a Wild fluorescence microscope equipped with a high-pressure mercury lamp HBO-200 (Osram). The light was filtered through a Schott K2 heat-absorbing filter and Schott BG12 filter. The stop filters in the tube were Leitz Euphos and Schott OG1.

The sections were examined by light microscope after toluidine blue staining to make sure of the proper area.

For elecetron microscopy, the rats were perfusion-fixed in Nembutal anaesthesia with 2.5 % glutaraldehyde in 0.1 M phosphate buffer, pH 6.9. The 15 minutes' perfusion fixation was further prolonged with 3 hours' immersion fixation in the same fixative and two hours' in OsO_4 (Rhodin 1954). Dehydration, embedding and trimming of the blocks were performed as described in Chapter I. The thin sections were poststained with uranyl acetate and lead citrate. The sections were examined and photographed with Philips EM 200 at 80 kV.

The number of large granular vesicles in the control and experimental specimens was counted in 50 synaptic terminals using photographs with the same magnification.

RESULTS

After sympathectomy ptosis and miosis of the eyes were always observed.

After four daily reserpine injections the rats were heavily sedated, as they were shortly after injection with 50 mg/kg and 70 mg/kg of Oxypertin. The sedative effect of Oxypertin was noticed as early as 5—10 minutes after the injection.

FLUORESCENCE MICROSCOPY

The fluorescence microscopic observations in rats after sympathectomy, reserpine and Oxypertin treatments are reported in Table I.

TABLE I. *Fluorescence intensity in the nerve terminals of SON*

	Nerve cells	Nerve fibres
Control specimens	—	+++
After sympathectomy	—	+++
After reserpine	—	—
After Oxypertin	—	+

— = no fluorescence
\+ = weak fluorescence
++ = medium fluorescence
+++ = strong fluorescence

ELECTRON MICROSCOPIC OBSERVATIONS

Neurosecretory cells

No changes were noticed in the neurosecretory cells of the sympathectomized rats when compared to the controls.

After reserpine treatment, the number of small inclusion bodies decreased in both the light and the dark neurosecretory cells. This decrease is illustrated in Figs 20 and 21. Empty vesicles of the same size as the small inclusion bodies

Fig. 20
A light neurosecretory cell of the SON after Serpasil (3 mg/kg four times) treatment.
Note almost complete loss of small inclusion bodies (neurosecretory granules). The amount of large inclusion bodies and ribosomes corresponds to that seen in Fig. 21. Glutaraldehyde perfused and immersion fixed, refixed in OsO_4. Poststained with uranyl acetate and lead citrate. × 10 200

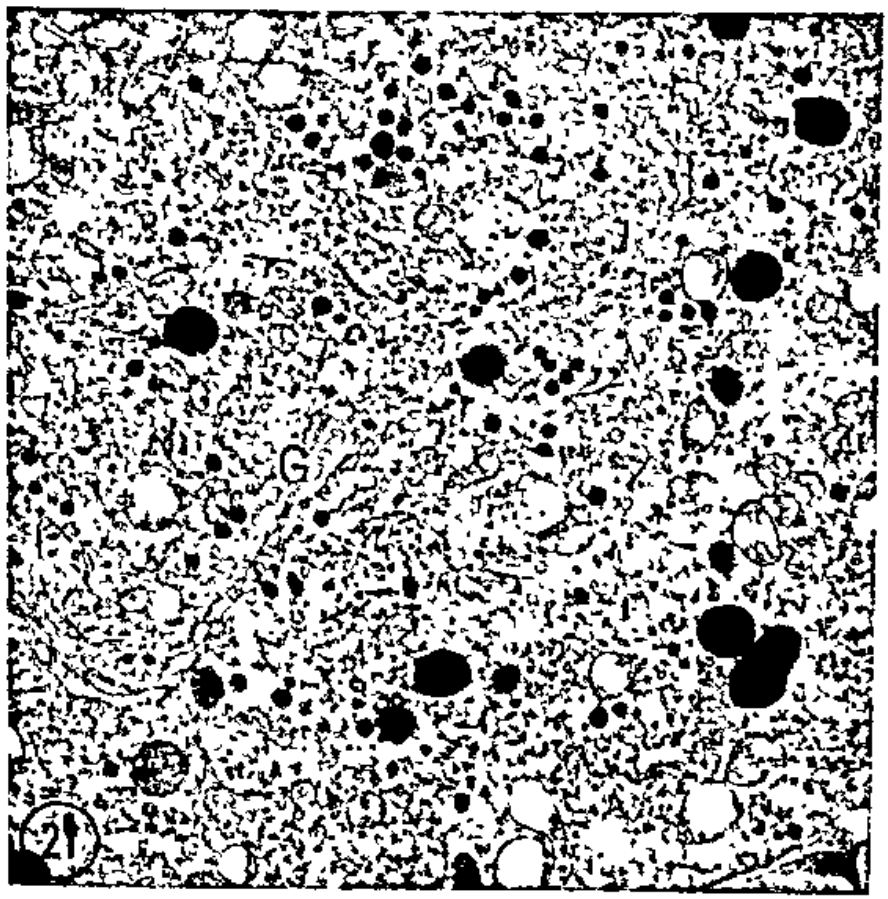

Fig. 21
Electron microscopic view of a light neurosecretory cell of control rat SON.
Note the amount of small inclusion bodies when compared to Fig. 20 and 23. Specimen processed as in Fig. 20. × 10 200

were found near the flattened Golgi cisternae, as seen in Fig. 22. The number of ribosomes and large inclusion bodies did not show essential changes (Figs. 20 and 21).

All the Oxypertin doses employed had the same effect on the neurosecretory cells as reserpine, the main effect being a decrease in the number of small inclusion bodies (*cf.* Figs. 23 and 21).

Synapses

With combined glutaraldehyde and OsO_4 fixation, only the large type of granular vesicles was demonstrable in axon terminals, among the numerous small agranular vesicles. Neither sympathectomy nor reserpine or Oxypertin treatments had any effect on the number of these large granular vesicles in the synaptic endings and axons. The size of the granular vesicles was also approximately equal to that in the control animals, and the same applies to the electron density of the central core. The localization of the large granular vesicles in the granular vesicle population in presynaptic endings was found to correspond to that of the controls. Axo-somatic, axo-dendritic and axo-axonal synapses after the experimental procedures are seen in Figs. 24, 25 and 26. The appearance of large granular vesicles can be compared to the control specimen in Fig. 27.

DISCUSSION

The histochemical fluorescence method developed and introduced by Eränkö (1951c, 1955, 1967), Falck *et al.* (1962), Corrodi and Hillarp (1963) and Corrodi and Jonsson (1967) has proved very sensitive and specific for monoamines in nervous tissue. With this valid method it was possible to demonstrate the fine, varicose fluorescent nerve fibre net round the non-fluorescent nerve cells of the rat SON. On the basis of several histochemical and pharmacological studies it has been firmly established that these greenish fluorescent fibres are evidently noradrenaline-containing nerve terminals (Carlsson *et al.* 1962, Fuxe 1965).

Carlsson *et al.* (1962) suggested that the superior cervical ganglia were not the source of monoamine terminals to the rat SON. The present writer's observations agreed with his. There was no detectable change in the fluorescence intensity of the fibres between the operated and control animals. At ultrastructural level no changes were seen in the morphology of the neurosecretory cells or in the synaptic endings. The pons and medulla oblongata possibly contain the neuronal cell bodies of the nerve terminals found in the rat SON (Fuxe 1968). This assumption is based on the stereotactic studies carried out by Andén *et al.* (1966 a, 1966b).

The fluorescent fibres of the rat SON are known to be very sensitive to reserpine when observed by fluorescent microscopy. After a single dose of 0.5 mg/kg i.p. reserpine no fluorescence could be detected in this area (Carlsson *et al.* 1962). Thus, it was not surprising that fluorescence was completely abolished by the four repeated doses 3 mg/kg i.p. of reserpine here employed.

At ultrastructural level no change was noticed in the amount or density of the large granular vesicles in the three types of synapses, respectively. This observation is in agreement with the reports of Fuxe *et al.* (1965, 1966) and Bloom and Agha-

janian (1967, 1968). According to them reserpine had no notable effect on the large granular vesicles in the rat hypothalamic nerve terminals.

It is a matter of dispute whether the large granular vesicles in brain tissue are catecholamine storage granules at all. However, several studies favour the view that in hypothalamic areas they form at least a part of the total monoamine reservoir. The number of large granular vesicles corresponds well with the biochemically determined concentration of noradrenaline (Ishii *et al.* 1965, De Robertis *et al.* 1965, De Robertis 1966). Aghajanian and Bloom (1966) found that, on autoradiography, tritiated H-noradrenaline accumulates on those hypothalamic nerve endings which contain large granular vesicles. Pharmacological studies with reserpine have also shown changes in amount and density of the large granular vesicles in rabbit (Shimizu and Ishii 1964) and in rat (Hökfelt 1968). As fixative Hökfelt used potassium permanganate by which he was able to demonstrate both small and large granular vesicles. Reserpine abolished both these types of vesicles in rat hypothalamus.

In the light of the recently accumulated extensive literature (cited by Hökfelt 1968) it seems evident that many factors are involved in the depletion of large granular vesicles. Reserpine sensitivity differs in the various animal species, in various brain areas, and is dependent on the doses employed. In addition, the controversial results are due to the different fixatives used. The mechanisms by which the fixatives react with the central cores in the large granular vesicles are of importance. Glutaraldehyde is known to react with proteins, while, on the other hand, potassium permanganate dissolves them (Hake 1965). In the present study, only glutaraldehyde-OsO_4 combination was used as fixative. With this fixation the central cores of the large granular vesicles were unchanged after a relatively large reserpine dose which histochemically abolished the fluorescence in the nerve fibres.

The small inclusion bodies were markedly reduced in the neurosecretory cells after reserpine and Oxypertin treatments. The noradrenaline containing nerve terminals are assumed to be inhibitory in the rat SON (Fuxe and Hökfelt 1967). Stimulation of antidiuretic hormone secretion after reserpine treatment was reported by Gaunt *et al.* (1955) and Gabe *et al.* (1961). The disappearance of the small inclusion bodies from the neurosecretory cells seems appropriate, because monoamine inhibition is blocked by reserpine and Oxypertin.

After Oxypertin treatments with doses 25 mg/kg, 50 mg/kg and 75 mg/kg i.p. there remained a faint but distinct fluorescent fibre net around the SON nerve cells. The same observations were reported by Fuxe *et al.* (1967) for rat hypothalamic noradrenaline containing fluorescent fibres.

The electron microscopic findings concerning the amount and density of the large granular vesicles in synaptic endings were similar to those after reserpinization. There was no difference in the effect of various doses of Oxypertin. It was believed that Oxypertin depleted selectively the different monoamines in brain tissue (Matsuoka *et al.* 1965, Bak and Hassler 1968). These authors reported a decrease in the number of large granular vesicles in hypothalamic areas, while no effect was noticed for instance in substantia nigra and nucleus caudatus, which have a high dopamine content (Bak 1967). Further it was suggested that the lower doses up to 35 mg/kg i.p. of Oxypertin depleted only noradrenaline, whereas higher doses had an equal effect on dopamine and serotonin (Makin

1968). Oxypertin acts *in vivo* as an uptake-storage mechanism blocker of the granular pool, and its effect is mainly the same as that of reserpine. In the present study the observations after Oxypertin treatment were independent of the doses employed.

It seems that in the rat SON the large granular vesicles in the synaptic terminals and axons at ultrastructural level are resistant to the depletory substances, reserpine and Oxypertin.

III. CHOLINESTERASE ACTIVITY IN THE SUPRA-OPTIC NUCLEUS OF NORMAL AND DEHYDRATED RATS

REVIEW OF THE LITERATURE

In 1939 and 1947 Pickford suggested that cholinergic synapses might be involved in the release of the neurohypophyseal hormones in the pituitary of the dog. This was later confirmed by Duke *et al.* (1950), Abrahams and Pickford (1954, 1956).

LIGHT MICROSCOPIC OBSERVATIONS

Several light microscopic studies have been published on the histochemical demonstration of ChEs in the neurosecretory systems of various animal species under normal conditions. The first report was published by Koelle (1954); he found a moderate ChE activity in the rat SON. The enzyme activity was confined to the neurons and fibres.

Abrahams *et al.* (1957) mapped the cholinergic areas of the dog hypothalamus. Three nuclei of the anterior hypothalamus were found to contain AChE: the SON, the paraventricular and the suprachiasmatic nuclei. In the SON, AChE was located in the perikarya of the neurons and in the very proximal parts of the axonal and dendritic fibres. Ns. ChE appeared to be localized as dense rings between the neurosecretory cells.

Uemura (1965) studied systematically the distribution of these enzymes in several animal species: frog, newt, turtle, bird and rat. He found a relatively strong enzyme activity in rat neurosecretory cells using acetylthiocholine as substrate and no activity at all with butyrylthiocholine. Ns. ChE activity was demonstrated in the capillaries of the neurosecretory areas.

There have been several reports of ChE in the neurosecretory nuclei of other animals: in the ox, sheep, pig, rabbit, fowl and pigeon (Arvy 1962) and in the sparrow (Kobayashi and Farner 1964). A moderate ChE activity was reported in the monkey SON by Iijima *et al.* (1967).

In 1957, Pepler and Pearse reported their observations that after 14 days' dehydration the neurosecretory cells in the SON of rats showed a decrease in the intracellular non-specific esterase activity. At the same time a rise in AChE activity in the cells was demonstrated. Ns. ChE and possible changes in its activity were not reported in this study.

ELECTRON MICROSCOPIC OBSERVATIONS

The present author (Rechardt 1967) published a short report of electron microscopic demonstration of ChE in the rat SON. Up to the present time there have been no extensive studies concerning ChE localizations at ultrastructural level in either normal or experimental conditions.

MATERIAL AND METHODS

Fifty-five adult male rats of about 300 g weight were used; 12 rats were kept without water for 7 days. The rest served as controls.

The rats were perfused under ether anaesthesia *via* the abdominal aorta. The fixation fluid consisted of 3.5 % formaldehyde in 0.3 M sucrose, buffered with 0.075 M phosphate to pH 7.2. The brain was dissected out after 15 minutes' perfusion and the hypothalamic area was immersed in the same fixative overnight. The tissue piece was then washed during two hours in several changes of ice-cold 0.075 M phosphate buffered 0.3 M sucrose pH 7.2. For light microscopy, 10 μ thick sections were cut with a freezing microtome. For electron microscopy, both SONs were dissected under a stereo microscope and cut with a razor blade in thin slices. Two methods for light microscopy were employed: the Koelle method (1951) as modified by Gomori (1952), and the copper-ferrocyanide method described by Karnovsky and Roots (1964). For electron microscopy, only the latter method was employed.

In the Koelle-Gomori method the incubation was carried out at 37°C. Preincubation without substrate but with various inhibitors lasted 20 minutes and incubation with inhibitors and substrates 4 hours. The pH was adjusted to 6.0.

In the Karnovsky-Roots method for electron microscopy the incubation was carried out at 0°C for 20 minutes and with substrates for 60 minutes. No sucrose was added to the incubation medium. The tissue slices were all handled free-floating.

The substrates used were acetylthiocholine iodide and butyrylthiocholine iodide (Fluka AG., Buchs). The inhibitors were 10^{-5} M eserine, 10^{-4} M, 10^{-5} M and 10^{-6} M iso-OMPA (tetra-isopropylpyrophosphoramide) (L. Light & Co. Ltd., Colnbrook, England) and 10^{-5} M 284C51 [1.5-bis(4-allyldimethylammoniumphenyl) pentan-3-one dibromide] (Wellcome Research Laboratories, England).

Some incubations were carried out without substrate in otherwise complete incubation medium.

For electron microscopy, the tissue pieces were washed after incubation in four changes of ice-cold 0.3 M sucrose and refixed for one hour in 1 % OsO_4 (Rhodin 1954). Dehydration was carried out in graded ethanol series and the pieces were embedded in Epon. Thick (1 μ) sections were stained with toluidine blue and examined under a light microscope to ascertain the proper SON area, which was further trimmed. Silver to grey sections were cut at the depth of 5—10 μ from the surface of the tissue piece. Sections were poststained with lead citrate for 5 minutes (Reynolds 1963). The specimens were viewed and photographed with Siemens Elmiskop I or Philips EM 200 electron microscopes.

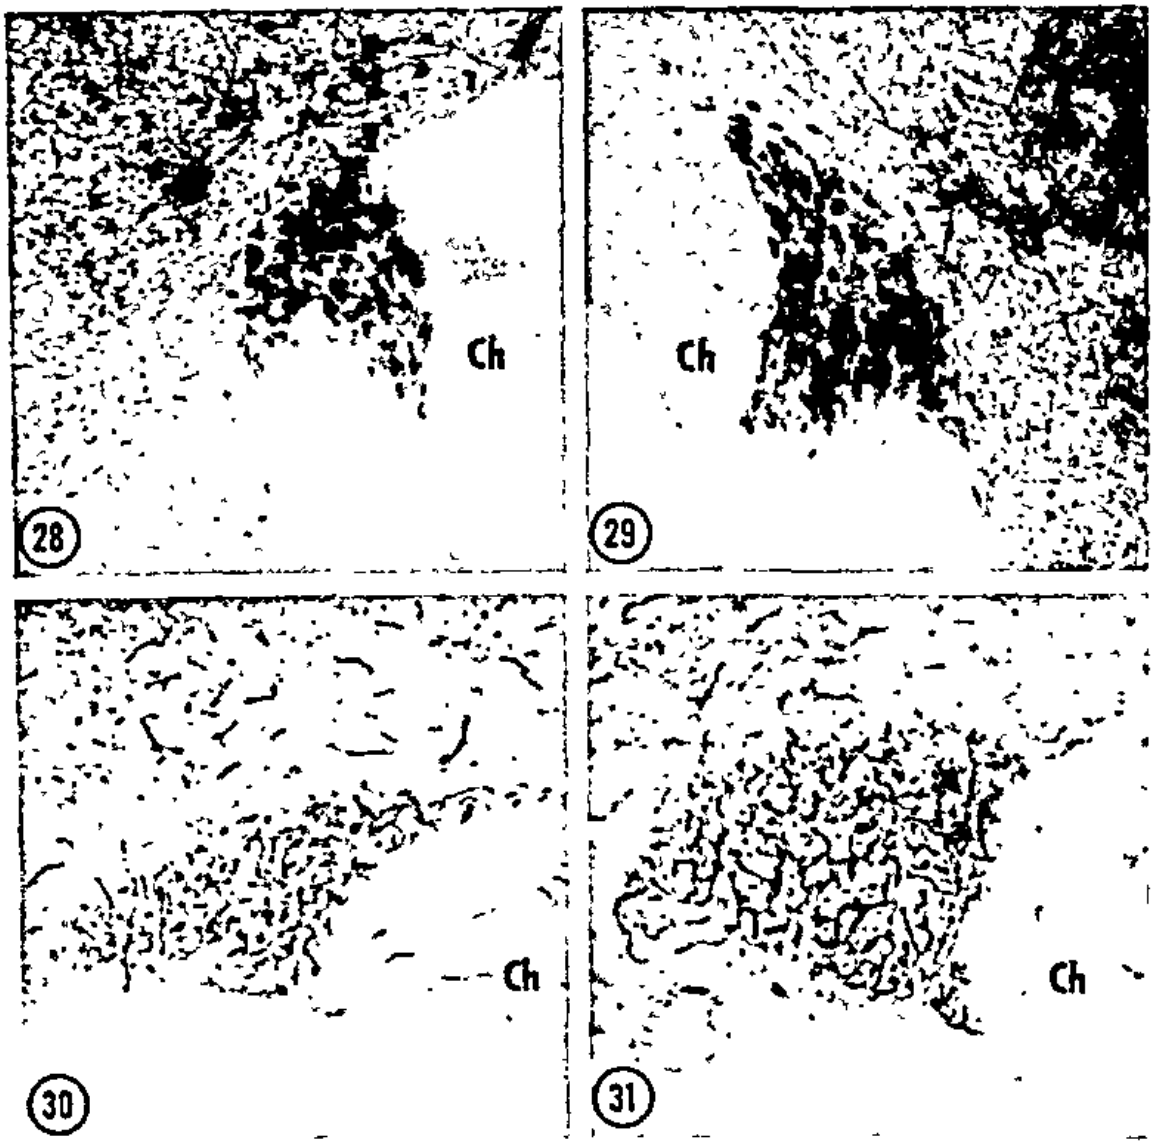

Fig. 28 A light microscopic view of AChE activity in control rat SON. A moderate activity is found in the neurosecretory cells. Some variations in the activity are noticed among the cells. The neuropile and capillaries appear negative.
Note the strongly positive neurons with related fibres in the accessory SON above. Formaldehyde perfused specimen incubated for 3 hours at +37°C in Koelle-Gomori medium acetylthiocholine as substrate and with iso-OMPA 10^{-4} M. Ch (chiasma opticorum) × 65

Fig. 29 A light microscopic view of AChE activity in rat SON after 7 days' dehydration. The reaction product is of equal amount and distribution as in the control specimens. *Cf.* Figs. 28 and 29.
Specimen processed identically to that in Fig. 28. Ch (chiasma opticorum) × 65

Fig. 30 A light microscopic view of ns. ChE activity in control rat SON. The capillary walls show a moderate activity. The reaction product in the capillary walls is of the same amount as in the surrounding hypothalamic capillaries. The specimen was handled as in Fig. 28, but butyrylthiocholine was used as substrate and 284C51 10^{-4} M as inhibitor. Ch (chiasma opticorum) × 65

Fig. 31 A light microscopic view of ns. ChE activity in rat SON after 7 days' dehydration.
The capillary walls show more reaction product than in the control specimens. *Cf.* Fig. 30. There is a distinct difference in activity between the capillaries of the SON and those of the surrounding hypothalamic areas, which show weaker activity.
Specimen processed as in Fig. 30. Ch (chiasma opticorum) × 65

RESULTS

A. AChE ACTIVITY

LIGHT MICROSCOPIC OBSERVATIONS

The reaction product was seen in the perikarya of nerve cells of the SON. The neuropile appeared negative, as did the capillaries, when iso-OMPA in 10^{-5} M concentration was used as inhibitor. When iso-OMPA 10^{-6} M was used, a weak capillary activity was noticed.

The AChE activity in the main SON was moderate but it was much stronger in the accessory SON neurons after one hour incubation in Karnovsky-Roots medium, or 4 hours' incubation in Koelle-Gomori medium (Fig. 28).

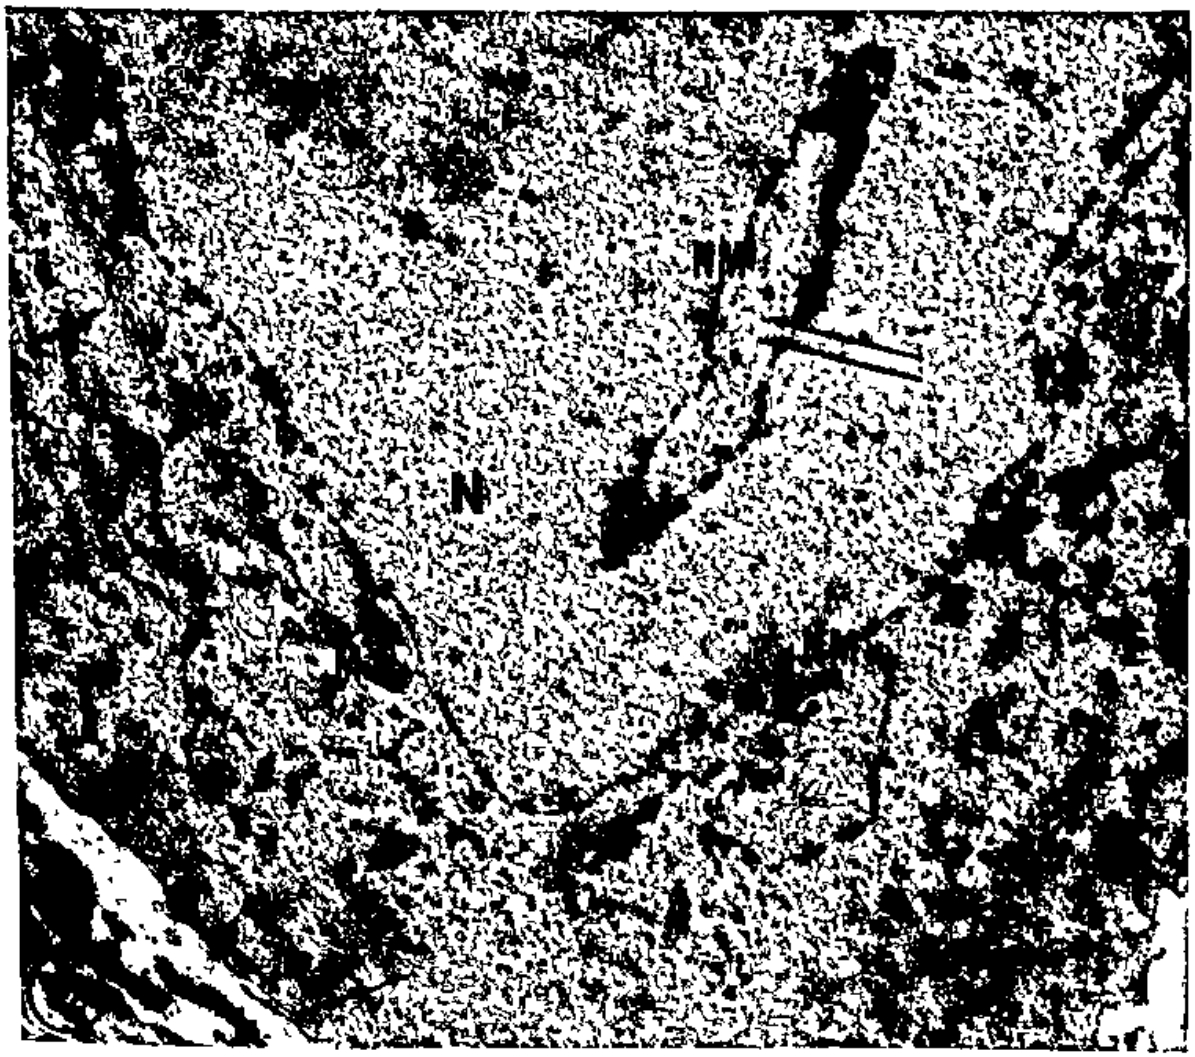

Fig. 32 AChE activity in the neurosecretory cell of control rat SON. The reaction product is localized in the rough surfaced endoplasmic reticulum (ER) and in the nuclear membrane (NM). A typical invagination of the nuclear membrane (NM) with reaction product is observed (double arrow). The Golgi apparatus, indicated by arrows, is negative.
Formaldehyde perfusion fixation, acetylthiocholine as substrate, iso-OMPA 10^{-5} M as inhibitor. Refixed in OsO_4 and poststained with lead citrate. × 11 300

After 7 days' dehydration the neurosecretory cells appeared larger than in the control sections. The reaction product was localized in the cytoplasm of the nerve cells without any other demonstrable localizations. The intensity of enzymatic activity was equal to that found in the control specimens (*cf.* Figs. 29 and 28).

ELECTRON MICROSCOPIC OBSERVATIONS

Considerable variation was observed in the activity of individual neurosecretory cells. The reaction product occurred in the nuclear membrane as a discontinuous line and in the rough surfaced endoplasmic reticulum cisternae at the periphery

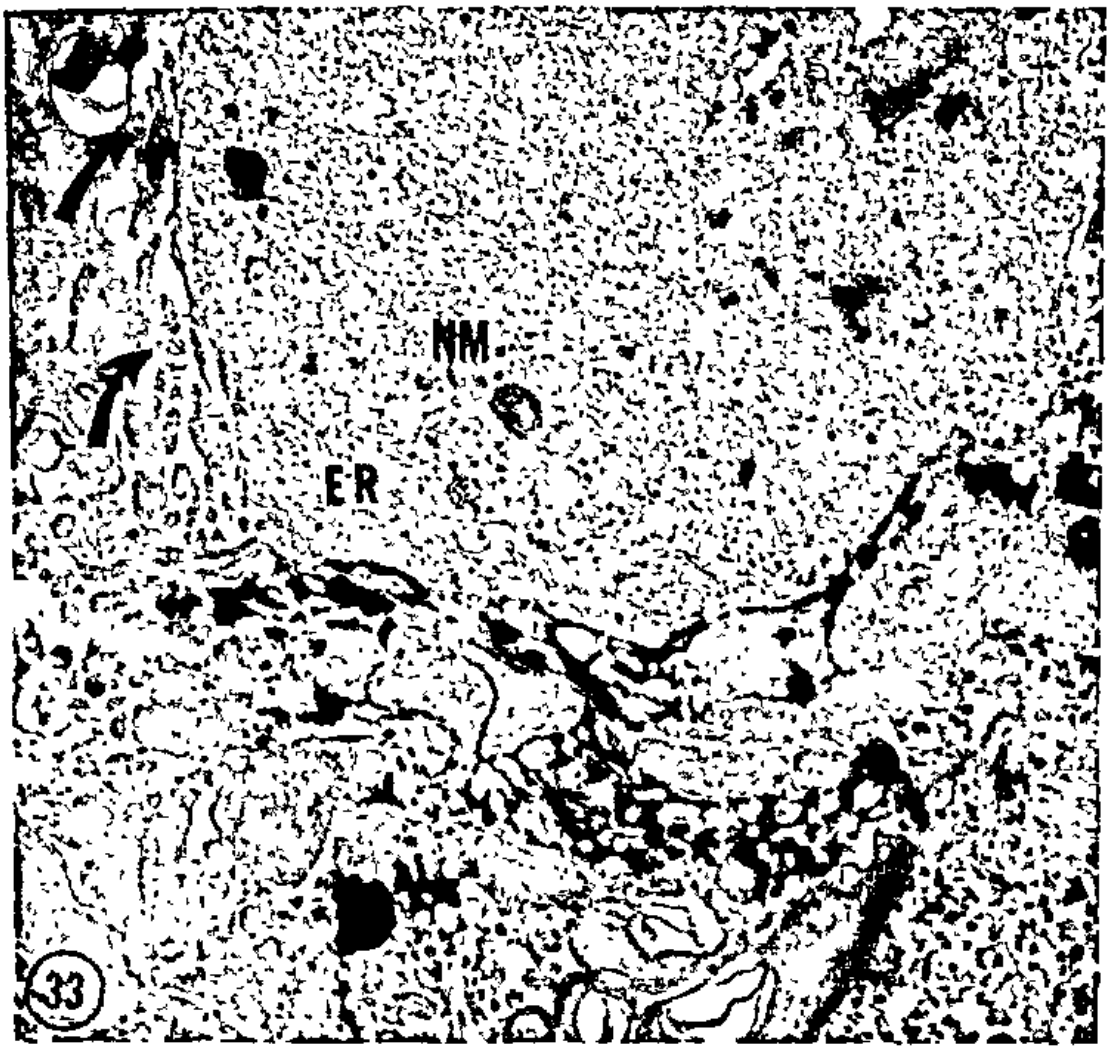

Fig. 33 AChE activity in the neuropile which adjoins an almost negative neurosecretory cell of the SON. The nerve fibres are surrounded by reaction product, which also occurs between them and the cell membrane. No reaction product is found in the cell membrane when adjoining a negative neuropile indicated by arrows. Specimen processed as in Fig. 32. · 11 300

of the cells (Fig. 32). The nucleus, the Golgi apparatus, the mitochondria and the small and large inclusion bodies were always non-reactive. The reaction product sometimes had affinity to the nucleolus. Among the reactive cells, like those seen in Fig. 32, there were always a few almost non-reactive cells (Fig. 33). Round these non-reactive cells, nerve fibres encircled by dense reaction product could be detected.

When the specific inhibitor of ns. ChE, iso-OMPA, was employed in concentrations 10^{-5} M and 10^{-6} M, a weak but distinct activity was seen in the capillary walls, the reaction product being randomly scattered in the cytoplasm of the endothelial cells. When the iso-OMPA concentration was raised to 10^{-4} M, no reaction product was found in capillaries, while the other sites were still reacting.

Glial cells remained non-reactive even when using only 10^{-6} M iso-OMPA.

Eserine essentially abolished the reaction product, so that only a few randomly scattered crystals were found. These had no special affinity to any structures

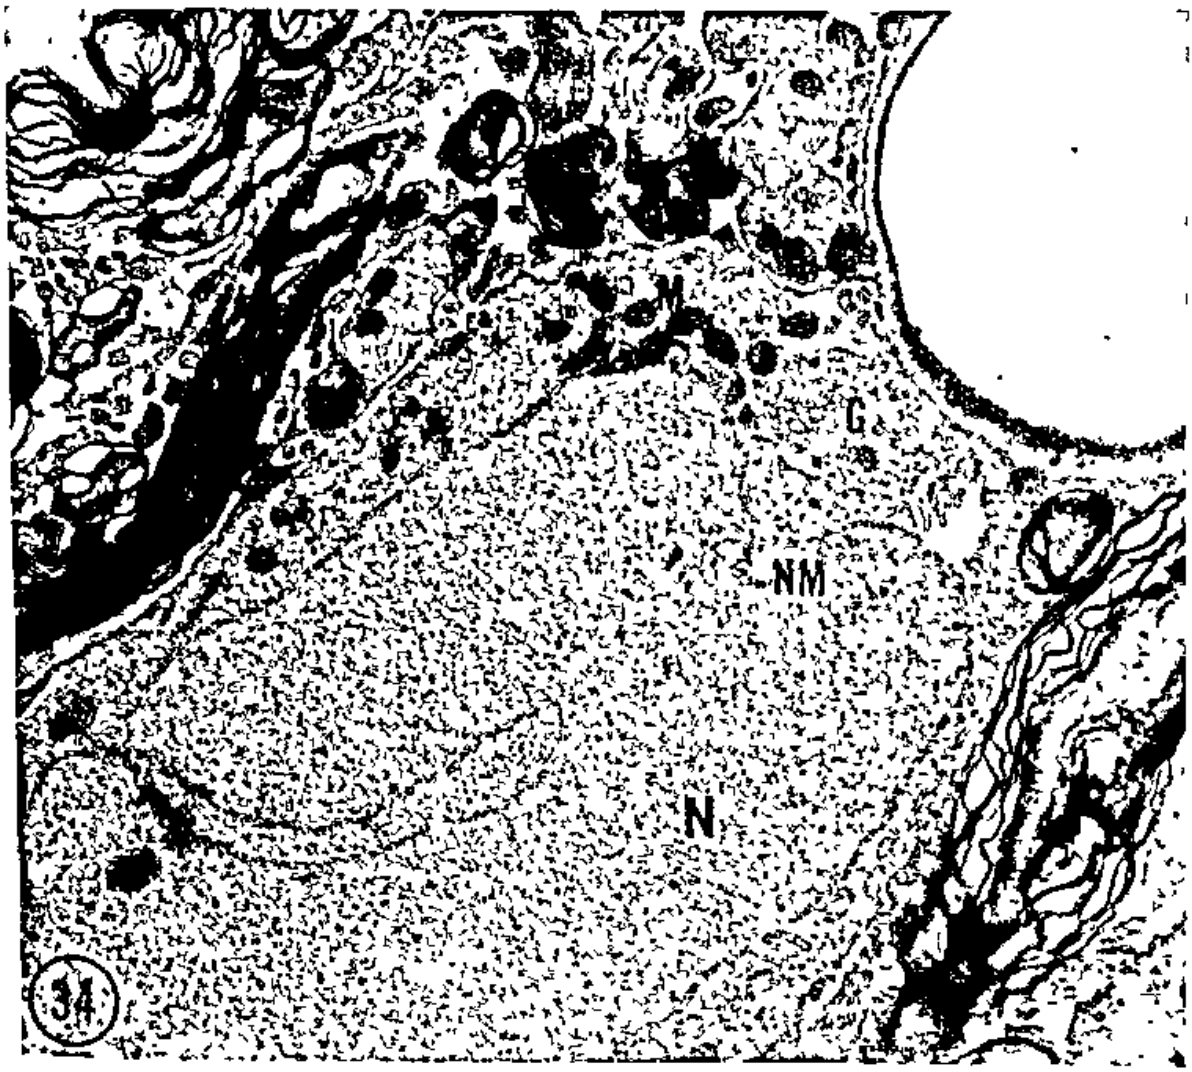

Fig. 34 An almost negative neurosecretory cell of the SON with eserine 10^{-5} M in the incubation medium. Some reaction product crystals are seen without special affinity for any structures.
Procedures as in Fig. 32, eserine 10^{-5} M was used instead of iso-OMPA. × 11300

(Fig. 34). When acetylthiocholine iodide was omitted from the incubation medium, no reaction product was obtained (Fig. 35).

No change was noticed in the distribution and amount of AChE activity even after 7 days' dehydration.

B. Ns.ChE ACTIVITY

LIGHT MICROSCOPIC OBSERVATIONS

The numerous capillaries of the SON exhibited moderate reaction (Fig. 30). The other structures appeared non-reactive.

After 7 days' dehydration, the capillaries appeared widened and their network denser than in the control sections. More reaction product was demonstrated in the walls of these enlarged capillaries (Fig. 31).

Fig. 35 A control section of the SON incubated without substrate. No reaction product is visible. Procedures as in Fig. 32, except that acetylthiocholine was omitted. × 11 300

ELECTRON MICROSCOPIC OBSERVATIONS

The reaction product was localized in the endothelial cells, especially in its nuclear membrane. The basal lamina showed no reaction (Fig. 36). The glial cells showed a weak activity in the cytoplasm and the nuclear membrane (Fig. 38). The neurosecretory cells and the nerve fibres between them were completely non-reactive.

The capillary walls showed an increased amount of reaction product after 7 days' dehydration when butyrylthiocholine was used as substrate and 284C51 10^{-5} M as inhibitor (Fig. 37).

DISCUSSION

TECHNIQUES

Perfusion fixation and the use of unfrozen sections proved essential for a satisfactory ultrastructural preservation. The moderate ChE activity of the rat SON cells favoured the choice of formaldehyde fixation instead of glutaraldehyde, which was tried in preliminary studies and found inhibitory. In this respect the present results agree with those of Brzin *et al.* (1966) and Anderson (1967).

Methodological problems with the Karnovsky-Roots technique have been discussed in detail (Eränkö *et al.* 1967). Especially in the brain, poor penetration of the reagents was hard to overcome. When unfrozen sections were used, an osmotic shock was necessary to demonstrate intracellular enzyme activity. This was also emphasized by Bell (1966) and Grant *et al.* (1967) at light microscopic level. The omission of sucrose from the incubation medium proved favourable in this respect.

A. AChE ACTIVITY

In light microscopic specimens AChE activity was detected only in the neuronal cell bodies when iso-OMPA in 10^{-6} M, 10^{-5} M or 10^{-4} M concentrations were used. This localization is in agreement with the findings of Pepler and Pearse (1957) and Uemura (1965) in the rat SON. Using his own technique, Koelle described AChE activity also in the adjacent nerve fibres, axons and dendrites of the neurosecretory cells in the rat (Koelle 1954) and in the dog (Abrahams *et al.* 1957). Some activity has been reported in the neuropile of monkey SON (Iijima *et al.* 1967).

After 7 days' water deprivation, no demonstrable increase was observed in AChE activity in the neuronal cell bodies, such as was reported by Pepler and Pearse (1957) and Pearse (1958). In their experiments, however, the rats were kept on a salt diet for 14 days, which may partly explain the different results.

The cytoplasmic localization of the reaction end product, copper-ferro cyanide, corresponds well to the findings at fine structural level reported by several authors. A reaction in the nuclear envelope and in the cisternae of the rough-surfaced endoplasmic reticulum has been noted previously in the following sites: Koelle and Foroglou-Kerameos (1965) found such a reaction in the sympathetic ganglion cells of the rat (gold-thiolacetic acid method); Brzin *et al.* (1966) in the sym-

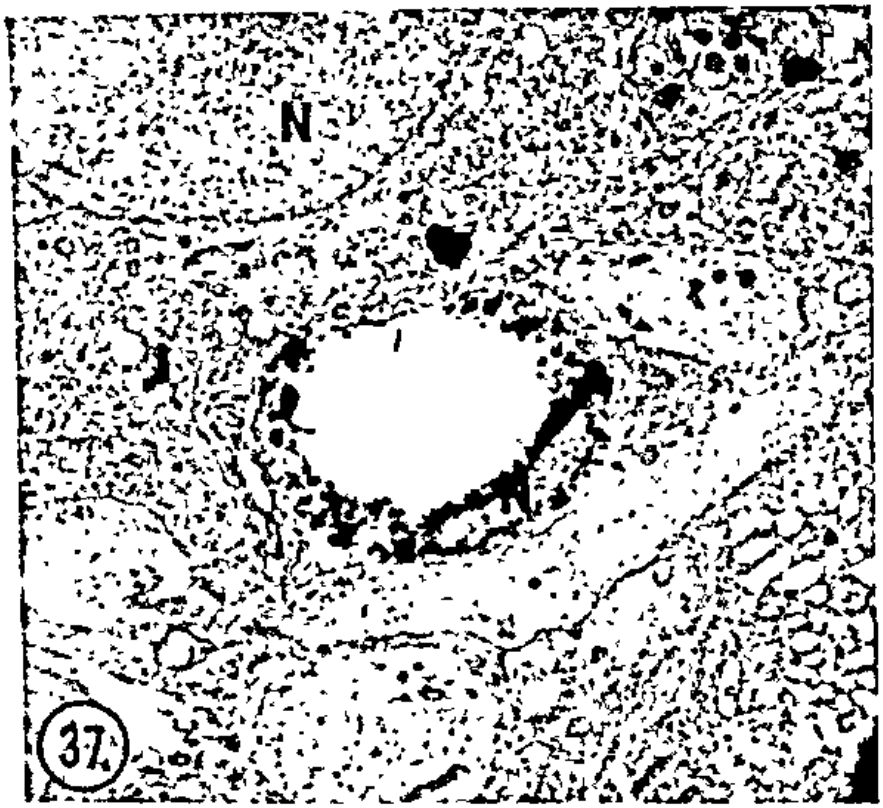

Fig. 37 Ns.ChE activity in the capillary wall of rat SON after 7 days' dehydration. A stronger activity is found, especially in the swollen cytoplasm of the endothelial cell, than in the control specimen, *cf* Fig. 36.
The neurosecretory cell with its nucleus (N) in the left corner above are negative. Procedures as in Fig. 36 × 6 600

pathetic ganglion cells of the frog (modified Koelle method); Lewis and Shute (1966) in ventral horn cells from the cervical cord of the rat (their own method); Shute and Lewis (1966) in the hippocampus cells of the rat; Bloom and Barrnett (1967) in the sympathetic ganglion cells of the rat (Lewis and Shute method); Erānkō *et al.* (1967) in the ventral horn cells of the rat (Karnovsky-Roots method), and Palkama (1967) in the adrenomedullary cells of the rat (modified Levis and Shute method). End product crystals were found with higher magnifications in the nuclear envelope between the two membranes and in the endoplasmic cisternae as also reported by Lewis and Shute with their thiocholine modification, which yields end product of very fine crystal size. In contrast to the findings of Kása and Csernovszky (1967), no activity related to ribosomes was ever obtained in the present work.

The present electron microscopic observation of AChE-positive fibres round the nerve cells of the SON suggests that at least some neurosecretory cells are innervated by cholinergic nerve fibres. The origin of these fibres is unknown, and stereotactic studies would be needed for further elucidation. Fibres coming to or running through the SON originate from several different brain areas: neocortical fibres mainly from the amygdaleum, and indirect fibres from fronto-cortical areas, fibres from the ventral thalamic nucleus and possibly from the retina. In addition, all the hypothalamic nuclei are closely connected to each other by fibres (see *e.g.* Krieg 1953 and Diepen 1962a).

AChE has been found in at least three of the sites where the fibres presumably originate. The paraventricular and suprachiasmatic nuclei in the hypothalamus and nucleus amygdaleum contain AChE-positive neurons (Koelle 1954, Abrahams *et al.* 1957 and Ishii 1957). The terminal stria, in which part of the cortical fibres run, contains also ChE-positive fibres (Shute and Lewis 1963).

Koelle and Geesey (1961) demonstrated a faint but distinct AChE activity throughout the neurohypophyseal tract and neurohypophysis in the cat. On the other hand, Abrahams *et al.* (1957) did not detect any activity in the dog's neurohypophyseal tract. Koelle and Geesey (1961) suggested that acetylcholine, in addition to neurosecretory products, was liberated in the nerve terminals of the neurohypophysis. The rate of hormone release was, according to him, under cholinergic control. Gerschenfeld *et al.* (1960) also proposed that the small agranular vesicles, which were assumed to contain acetylcholine and were found in the nerve terminals of the neurohypophysis, might be involved in the liberation of neurohypophyseal hormones.

The presence of cholinergic mechanisms is further supported by biochemical observations demonstrating acetylcholine, as well as AChE and choline acetyl-

Fig. 36 Ns.ChE activity in the capillary wall of control rat SON. The reaction product occurs randomly in the endothelial cell, and as a continuous line in the nuclear membrane (NM).
Note the markedly better preservation of the structures when butyrylthiocholine was used as a substrate instead of acetylthiocholine. 284C51 was used as inhibitor, other procedures as in Fig. 32. × 8 600

Fig. 38 Ns.ChE activity in the glial cell (oligodendrocyte) of the control rat SON. The activity is weak in the cytoplasm of this oligodendrocyte but more prominent in the nuclear membrane (NM). Procedures as in Fig. 36. × 9 600

transferase activities in the neurohypophysis (Lederis and Livingston 1966, Livingston 1966, LaBella and Shin 1968).

Because the SON neurons are only moderately positive, AChE might be needed for purposes other than neuronal transmission. The enzyme could be involved in the metabolic procedures of these highly active cells (Eränkö 1968, Welsch and Pearse 1969).

B. Ns. ChE ACTIVITY

It has long been known that blood vessels and glial cells in central nervous tissue contain ns. ChE (see Koelle 1954, 1955). When AChE inhibitor 284C51 was used in a concentration of 10^{-5} M, a distinct capillary activity, due to ns.ChE, was detected. After 7 days' dehydration the ns. ChE activity in capillaries was highly increased — a new observation of considerable interest.

The scattered reaction product crystals in the endothelial cells were unrelated to any special cytoplasmic organelle. They are probably localized in the intra-endothelial pinocytotic vesicles, as was also suggested by Joó and Csillik (1966).

The ns. ChE activity has been found in the blood-brain barrier type capillaries (Koelle 1954, Gerebtzoff 1959, Joó and Csillik 1966). It has been supposed to be related to their barrier function. The mechanism is, however, not understood. Eserine and acetylcholine have been reported to increase the permeability of the blood-brain barrier (Greig and Holland 1949). On the other hand, it has been suggested that ns. ChE in brain tissue inhibits the entrance of the excess acetylcholine, not hydrolysed by AChE, into the cerebrospinal fluid space (Abrahams *et al.* 1957).

The increase of ns. ChE activity after dehydration, as observed in the present study, would fit well into both of these concepts. It would be needed to stabilize the permeability after dehydration stress and to hydrolyse the increased amounts of acetylcholine in the SON after dehydration.

IV. ACID PHOSPHATASE ACTIVITY IN THE SUPRAOPTIC NUCLEUS OF NORMAL AND DEHYRATED RATS

REVIEW OF THE LITERATURE

LIGHT MICROSCOPIC OBSERVATIONS

The first enzyme ever demonstrated histochemically in the SON was acid phosphatase (AcPh) (Eränkö 1951a). The neurosecretory cells of the rat SON showed a very strong activity. Since then, several observations on AcPh in the rat SON have been reported (Eichner 1958, Kivalo *et al.* 1958, Rinne and Kivalo 1958, Samorajski and Fitz 1960). Strong activity was also found in the SON of other species: in cow embryo (Talanti *et al.* 1958), in ox, pig, sheep, rabbit, pigeon and domestic fowl (Arvy 1962), in guinea pig (Felgenhauer 1963) and in monkey (Friede and Knoller 1965, Iijima *et al.* 1967).

Only few reports deal with AcPh in the rat SON after dehydration. Rinne and Kivalo (1958) and Pilgrim (1967) found an increased activity after dehydration stress. Biochemical quantitations of hypothalamic AcPh activity have, however, been made by Kobayashi *et al.* (1962) and Ferreyra Moyano (1967) in dehydrated rats. Kobayashi *et al.* detected no change in hypothalamic AcPh activity but a significant increase of AcPh in the neurohypophysis, wheras Ferreyra Moyano (1967) reported a marked increase in the AcPh activity in the hypothalamic neurosecretery areas after 7 days' dehydration.

ELECTRON MICROSCOPIC OBSERVATIONS

Osinchak (1964a) found AcPh in the large inclusion bodies of 0.4—1.0 μ size and in some Golgi cisternae of the rat SON. Since AcPh has been widely used as a marker for lysosomes, he related these active bodies to the lysosomes of other cells.

No previous reports on electron microscopic findings concerning the AcPh activity in the SON of dehydrated rats have been published so far.

MATERIAL AND METHODS

Thirty-two male rats, about 300 g in weight, were perfused under ether anaesthesia as described in the first part of the present paper. 3.5 % formaldehyde in 0.1 M cacodylate buffer, pH 7.2, was used as fixative. Ten adult male

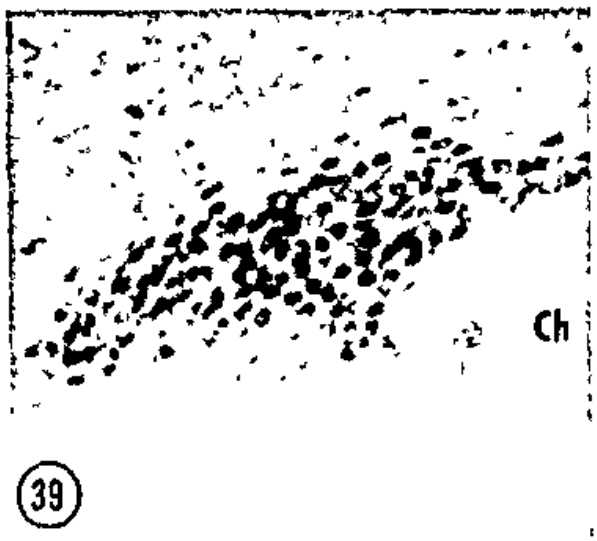
rats weighing about 300 g were kept without water for seven days and perfused with the controls.

After perfusion, the hypothalamic slices containing each SON were immersed for 4 hours at 4°C in the perfusion fluid. The slices were then washed overnight in Holt's (1958) gum-sucrose buffered with 0.1 M cacodylate buffer to pH 7.2. After freezing the tissues quickly in Holt's gum-sucrose, frozen sections 10 μ and 80 μ thick were cut with a freezing microtome. The sections were incubated free.

Two modifications of Gomori's (1941b) original AcPh lead method were applied, those of Eränkö (1951a) and of Miller (1962), this latter described by Ericsson and Trump (1965). The substrates, α- and β-glycerophosphates, were of Grade I purity (Sigma Chemical Company, St.Louis, Missouri). The pH of the incubation media was 5.0—5.1 in both modifications. The incubations were carried out at 0°C temperature for 30 minutes. In some incubations 0.3 M sucrose was included. In control studies, the substrates were omitted or 0.01 M sodium fluoride was added to the incubation medium.

The sections were rinsed for 15 minutes in three changes of 0.05 M acetate buffer to which 0.3 M sucrose had been added. For light microscopy the sections were treated with dilute ammonium sulphide for a few seconds. SON areas were dissected under a stereo microscope and refixation in 1 % OsO_4 (Rhodin 1954), embedding, dehydration and sectioning were performed as described in the previous chapter. No poststaining was used. The sections were examined and photographed with Philips EM 200.

RESULTS



TECHNIQUES

After preliminary trials, 3.5 % formaldehyde proved to be the best fixative. It gave the most reproducible results. When glutaraldehyde was used alone or combined with formaldehyde the incubation time increased and the ultrastructure suffered. Eränkö's (1951a) modification was chosen, and it was also employed in electron microscopy. Miller's (1962) modification proved to be very sensitive to overincubation in a tissue with an intense enzyme activity, such as the SON, often yielding nuclear staining.

LIGHT MICROSCOPIC OBSERVATIONS

In the light microscopic specimens a strong granular reaction product filled the cytoplasm. The activity varied from cell to cell to some extent. No capillary activity was noticed. Using 30 minutes' incubation at 0°C, non-specific nuclear staining was totally avoided.

After 7 days' dehydration, the enzyme activity increased in all nerve cells and the granular reaction product was observed not only in the cytoplasm of the neurosecretory cells but also in the nuclei. The intervening neuropile and the capillaries were negative. The difference in overall AcPh reactivity in the SON after dehydration is demonstrated in Figs. 39 and 40.

ELECTRON MICROSCOPIC OBSERVATIONS

In electron microscopic specimens, which were always examined unstained, the large inclusion bodies, 0.5—1 μ in size, contained a very fine granular precipitate. There were variations among these bodies in amount of reaction product, as seen in Fig. 43. Some activity was noticed in the lamellar Golgi cisternae (Fig. 41). Neurosecretory elementary granules were negative, as were the granular vesicles in the nerve endings and the capillary walls (Fig. 41).

When the substrates were omitted or 0.01 M sodium fluoride was included in the otherwise complete incubation medium, no reaction product was visible.

After 7 days' dehydration there was an increase in the number of large inclusion bodies filled with very dense reaction product in all neurosecretory cells. The increase was even more marked in the small dark cells, where only a few non-reactive, large inclusion bodies were seen, as shown in Fig. 42. Reaction product was also demonstrated in the lamellar Golgi cisternae, especially in the dark cells (Fig. 44). The Golgi lamellae showed more abundant reaction product in the neurosecretory cells of dehydrated rats than of the controls. Compare Figs. 44 and 41.

DISCUSSION

After preliminary experiments with glutaraldehyde-containing fixatives, known to give excellent preservation of fine structural details, 3.5 % buffered formaldehyde was chosen as fixative.Glutaraldehyde proved to be so inhibitory for enzyme activity that incubation times had to be doubled after fixation with it. So the benefit of better structure preservation was lost because of longer incubations in the acid milieu. It is known that some part of the brain AcPh is especially sensitive to this dialdehyde (Torack 1965). Glutaraldehyde from Taab Laboratories is routinely used in this laboratory without previous distillations or other purification procedures. This stock solution may therefore contain inhibitory impurities. Inhibitory effects of commercial glutaraldehyde solutions on AcPh activities have been reported in other tissues by Smith and Farquhar (1966) and Fahimi and Drochmans (1968).

Washing and freezing in Holt's gum-sucrose proved favourable for both enzymatic activity and ultrastructural preservation.

The SON area showed strikingly intense AcPh activity compared with other brain regions, as has been unanimously stated by all previous authors (Eränkö 1951a, Leduc and Wislocki 1952, Scharrer and Scharrer 1954, Cohn and Richter 1956, Kivalo *et al.* 1958, Pilgrim 1967).

In the present work, a heavy brownish black final reaction product was observed in all cell bodies of the neurosecretory cells and the differences between activities of individual cells had disappeared after 7 days' dehydration. All the cells showed more intense AcPh activity than the most active cells in the control sections. Pilgrim (1967) also demonstrated increased activity after 5—6 days' water withdrawal. However, he differentiated two types of neurosecretory cells

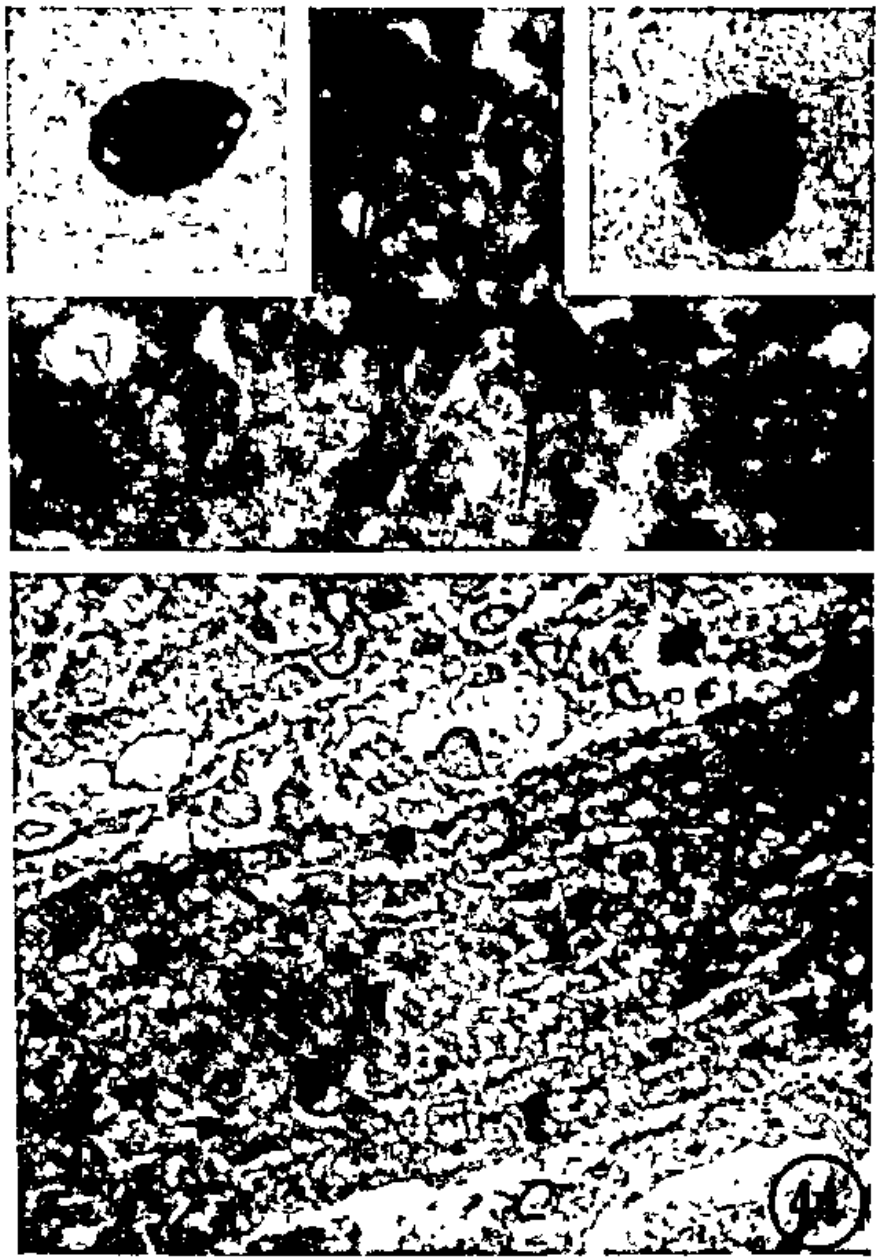

Fig. 43 AcPh activity in the large inclusion bodies of a light neurosecretory cell in control rat SON. Two large inclusion bodies (arrows), which are seen vary in the amount of reaction product. The lead salt is very finely granular as seen in the inset pictures with higher magnification. Procedures as in Fig. 41. × 25 500
× 39 000

Fig. 44 AcPh activity in the dark neurosecretory cell of rat SON after 7 days' dehydration. The large inclusion bodies are heavily covered with lead precepitate. The Golgi lamellae (G) are also reactive. Specimen processed as in Fig. 41. × 6 600

according to their AcPh reactivity. The small, dense-looking cells were more active than the larger, more vacuolated cells.

On the basis of electron microscopy, the reaction product was found in the large inclusion bodies of both light and dark neurosecretory cells. There were always non-reactive large inclusion bodies among the reactive ones, both in the light and the dark cells. In the control animals, some flattened Golgi cisternae showed reaction product, but the small inclusion bodies were as a rule negative. These observations are in agreement with those of Osinchak (1964a). He was the first to propose that the large inclusion bodies were identical with the lysosomes of other nerve cells and different from the small inclusion bodies. According to Novikoff (1961), the bodies limited by single membranes and showing AcPh activity fulfill the criteria of lysosomes.

After 7 days' dehydration, the neurosecretory cells showed an increased number of reactive lysosomes and more reaction product in the flattened Golgi cisternae than in the control animals. Individual lysosomes also had more reactive material inside the matrix.

High AcPh activity has often been related to lytic events and degenerative changes of the cell (Novikoff 1961, Bitensky 1963, Söderholm 1965). Such an explanation does not seem likely in the neurosecretory cells under dehydration, in which increased protein synthesis can be expected.

Indeed, high AcPh activity outside the hypothalamic neurosecretory cells has been related to increased protein synthesis for increased metabolic demands (see *e.g.* Novikoff 1963 and Kokko 1965). The appearance of AcPh in non-lytic sites like the Golgi cisternae was reported by Smith and Farquhar (1966) in the hormone-producing cells of the rat adenohypophysis and by Holtzman and Dominitz (1968) in rat adrenal medullary cells. Smith and Farquhar (1966) suggested that lysosomes are needed to abolish the overproduction of the secretory products serving as a protein-degrading apparatus. Increased activity of AcPh was also reported by Szabó *et al.* (1967) in the lysosomes of stimulated adrenal cortex cells. Recently, Gordon *et al.* (1968) demonstrated synaptic lysosomes with both histochemical and biochemical AcPh activity in the cortical terminals of the rat brain. They suggested that *via* proteolysis these presynaptic lysosomes produced amino acids for fresh protein synthesis.

In the light of the present observations it is conceivable that increased AcPh activity in the neurosecretory cells under dehydration stress may well reflect an activated polypeptide hormone synthesis. The increased activity of Golgi apparatus cisternae of the SON, first observed in the present study, may be related to increased lysosomal activity or is directly involved in the packing and releasing mechanism of the neurosecretory granules.

V. NUCLEOSIDE PHOSPHATASE ACTIVITY IN THE SUPRAOPTIC NUCLEUS OF NORMAL AND DEHYDRATED RATS

REVIEW OF THE LITERATURE

On the basis of biochemical assays the existence of at least two different ATPases in nerve tissue is fairly well established: (1) the Na^+ -K^+-dependent Mg^{++} activated ATPase, which is related to the membrane structures and inhibited by g-strophantin (ouabain) (Skou 1957, 1960, 1965, Bonting *et al.* 1961, Järnefelt 1961, Lewin and Hess 1964, Fried 1965, Samaha 1967, Fahn and Côté 1968), and (2) the Mg^{++} -activated and Na^+ -K^+ -independent ATPase, which is related to mitochondria and blood vessels and is not inhibited by g-strophantin (see *e.g.* Lehninger 1964, Parsons 1965).

LIGHT MICROSCOPIC OBSERVATIONS

Light microscopic observations of ATPase activity in nervous tissue were made by McClurkin 1964, Fried 1965, Söderholm 1965, Iijima *et al.* 1967, and Sabatini *et al.* 1968. Of these authors, Iijima *et al.* (1967) studied the magnocellular nuclei of hypothalamus and reported ATPase activity in almost all of its structures: in nuclei, nucleoli, capillaries, neuropile and glial cells.

ELECTRON MICROSCOPIC OBSERVATIONS

Only a few electron microscopic studies have been published on ATPase activity in nervous tissue (Torack and Barrnett 1963, Torack 1965, Rechardt and Kokko 1967, Sabatini *et al.* 1968). Mitochondrial ATPase activity has been demonstrated in the mitochondria of many other tissues (Lazarus and Barden 1962, Ashworth *et al.* 1963, Otero-Vilardebó *et al.* 1963, Essner *et al.* 1965, Moses *et al.* 1966, Wood 1967).

Of the histochemical methods for demonstration of ATPase the lead method introduced by Wachstein and Meisel (1957) is suitable for electron microscopic purposes. Recently, however, severe criticism has been directed against the lead methods for demonstration of ATPase (Moses *et al.* 1966, Moses and Rosenthal 1968, Rosenthal *et al.* 1966, Palkama and Uusitalo, 1968).

MATERIAL AND METHODS

Forty adult male control rats about 300 g in weight, and 10 rats of equal weight kept 7 days without water, were perfused under ether anaesthesia *via* the left cardiac ventricle with 0.075 M cacodylate-buffered 3.5 % formaldehyde in 0.3 M sucrose, pH 7.2. Perfusion time was 10 minutes. The hypothalamic area was excised and the tissue piece washed overnight in cacodylate-buffered gum-sucrose, pH 7.2 (Holt 1958). Frozen sections, cut with the freezing microtome at 10 μ for light microscopy and at 80 μ for electron microscopy, were incubated free-floating for 30 minutes at 0°C. The standard incubation medium consisted of ATP *disodium salt (C. F. Boehringer & Soehne, Mannheim)* or *dibarium salt* (Sigma Chemical Company, St.Louis, Missouri) 8.3×10^{-5} M, Tris-maleate buffer pH 7.2 0.08 M, $MgCl_2$ 0.05 M, $Pb(NO_3)_2$ 2.5×10^{-3} M, sucrose 0.3 M was added and the pH was adjusted to 7.2 (Otero-Vilardebó *et al.* 1963). After incubation the sections were rinsed in 4 changes of ice-cold 0.3 M sucrose for 20 minutes. Light microscopic specimens were treated with diluted ammonium sulphide.

Controls were made by incubating the sections either without the activator and substrate, or by substituting β-glycerophosphate, ADP, IDP, ITP, TPP or UDP for ATP, respectively. The effects of 0.01 M sodium fluoride and of ouabain 3×10^{-3} M (Fluka AG,Buchs SG) were studied, as well as that of 0.1 M Na^+ and 0.02 M K^+.

For electron microscopy, the SON areas of incubated sections were dissected under a stereo-microscope and the pieces were fixed in 1 % OsO_4 for one hour. Dehydration, embedding and sectioning were performed as described in Chapter III. The thin sectios were examined unstained and photographed with Siemens Elmiskop I and Philips EM 200 operated at 80 kV.

RESULTS

LIGHT MICROSCOPIC OBSERVATIONS

Compared with the other hypothalamic areas, a strong nucleoside phosphatase activity was demonstrated in the SON area with disodium ATP as substrate. The negative neurosecretory cells were surrounded by a strongly positive network consisting of capillaries and a scanty neuropile between the nerve cells (Fig. 45). Pia arachnoidea, which usually was attached to the lower surface of the nucleus, showed a very strong activity. Reaction product was also detected in a few blood vessels in the optic chiasma.

After 7 days' dehydration the localization of reaction product was unchanged but the overall activity was weaker in all sites (Fig. 46).

ELECTRON MICROSCOPIC OBSERVATIONS

Neurosecretory cells

In the neurosecretory cells, finely granular reaction product was localized between the endoplasmic cisternae both with sodium- and barium-ATP salts and ITP as substrates. The localization was the same as that of free ribosomes (Fig. 47).

In some cells, the large inclusion bodies showed a certain affinity to the reaction product, but the Golgi apparatus was negative in all cells. The mitochondria were also negative. Neither did the nuclear and plasma membranes show any reaction product, not even when K^+ and Na^+ ions were added to the incubation medium.

When ADP, IDP or UDP was used as substrate, the reaction product was localized in the Golgi apparatus, mainly in the flattened cisternae and also in the large inclusion bodies. This kind of localization was more prominent in the dark cells (Fig. 48). Using TPP as substrate, the only localization was the Golgi apparatus.

After 7 days' dehydration, ATPase and ITPase activity was noticed in the flattened Golgi cisternae in the form of dense granules. Some large inclusion bodies also showed reaction product, as seen in Fig. 49.

The nerve fibres

Both myelinated and unmyelinated nerve fibres contained mitochondria which showed nucleoside triphosphatase activity in the matrix between the cristae

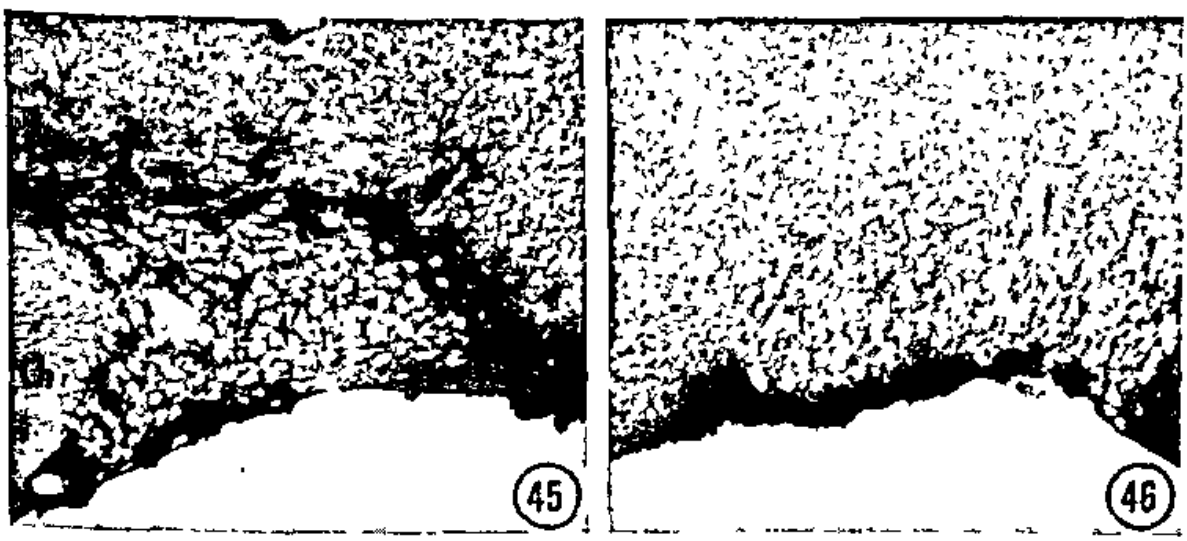

Fig. 45 A light microscopic view of nucleoside phosphatase activity in control rat SON. Enzyme activity is noticed round the neurosecretory cells, which appear negative. 10 minutes' formaldehyde perfusion fixation, incubated 30 min. with ATP disodium salt as substrate. Ch (chiasma opticorum) × 65

49

(Fig. 50). Non-reactive mitochondria were always found among reactive ones. The axon terminals in synapses did not contain more reactive mitochondria than the other fibres. No reaction product was demonstrated in the neuroglial processes around the capillaries.

The same kind of mitochondrial activity was obtained with ITP as substrate. When ADP, IDP or UDP were employed no mitochondrial activity could be detected.

There was no change after 7 days' dehydration in the amount and distribution of the reaction product in the mitochondria. The mitochondria in the neurosecretory cells remained negative as in the control specimens.

Capillaries

Both finely and coarsely granular reaction was found in all capillaries of the SON. The strongest activity was localized in the basal lamina as a continuous or interrupted line (Fig. 51). The cytoplasm of the endothelial cell showed only a few randomly scattered granules. The mitochondria of the endothelial cells were negative.

The glial elements round the capillaries were negative.

When ITP was substituted for ATP, the amount and localization of the reaction product were unchanged. With *ADP*, *IDP* or *UDP* as substrate the enzyme reaction was distinctly weaker in the capillaries and the reaction product was of greater amount in the endothelial cytoplasm than in the basal lamina.

After 7 days' dehydration, a decrease was noticed in nucleoside phosphatase activity. Electron microscopy showed this decrease to be due to a loss of reaction product from the capillary walls.

The basal laminae of the capillaries of the dehydrated rats did not show as much precipitate as in the control capillaries (Figs. 51 and 52).

CONTROL STUDIES

When the substrates were omitted from the incubation medium, no reaction product was visible in any structure, except for some finely granular precipitate occasionally seen in the nuclei of the endothelial cells. No reaction product was demonstrated in the cytoplasm of the cells, neuropile or capillaries when β-glycerophosphate was used as substrate. Sodium fluoride had a slight inhibitory effect especially on mitochondrial activity but capillary activity was equally strong as without any inhibitors. Ouabain had no inhibitory effect in any localizations. The addition of Na^+ - and K^+ -ions to the incubation medium did not affect the distribution of the end product. Without Mg^{++} -ions no activity could be demonstrated.

Fig. 50 General view of the nucleoside triphosphatase activity in the mitochondria (M_1) of the nerve fibres. Both myelinated and unmyelinated nerve fibres, axons (Ax) and dendrites (D) contain mitochondria with reaction product. One mitochondrion (M_2) without any reaction product is noted in the vicinity of an active mitochondrion. The reaction product is localized between the cristae in the matrix part. Specimen processed as in Fig. 47. × 28 200

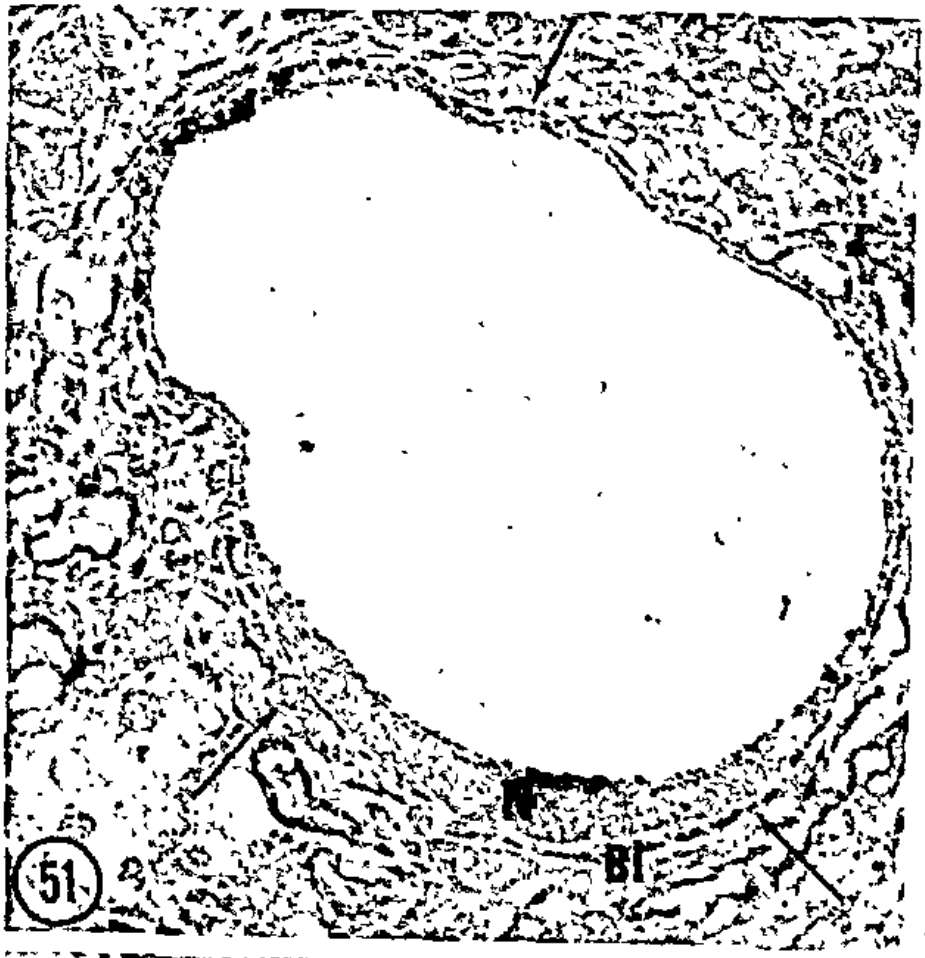

Fig. 51 Nucleoside triphosphatase activity in the capillary wall of control rat SON. The reaction product (arrows) is localized mainly to the basal lamina (Bl). Some reaction product is also demonstrated in the endothelial cell. Very fine nonspecific precipitate covers the endothelial cell nucleus. Procedures as in Fig. 47. × 11 800

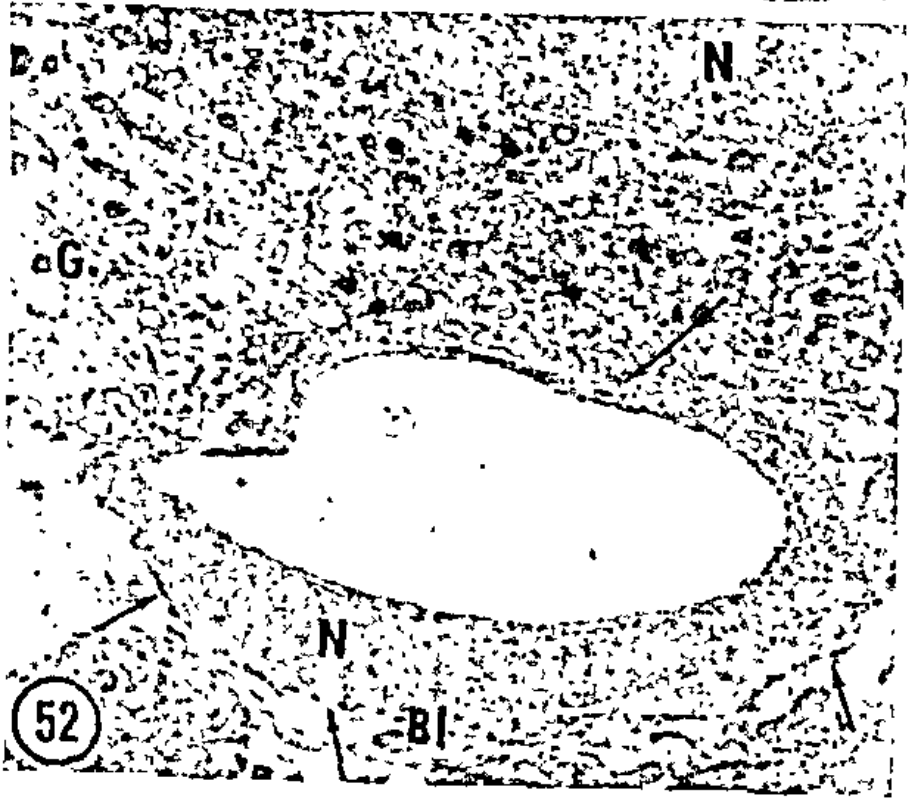

Fig. 52 Nucleoside triphosphatase activity in the capillary wall of rat SON after 7 days' dehydration. The reaction product now occurs as a weaker and discontinuous line (arrows) in the basal lamina (Bl) when compared to Fig. 51. Procedures as in Fig. 47. × 11 900

DISCUSSION

Of the methods available for demonstration of nucleoside phosphatases, the lead method introduced by Wachstein and Meisel (1957) is most widely used. Its advantage for electron microscopic purposes is that the end product, lead phosphate, is highly electron-dense. The method has, however, many pitfalls which restrict its validity (*e.g.* Moses and Rosenthal 1968). These authors have biochemically shown that the lead concentrations used in the Wachstein-Meisel method inhibit nucleoside phosphatase activity and, moreover, favour non-enzymatic hydrolysis of the substrates (Moses *et al.* 1966, Moses and Rosenthal 1967). On the other hand, Novikoff (1967) has presented observations indicating non-enzymatic hydrolysis of ATP after long incubations. However, he also showed that such hydrolysis can be avoided by using appropriate fixation and incubation conditions. Modifications, mainly by changing reagent concentrations have been developed for histochemical demonstration of nucleoside phosphatases (Otero-Vilardebó *et al.* 1963, McClurkin 1964).

Recently Palkama and Uusitalo (1968, 1969), using a technique further modified from that of Wachstein and Meisel (1957) have bio- and histochemically demonstrated ouabain-sensitive Mg^{++} —activated and Na^{+} -K^{+} -dependent adenosine triphosphatase in the rabbit ciliary processes, although this nucleoside phosphatase has been reported to be especially sensitive to lead ions and fixatives (Gordon and Torack 1967, Moses and Rosenthal 1968).

In the modification of the Wachstein-Meisel method used in the present study, the concentration of lead was reduced from the original, and Mg^{++} concentration was increased (Otero-Vilardebó *et al.* 1963). The mitochondrial nucleoside phosphatase activity is known to be especially sensitive to fixatives (Essner *et al.* 1965). With very brief perfusion fixation it was possible, however, to demonstrate the mitochondrial activity in nervous tissue. The methodological problems have been discussed in detail in a previous paper (Rechardt and Kokko 1967).

Both myelinated and unmyelinated nerve fibres showed mitochondria in which the granular end product was localized in the matrix between the cristae. Similar intercristal localization was reported by Lazarus and Barden (1962) in rabbit pancreas, by Ashworth *et al.* (1963) in rat intestine, kidney and liver, by Otero-Vilardebó *et al.* (1963) in rat colonic epithelial cells, by Essner *et al.* (1965) in cultured human amnion cells and by Grossman and Heitkamp (1968) in rabbit's skeletal muscle mitochondria.

The nerve fibre mitochondria showed heterogeneity in reactivity. There were always negative mitochondria in the immediate vicinity of positive ones.

It is interesting that the mitochondria in the nerve cell bodies were negative. No activity could be detected with any of the substrates employed. A similar observation was made by Rechardt and Kokko (1967) in the mitochondria of the motor nerve cells of rat's spinal cord. The possibility that the mitochondria inside the neurons contain the enzyme although its activity is not demonstrable with the present method cannot be excluded. These mitochondria may be more resistant to freezing and thawing, which is necessary for the penetration of the reagents and thus for nucleoside phosphatase demonstration. It is also possible that their metabolism is different or that formaldehyde inhibits their activity.

In the present study, di- and triphosphatase activity was observed between the endoplasmic cisternae of the neurosecretory cells. This localization was reported in the secretory cells of rat and rabbit pancreas with various triphosphates as substrates (Wachstein and Fernandez 1964).

After 7 days' dehydration, reaction product was found in the flattened Golgi cisternae when ATP or ITP was used as substrate. During dehydration the Golgi apparatus of the neurosecretory cell is possibly the most active cell organelle, packing and liberating the neurosecretory granules. However, no activity was observed in the neurosecretory granules of these neurosecretory cells, although adenosine triphosphatase activity has been biochemically determined in the neurosecretory granules from the bovine neurohypophysis (Poisner and Douglas 1968). Nucleoside phosphatases may be involved in the release of the neurosecretory product, as has been suggested in the case of the chromaffin granules in the adrenal gland (Oka *et al.* 1965, Poisner and Trifaró 1968).

The reaction in the capillary wall was similar with all the substrates except β-glycerophosphate, with which no activity was observed in the present study. Similar observations were reported by Torack and Barrnett (1964). It seems that the capillary wall activity is not due to alkaline phosphatase activity, but to an enzyme or enzymes splitting several di- and triphosphates.

With the aid of electron microscopy reaction product was found mainly in the basal lamina though some activity was detected in the endothelial cells, presumably in pinocytotic vesicles. The sparse, fine granules in the endothelial cell nuclei were considered non-specific. Nucleoside phosphatase activity in the basal lamina has been related to the blood-brain barrier function of the blood vessels (Becker *et al.* 1960, Torack and Barrnett 1964, Torack 1965). In brain areas in which there is no blood-brain barrier the basal lamina is non-reactive and the endothelial cells show nucleoside phosphatase activity in their pinocytotic vesicles. Torack and Barrnett (1964) described a weak activity also in the plasma membranes of the glial end feet and oligodendrocytes, which, however, was not confirmed in the present study.

After 7 days' dehydration, activity of the basal lamina was reduced, while more activity was noticed in the endothelial cells. If nucleoside phosphatase activity is related to the barrier function, the decreased activity of the basal lamina is suggestive of a change in permeability after dehydration stress. There might be a loss in the barrier function. However, a change in nucleoside phosphatase activity could be explained also on the basis of the theory that nucleoside phosphatases are involved in the synthesis and degradation of mucopolysaccharides in the basal lamina, which as such is an extracellular structure (Campbell 1968). Mucopolysaccharide synthesis possibly undergoes changes during dehydration.

SUMMARY AND CONCLUSIONS

The present investigation was carried out to study the SON of the rat with fluorescent and electron microscopic methods, especially to examine hitherto controversial views and to use new techniques not yet applied to this nucleus. In Chapter I the effect of dehydration on the fine structure of the SON was studied. The behaviour of adrenergic nerve fibres after experimental conditions was studied in Chapter II. Some hydrolytic enzymes demonstrable electron microscopically were studied in Chapters III—V in the normal SON, and after increased hormone production due to water deprivation.

I. Two distinct types of neurosecretory cells, dark and light, were observed without doubt by both light and electron microscopy in the SON using material fixed by perfusion with formaldehyde and glutaraldehyde. The difference between the dark and light cells depended on the great difference in the number of free ribosomes, as was seen by electron microscopy. Dehydration caused a further distinct increase in the number of ribosomes in the dark cells, while in the light cells such a change was less evident. While the presence of dark and light nerve cells in the SON has often been considered artifactual due to poor preservation and handling of the tissue, it can be concluded from the present study that two different types of neurosecretory cells really exist.

Small inclusion bodies, also called neurosecretory granules, were observed in both types of cells. Dehydration caused a loss of these bodies, and the loss was almost complete after 7 days in both types of cells. In such cells, empty vesicles of the same size were found near the Golgi apparatus. No changes due to dehydration were noticed in the amount or appearance of mitochondria or lysosomes.

Three kinds of synaptic vesicles were observed in the axo-somatic, axo-dendritic and axo-axonal synapses: small agranular, small granular and large granular vesicles. The small granular vesicles were observed only in material fixed by perfusion with potassium permanganate. Such vesicles, related to adrenergic neuronal transmission, were in the present study demonstrated for the first time in the axo-somatic and axo-dendritic synapses of rat's SON area. Dehydration had no effect on the appearance or number of the vesicles.

The capillaries were of the blood-brain barrier type with few pinocytotic vesicles in the endothelial cells. In normal rats, intimate contacts between the nerve cells and the capillaries were found. After dehydration, the glial processes were hyper-

trophic and swollen, and the distance between the neurosecretory cells and capillaries was increased. These new observations suggest participation of the glial tissue in the osmoregulatory function of the SON.

II. The effect of sympathectomy and of administration of reserpine or Oxypertin, not earlier examined in the rat SON, was studied by fluorescence and electron microscopy. Bilateral cervical sympathectomy had no effect on the fluorescent nerve net round the non-fluorescent nerve cells, whereas reserpine treatment totally abolished the fluorescence and Oxypertin treatment diminished it.

Bilateral cervical sympathectomy affected neither the neurosecretory cells nor the large granular synaptic vesicles. Reserpine and Oxypertin treatments caused a loss of neurosecretory granules from the cells but had no noticeable effect on the large granular vesicles in any of the three types of synapses.

III. Cholinesterases were demonstrated using the acetylthiocholine method of Koelle and Gomori and that of Karnovsky and Roots, together with the specific inhibitors iso-OMPA and 284 C51. Moderate acetylcholinesterase activity was observed light and electron microscopically in the neurosecretory cells. The relatively weak enzyme reaction in the neurosecretory cells suggests that this enzyme is needed for other purposes than neuronal transmission, possibly for metabolic demands. Only few unmyelinated nerve fibres and some synaptic endings on the neurosecretory cells showed a reaction, located in the cell membrane. After 7 days' dehydration, no change was noticed in the acetylcholinesterase activity of any tissue.

The non-specific cholinesterase activity was localized light microscopically in the capillary walls only. Electron microscopically, the reaction was found both in the endothelial cells and in the glial cells. After dehydration, the intensity of the reaction increased in the endothelial cells, suggesting a change in their metabolism.

IV. Acid phosphatase activity was demontsrated with glycerophosphate as a substrate using Gomori's lead method, as modified by Eränkö. Strong acid phosphatase activity was detected in the neurosecretory cells and the intensity of this activity increased after dehydration. The reaction product was localized electron microscopically in the large inclusion bodies of both types, *i.e.* the lysosomes and the multivesicular bodies, as well as in some Golgi lamellae. After 7 days' dehydration acid phosphatase activity increased markedly, and in electron microscopic specimens the number of reactive lysosomes was found to be increased suggesting increased cellular turnover rate. The intensity of the reaction also increased in individual lysosomes and in the Golgi apparatus.

Pronounced acid and nucleoside (see V below) phosphatase activity in the Golgi apparatus and intense acid phosphatase activity in the lysosomes, as well as abundant ribosomal content and intracisternal material suggest that contrary to earlier assumptions, the dark neurosecretory cells are not resting cells but metabolically active cells, which react during dehydration.

V. Nucleoside phosphatase activity not previously examined in the SON, was demonstrated with the lead method introduced by Wachstein and Meisel using

ADP, IDP, UDP, ATP, ITP, TPP and β-glycerophosphate as substrates. Light microscopically, the reaction with di- and triphosphates was observed round the nerve cells, which were themselves non-reactive, in the capillaries and in the neuropile.

Electron microscopically, triphosphatase activity was found in the mitochondria of the nerve fibres and in the basal laminae of the capillaries. In the neurosecretory cells, triphosphatase activity was localized between the endoplasmic cisternae.

After 7 days' dehydration mitochondrial triphosphatase activity was unchanged, but the basal laminae showed reduced activity in all capillaries. The change in the triphosphatase activity in the capillary wall, *i.e.* basal lamina, after dehydration is suggestive of altered capillary function comparable to that indicated by increase in the non-specific cholinesterase activity, both enzymes being apparently related to the blood-brain barrier function.

SYMPOSIA

Physiological adjustments and limiting factors at maximal work	1–10
Secretion	11–17
Uptake, storage and release of biogenic amines	18–34
Excitation-contraction coupling	35–39
Motor cortex-afferents and efferents	40–45

INVITED LECTURES

Transfer of signals from muscle stretch receptors	46
Neural control mechanisms determining pace and depth of respiratory movements	47
Etiological and curative aspects on obesity	48
Photochemical aspects of the receptor process in vision	49
The molecular basis for the active transport of Na^+ and K^+	50
The role of gastrointestinal wall in drug metabolism	51
The dynamics of aqueous humor	52
On the role of central monoamine neurons in neuroendocrine mechanisms	53
Plasma kinins in physiology and pathophysiology	54
Reception of sound and vibrations by the fish ear	55
Functional organization of the monkey visual cortex	56
The blood-brain barrier	57

FREE COMMUNICATIONS

Amine storing cells	58–63
Nerve degeneration, supersensitivity	64–68
Release and metabolism of amines	69–79
Behaviour	80–88
Pharmacokinetics	89–95
Gastric secretion	96–97

Endocrinology	98–102
Metabolism: general aspects	103–109
Muscle metabolism	110–114
Respiration	115–119
Exercise physiology	120–132
Central haemodynamics; circulatory control	133–146
Regional circulation	147–156
Capillary exchange	157–162
Membranes and active transport	163–170
Muscle physiology	171–179
Central nervous system	180–188
Receptors and sensory transmission	189–196

Hohwü-Christensen,E.(Department of Physiology, Gymnastik-och idrottshögskolan, Stockholm, Sweden): INTRODUCTION. 1

How can the working organism solve the problems of energy delivery when a motoreffect of 3 to 5 HP are needed for some 10 sec. maximal effort during a 100 m run, or when a total of 1500 kcal per hour are consumed during 6 hours (Vasaloppet)? When are the energy stores in the working muscles adequate and sufficient, and when will a certain supply from other stores have to be transported with the blood to the muscles? How many kcal are available for muscular work as ATP and CrP, and how fast can these energy quantities be released and replaced? Is the limitation for speed during a 100 m run due to lack of acceptable, fast energy sources, due to an accumulation of waste products or are there mechanical limitations? At which level of metabolic turn over rate have calories from fat to be replaced entirely by those from carbohydrate to secure sufficient fast energy delivery for the resynthesis of ATP? Which role plays the local oxygen tension in this "regulation" of muscle metabolism? How do we solve the varying local oxygen supply? Which are the lowest acceptable oxygen tensions in the blood capillaries in the muscles if anaerobic metabolism shall be omitted? How many ml of oxygen per g and min can be delivered to the working muscles, and where are the bottle necks in the oxygen transport system from the air via the lungs and blood to the mitochondria? Is the oxygen flow limited by the bellow function of the pulmonary system, the pulmonary capillary membranes, or is it limited by the pumping capacity of the heart? What are the pro and contra as to respiratory work as a limiting factor when pulmonary ventilation surpasses 150 to 200 litres per min? How far and how can the blood flow-oxygen flow - be directed towards the working muscles and away from less "important" tissues? What extra load is involved in the elimination of waste products, including heat from the working muscles? How many litres of the cardiac output must the organism spend for heat transport to the skin, and under which conditions may this extra load on the blood circulation limit work performance?

Those are some of the questions which I do hope will get an answer in this symposium. What we want to be informed about is: What do we actually know today and where are the main lacks in our knowledge? Where are the front lines of research in this rather complex field of physiology?

2 Asmussen, E. (Laboratory for the theory of gymnastics A, University of Copenhagen, Denmark): RESPIRATION.

During exercise the pulmonary ventilation ($\dot{V}E$) increases in proportion to the increase in aerobic metabolism ($\dot{V}O_2$) up to a certain value, corresponding to about 60% of $\dot{V}O_2$ max, after which $\dot{V}E$ increases at a relatively higher rate. This is effected by an increase in depth and in respiratory frequency, but neither of these reach the highest possible values in exercise. Exercise results in an increase in the overall $\dot{V}A/Q$-ratio, and the distribution of $\dot{V}A$ and $\dot{Q}$ in the different parts of the lungs becomes less uneven (West & Dollery, J.Appl.Physiol. 1960. 15. 405). This would tend to diminish the $P(A-a)O_2$-difference. The increased gradient found at maximal exercise (fig.1) may, therefore, be due to the shortened time for reaching diffusion equilibrium in the alveoli. The increased $P(A-a)O_2$-difference is mainly due to an increased PAO_2 at maximal work, the PaO_2 remaining nearly constant. $\dot{V}E$ is hardly the limiting factor in hard exercise at normoxia: Each liter of inspired air will deliver 30 to 40 ml O_2 to the blood in hard exercise, and the extra cost of breathing in the interval 120 to 150 l/min is only about 10 ml O_2 per extra liter ventilation (Bartlett, Brubach & Specht, J.Appl.Physiol. 1958. 12. 413). Local fatigue due to anaerobiosis in the respiratory muscles may, however, play a role: Eldridge (J.Appl.Physiol. 1966. 21. 853) has shown that increased ventilation against an added inspiratory resistance may cause increases in blood lactate and pyruvate. By substituting $He-O_2$ mixtures for air in the inspired air, Murphy, Clark, Bucking & Young, (J.Appl.Physiol. 1969. 26. 303) found in hard exercise that $\dot{V}E$ remained the same at the same external work loads in spite of a drop in $\dot{V}O_2$, caused by the diminished air density. The different steps in the O_2-transport from atmosphere to tissues at increasing $\dot{V}E$ are illustrated by the composite diagram in fig.1. The data are from young average students. A $\dot{V}O_2$ of about 3.5 l/min must be considered maximal in their case.

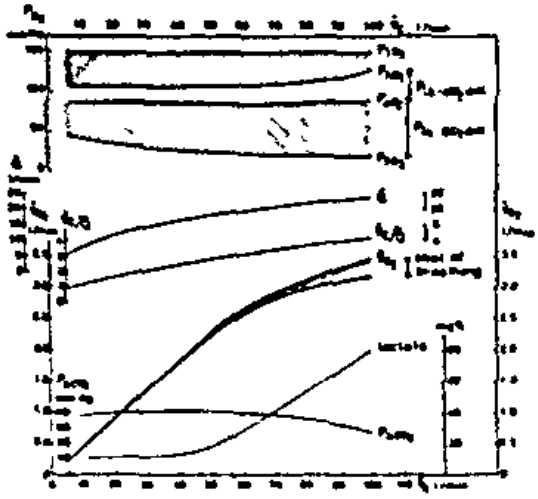

fig.1.

Saltin, B. (Department of Physiology, GIH, Stockholm, Sweden): 3

CENTRAL CIRCULATION AND BLOOD FLOW DISTRIBUTION.

Methods: A comparison of the direct Fick and the dye-dilution technique for determination of the cardiac output in the range from 4 to 32 l/min demonstrated no systematic difference.

Maximal exercise (3-10 min): When the dye-dilution technique was applied in three subjects, who on separate days exercised at a maximal (6-10 min) and a super maximal (3-5 min) work load on a bicycle ergometer, 1.5-4 l/min higher cardiac outputs were observed in the longest run. Maximal oxygen uptakes were the same in both runs. Hence, arterio-venous oxygen difference was less in the long run. The higher oxygen tension in the brachial vein, found in the longest maximal run may indicate a larger skin blood flow, which in this situation may be necessary to avoid overheating. An additional explanation for the observed difference in cardiac output may be that in a super maximal effort the pressure within the muscle may inhibit a maximal muscle blood flow to occur. Perfusion pressure is, however, in the super maximal effort higher, as maximal arterial pressure (mean) is related to the work load. The finding that maximal oxygen uptake can be achieved with different "maximal" cardiac outputs may indicate that the central circulation is not a limiting factor in this type of exercise. On the other hand the increase in maximal oxygen uptakes caused by physical training in young men is almost directly related to the increase in maximal cardiac output (stroke volume).

Maximal values for	Two months training		Several years training	Athletes
	Before	After		
Oxygen uptake l/min	2.52	3.41	4.93	5.57
Arterio-venous oxygen diff. vol%	14.6	17.0	17.1	15.6
Cardiac output l/min	17.2	20.0	28.9	36.0
Heart rate beats/min	192	191	186	190
Stroke volume ml	90	105	155	189
Heart volume ml	740	830	1070	1140

Maximal exercise (30-180 min): During prolonged heavy exercise cardiac output is rather constant after 10-15 minutes of exercise. Heart rate, however, increaseseven after this time with a corresponding reduction in stroke volume. Increased venous pooling of blood and reduced ventricular filling has been suggested, but as exercise in supine position does not change the heart rate/stroke volume relationship, this possibility seems unlikely. A changed balance in the autonomic nervous system with a reduced sympathetic activity (mean arterial blood pressure goes down) on the heart may be excluded as this ought to have influenced also the heart rate. The vagus on the other hand, has mainly a chronotropic effect on the heart and the increase in heart rate may be due to a gradual reduction in vagus activity. When atropin is given before a prolonged exercise period a constant heart rate has been observed between 8 and 60 minutes of exercise. It can be concluded, however, that an impaired central circulation is not a primary factor limiting prolonged heavy exercise.

4 Bevegård, S. (Laboratory of Clinical Physiology, Södersjukhuset, Stockholm, Sweden): CENTRAL CIRCULATION AND BLOOD FLOW DISTRIBUTION.

The capacity of the cardiovascular system to transport oxygen, measured as maximal aerobic capacity or as submaximal exercise tolerance at a given heart rate is closely correlated to static dimensions of the various links of the oxygen transport chain such as total amount of hemoglobin, blood volume and heart volume. These correlations are helpful in defining the borderlines between normal and abnormal and for prediction of functional capacity from static dimensions.

Up to maximal levels of work, heart rate and cardiac output increase as approximately linear functions of oxygen uptake. In order to effect an increase in oxygen transport of 1 liter/min. the cardiac output increases on average by 6 liters/min. During supine leg exercise the stroke volume may increase by 10-20% of the resting value. This is true for healthy males and females, athletes and nonathletes, regardless of the type of supine exercise carried out and the number of muscles involved. Heart volume remains practically unchanged or decreases slightly during supine leg exercise.

Since cardiac output and heart rate during work increase as linear functions of oxygen uptake the arterio-venous oxygen difference is a rectangular hyperbolic function of both oxygen uptake and heart rate.

With transition from supine to upright position at rest about 20% of the blood volume in the heart and lungs is shifted to the lower part of the body. This hydrostatic shift of blood results in decreased filling of the heart and stroke volume decreases. On transition from rest to exercise in the erect position the mechanical effect of the leg muscles redistributes blood centrally and heart volume and stroke volume increase according to the Frank-Starling mechanism. For the same amount of submaximal work performed in the upright compared with the supine position the cardiac output is less because of a smaller stroke volume. From the viewpoint of oxygen transport the difference in stroke volume between the two body positions is compensated for by a higher arterio-venous oxygen difference in the upright position.

With increasing work systemic arterial and pulmonary arterial mean pressures increase approximately linearly in relation to the increase in cardiac output. There is no significant change in pulmonary arterial wedge pressure with submaximal exercise in ordinary subjects. In athletes higher pulmonary arterial wedge pressures have been measured during heavy exercise. Right ventricular end-diastolic pressure remains unchanged or decreases slightly. The increase in blood pressure and heart rate during exercise is tempered by the arterial baroreceptors. They continue to oppose the increase but cannot prevent it.

Efficient distribution of left ventricular output according to metabolic needs and temperature regulation is provided through reflex constriction of resistance vessels. The effects of the increased noradrenergic activity in the exercising muscles are overcome by the local vasodilator mechanism.

The circulatory adaptation to exercise varies according to the muscles involved and whether the work is carried out rhythmically or by isometric contractions. Arm work results in higher heart rate and blood pressure than leg work at a given oxygen uptake.

The increase in cardiac output with exercise is linked to the vasodilation in active muscles and hence to metabolism. Superimposed on this basic relationship is a reflex activation of the sympathetic nervous system to the heart and systemic resistance and capacitance vessels.

Mellander, S. (Department of Physiology, University of Lund, Sweden): CIRCULATION IN SKELETAL MUSCLES.

The increased metabolic demand of skeletal muscle during exercise is met by adjustments of tone in resistance vessels determining blood flow and capillary filtration pressure, in precapillary sphincters determining size of functional capillary surface, and in capacitance vessels influencing venous return. Such vascular adjustments can be evaluated quantitatively and simultaneously by recording blood flow, arterial and venous pressures, capillary filtration or diffusion capacities, tissue volume, and regional blood volume. The local chemical factors (e.g. K^+, hypoxia, and hyperosmolality) can relax precapillary vessels completely at maximal work. In "white" skeletal muscle, this provides for an increase of flow from a resting value of < 50 to > 500 ml/kg tissue x min, and a threefold increase of functional capillary surface, or from about 2 to 7 m^2/kg tissue. The corresponding values are about three times larger in "red" muscle, both at rest and maximal dilatation. Local chemicals cause no active dilatation of capacitance vessels, but decrease the pre-/postcapillary resistance ratio. This leads to net transcapillary fluid loss, in initial stages of exercise at a rate of 5 to 10 ml/kg x min, part of which is regained via the lymph vessels. Other control systems, and mechanical factors, can modify this metabolic pattern of response. Cholinergic dilator fibres, if engaged in exercise, and release of adrenaline (β-adrenergic effect), would contribute to the precapillary vessel dilatation. Increased constrictor fibre discharge, and noradrenaline release, during exercise lead mainly to constriction of capacitance vessels. Rhythmic tetanic muscle contractions can impede muscle flow significantly due to mechanical occlusion of vessels, but also promote venous return by compression of veins. In dependent limbs this latter effect can cause marked phasic reduction of venous pressure, and hence increase the pressure gradient to such an extent that average flow approaches that in an unobstructed, maximally dilated muscle vascular bed. The high transmural pressure in dependent exercising limbs leads to myogenic constriction of precapillary sphincters which is an important reaction to prevent gross oedema formation. It thus appears that during rhythmic exercise, dependent muscle regions are characterized by high blood flows and restricted capillary flow distribution, whereas regions at, or above, heart level receive smaller flows which are distributed over the entire capillary network. This might help to explain the greater solute extractions noted in the latter regions. With regard to transport, limitation in strenuous exercise may be related not only to inadequate supply of O_2 and substrates via the blood stream, but also to exchange problems across the barriers in the tissue, for instance in the interstitial compartment. There is evidence to indicate that the net transcapillary fluid movement occurring in muscle during exercise can help to improve solute transfer through this space.

6 Pernow, B. (Department of Clinical Physiology, Serafimerlasarettet, Karolinska Institute, Stockholm, Sweden): CIRCULATION IN SKELETAL MUSCLES.

The blood flow through resting skeletal muscle amounts to about 3 - 5 ml blood/100 g tissue · min. During maximal muscular exercise the corresponding value is 50 - 85 ml/100 g · min. During both rhythmic isometric and isotonic exercise at submaximal levels the blood flow and oxygen uptake rise in linear proportion to the work intensity, the arteriovenous oxygen difference remaining unchanged. During exercise above 80 % of the maximal work load no further increase in blood flow seems to occur. The size of the blood flow during exercise is dependent on the position of the exercising muscles in relation to the heart level. Studies on forearm blood flow have thus shown lower blood flow values during exercise with the arm vertically elevated than with the arm horizontal. This difference in flow was partly compensated for by a larger arteriovenous oxygen difference resulting in an almost identical oxygen uptake. Production of lactate was, however, significantly greater at work performed with the elevated arm, indicating a greater anaerobic component of the total muscular metabolism in this position.

Muscular exercise elicits an increase in sympathetic adrenergic vasomotor tone, resulting in a constriction of the resistance vessels in skeletal muscle, skin and in the splanchnic region, the increase in vasomotor tone being related to the relative intensity of the work performed. In the exercising muscles this increase in resistance is, however, overcome by a local metabolic vasodilating mechanism, which results in a distribution of blood flow to the exercising muscles well adapted to meet the metabolic demand. Thus, during leg exercise blood flow in the forearm is markedly reduced. The oxygen saturation of femoral venous blood of the exercising leg is decreased in proportion to the work intensity down to values of less than 10 % at maximal levels, indicating a distribution of blood from non-muscular tissues to the exercising muscles. Studies on exercise with arms or legs have shown that an identical external work performed with small muscle groups is accompanied by higher heart rate, arterial blood pressure and pulmonary ventilation, indicating a higher sympathetic tone.

Nielsen, Bodil (Laboratory for the Theory of Gymnastics, University of Copenhagen, Denmark): HEAT REGULATION. 7

In homeothermic organisms the deep body temperature is maintained at a constant level securing a constant high rate for the chemical and physical processes in the body. The temperature distribution in the body is the outcome of a balance between the local heat productions and losses. Due to the forceful stirring of the body core by the circulation the local variations within the core are, however, small. During muscular exercise the temperature of the whole body core is maintained at a higher level than during rest, independent of wide variations in ambient temperature and heat production. The plateau levels of core temperature seem to be a function of the oxygen uptake, and further to be correlated with the individuals maximum oxygen intake capacity.

The regulated core temperature is the result of the action of the temperature centres which regulate the rate of sweat secretion so that the total heat loss by convection, radiation plus by evaporation of sweat equals the heat production.

The possible mechanisms for the temperature setting and for the sweat regulation will be subjects for the discussion.

Nielsen, B.: Thermoregulation in rest and exercise. Acta physiol. scand. 1969. Suppl. no. 323.

10 Karlsson, J., S. Rosell and B. Saltin. (Dept. of Physiology, Gymnastik- & Idrottshögskolan, Stockholm and Dept. of Pharmacology, Karolinska Institutet, Stockholm, Sweden): BLOOD-BORNE SUBSTRATES.

Glucose and free fatty acids (FFA) can be mobilized within minutes from the storage sites in the liver and adipose tissue. It has also been proposed that muscular activity promotes the uptake of blood glucose into skeletal muscle. Therefore, the substrates required for muscular activity may be supplied from the blood rather than from storage sites within the muscle.

In order to clarify the quantitative aspects of the uptake of blood-borne substrates during muscular activity, experiments were performed on canine gracilis muscle. After a resting period of 20-30 min the mixed nerve to the muscle was stimulated electrically for 60 min with 5 imp x sec^{-1}, duration 0.1 msec. This resulted in a 30-fold increase in O_2-uptake, indicating heavy muscular contractions.

During rest the blood flow averaged 7 ml (all values refer to 100g x min^{-1}), oxygen uptake 7 µmoles and uptake of glucose 0.8 µmoles. FFA showed no significant uptake or release. Lactate production averaged 1.1 µmoles.

During muscular contractions there was a pronounced increase in O_2-uptake and lactate production. A small but significant rise in uptake of glucose occurred.

The results indicate that blood-borne FFA was not a major source for increased substrate consumption. The total consumption of lipids could not be calculated since the changes in the lipids stored in the muscle tissue was not determined.

The RQ values indicated a predominating carbohydrate metabolism during muscular contractions. However, the uptake of blood glucose could only account for approximately 20-30 per cent of the total calculated carbohydrate metabolism. The major part of the carbohydrates thus seemed to be derived from glycogen stored in the muscle. This suggestion was supported by measured decrease in the glycogen depots. Thus, blood-borne substrates seemed to be of minor importance during heavy muscular contractions.

Thorn, N.A. (Institute of Medical Physiology C, University of Copenhagen, Denmark): CURRENT PROBLEMS CONCERNING THE MECHANISM OF SECRETION OF WATER AND ELECTROLYTES BY EXOCRINE GLANDS. 11

Studies in recent years have demonstrated the importance of the duct system in the formation of glandular secretions. On the basis of indirect studies Thaysen, Thorn and Schwartz (Amer.J.Physiol. 1954.178.155) formed the hypothesis that parotid saliva is formed as a precurser fluid isotonic with plasma and that sodium is reabsorbed actively in the duct system. This reabsorption seemed to be influenced by aldosterone (Thorn, Schwartz and Thaysen, J.Appl.Physiol. 1956.9.477.) The hypothesis has been confirmed by more direct studies, comprising duct destruction and micropunctures (see Young & Schögel, Pflügers Arch. 1966.291.85.) Such studies have also revealed passive exchange over the duct epithelium (reequilibration processes) at low flow rates. Evidence is now accumulating that the duct system of the pancreas also participates in the formation of the final secretory product (Case, Harper & Scratcherd, J.Physiol. 1969.2o1.335).

As regards the formation of the primary saliva there is still much ignorance concerning the time relations of the different partial processes as well as their causal interrelations. Most evidence seems to be in agreement with the hypothesis of a non-electrogenic pump transporting Na and Cl across the acinar part. It seems that the secretory potential over the basal membrane is more likely due to a transport of cations from cell to blood than to transport of anions in the opposite direction. The secretory potential demonstrated by Lundberg (Physiol.Rev. 1958.38.21) may be a step in the activation of the secretion, but is probably not an expression of an ion transport quantitatively significant in the secretion proper (Petersen & Poulsen, Experientia 1968.24.919). Recent years have brought other interesting information concerning the activation of the secretory process. It has been demonstrated that calcium lack inhibits the secretion (Douglas & Poisner, J.Physiol.(Lond.) 1963.165.528). The fact that the secretory potential was nearly unchanged as was the K-loss to the perfusion fluid in glands perfused with a Ca-free-fluid (Petersen, Poulsen & Thorn, Acta Physiol.Scand. 1967.71.2o3, Proc.Int.Union Physiol.Sci. 1968, vol. VII.345), would seem to be in accordance with the hypothesis that the activation of the basal cell membrane is normal when Ca is lacking, and that Ca is essential for the link between activation and secretion. This is analagous to conditions in certain neurosecretory systems (Berlind & Cooke, Gen.Comp.Endocrinol. 1968.11. 458). In the initial state of secretion seemingly correlated transient changes in conc. of K^+ and Na^+ in saliva occur (Petersen & Poulsen, Acta Physiol.Scand. 1968.73.93) which seem to reflect special conditions before a steady state is reached.

12 Emmelin,N. (Institute of Physiology, University of Lund, Sweden): CURRENT PROBLEMS CONCERNING INNERVATION OF SALIVARY GLANDS.

Morphological observations on salivary glands show that the various effectors, secretory, vascular and myoepithelial, receive nerves (Garrett,J.R., J.R.microsc.Soc. 1966.85.149); this is supported by physiological experiments. The secretory cells are mainly activated by parasympathetic impulses at a rate normally seldom exceeding 8/sec. Some glands are activated by sympathetic impulses also, acting on α-receptors (cat submaxillary), β-receptors (dog submaxillary) or both (rat submaxillary). From the nerves transmitter leaks, normally causing no secretion but lowering the sensitivity of the cells; after nerve section a transiently increased leak causes "degeneration secretion". Some glands secrete spontaneously but most of them only when acted on by the transmitters or related drugs. Certain polypeptides (physalaemin, substance P, sialotonin) may also evoke secretion but it is unknown whether polypeptides physiologically activate the gland cells. Moderate doses of kallidin or bradykinin cause no salivation. Sympathetic nerves constrict the blood vessels and recent experiments suggest that the vasodilatation during parasympathetic stimulation is in fact due both to vasodilator nerves and a kinin mechanism (Gautvik,K., personal communication). The myoepithelial cells receive both sympathetic and parasympathetic motor nerves (see Emmelin,N., Garrett,J.R. and Ohlin,P., J.Physiol. 1969.200.539). Stimulation of such nerves causes a pressure rise in the salivary duct even without secretion, e.g. when single shocks are applied or secretion is abolished by drugs. Thus in the dog submaxillary gland sympathetic stimulation raises the pressure even after propranolol, but not after an α-blocker also. Kallidin and bradykinin contract the myoepithelial cells but it is unknown if this has any physiological significance.

Stimulation experiments thus suggest that the various effectors are innervated, often both by sympathetic and parasympathetic nerves; but this does not necessarily imply that specific secretory, vasomotor and motor nerves exist. The electron microscopical studies show that the salivary nerves enter into contact with the effectors by en-passant contacts. A single axon might thus affect several secretory cells, perhaps by a more or less close contact, but might possibly also affect different types of effectors. The existence of separate sympathetic glandular vasoconstrictors is suggested by the fact that bleeding causing a marked vasoconstriction in the cat submaxillary gland is not accompanied by salivary secretion which occurs when similar vasoconstriction is produced by electrical stimulation of the sympathetic (Emmelin,N. and Engström,J., J.Physiol. 1960.153.1); this specificity is reasonable in view of the general functions of the vasoconstrictors. But secretion and myoepithelial contraction may be caused by the same sympathetic axon. Similarly, impulses in one parasympathetic axon might start secretion, open up blood vessels to increase the blood supply and contract myoepithelial cells to promote salivary flow. At the same time excitation of the secretory cell starts the kinin mechanism, causing vasodilatation and perhaps myoepithelial contraction.

Flemström, G. (Institute of Physiology and Medical Biophysics, University of Uppsala, Sweden): **13**

IN VITRO STUDIES ON GASTRIC MUCOSA.

Sodium and hydrogen ion transport and some electrical properties of frog gastric mucosa (Rana temporaria) in vitro were investigated with different oxygen tensions in the bathing solutions. Experiments were performed under voltage clamp conditions. ^{22}Na and ^{24}Na were used as tracers.

Active transport of sodium ions from the mucosal to the serosal side was 0.12 uEqv/hr,cm^2 with a pO_2 of 700 mm Hg, 0.41 uEqv/hr,cm^2 at 300 mm Hg and 0.05 uEqv/hr,cm^2 at 50 mm Hg. This transport contributed to 5%, 20% and 4% respectively of the total shortcircuit current.

Reduction of pO_2 to 300 mm Hg or less gave rise to an decrease of the hydrogen ion transport not completely reversible. The ratio between active transport of hydrogen ions and chloride ions remained the same at oxygen tensions between 700 and 150 mm Hg (chloride transport calculated as short-circuit current + hydrogen transport - sodium transport).

It is concluded that a degree of hypoxia which reduces hydrogen ion transport also stimulates sodium ion transport in the frog gastric mucosa. Recently sodium transport was demonstrated in the mammalian gastric mucosa in vitro. As it is difficult to obtain satisfactory oxygenation in isolated mammalian tissues this transport may be at least in part due to hypoxia in the mucosa.

The hydrogen and chloride ion transport mechanisms showed the same sensitivity to hypoxia which supports the suggestion (Forte, J.G., Am. J. Physiol. 1969.216.167) that they are mutually coupled biochemically or electrically.

14 Helander, H.F. (Department of Anatomy, University of Umeå, Sweden): *MORPHOLOGICAL ASPECTS OF GASTRIC SECRETION*

Five different types of secretory cells are intermingled in the fundus glands of the mammalian gastric mucosa. The zymogen cells produce pepsinogen and are characterized by their basophilia and their secretory (zymogen)granules. Correspondingly, in the electron microscope these cells exhibit a large granular endoplasmic reticulum, mainly concentrated to the basal part of the cytoplasm, and numerous secretory granules in the apical part. The Golgi apparatus is also fairly large. During secretion there is an increase in the RNA content of these cells, and the cisternae of the endoplasmic reticulum become dilated, probably as a result of an accumulation of secretory material. The Golgi apparatus expands, but the mean size of the zymogen granules is reduced. Emptying of zymogen granules into the gland lumen is accomplished by a granulocrine type of secretion. Inhibition of the gastric secretion by atropine, results in a piling up of zymogen granules, and a concomitant increase in the peptic activity of gastric mucosa homogenates.

Although it has not definitely been proved, it is generally accepted that the parietal cells secrete HCl. These cells are acidophilic and contain very little RNA. Their granular endoplasmic reticulum is very sparse, and the Golgi apparatus discrete. Mature parietal cells contain no secretory granules. A very large number of mitochondria indicates a high respiratory capacity . Another striking feature is the presence of cytoplasmic vacuoles, mainly accumulated in the apical half of the cytoplasm. During ontogeny these vacuoles appear at about the same time as the production of HCl starts. The most unique characteristics of the parietal cells are the intracellular canaliculi which start deep in the cytoplasm and open onto the apical cell surface. These canaliculi with their numerous microvilli greatly increase the "secretory surface" of the parietal cells. During secretion, the cytoplasmic vacuoles become less numerous and the microvilli of the secretory surface increase greatly in number, so that the canaliculi become almost obliterated.

The mucoid cells of the fundus glands, i.e. the surface epithelial cells and the mucous neck cells generally exhibit little endoplasmic reticulum, a moderately sized Golgi apparatus, and a varying number of secretory granules. The surface epithelial cells are tall columnar cells, whereas the mucous neck cells often are pear-shaped. The larger number of secretory granules in the surface epithelial cells may also serve to distinguish these two cell types from each other. There are no greater changes in the morphology of the mucoid cells after stimulation by feeding.

Argyrophile cells occur in small numbers, mainly concentrated to the basal half of the gastric mucosa. Since they hardly ever reach the glandular lumen, they have been ascribed an endocrine function. They are rather similar to other cells of the enterochromaffine system, and may be the source of gastrin.

Poulsen, J.H. (Institute of Medical Physiology C, University of Copenhagen, Denmark): THE NATURE OF THE RESTING MEMBRANE POTENTIAL IN THE ACINAR CELLS OF THE CAT SUBMANDIBULAR GLAND. 15

While the nature of the secretory transmembrane potential in salivary glands has been the subject of a number of investigations, only little attention has been paid to the corresponding resting potential. As the size of the resting membrane potential of the acinar cells in the cat submandibular gland is comparatively small (about -2o mV) it seems likely that the mechanism underlying it, differs from the one of the much more thoroughly investigated nerve- and muscle cells.

The submandibular gland of the cat was artificially perfused by Locke's solutions of different ion composition. Transmembrane potentials were recorded by use of ordinary glass microelectrodes filled by either 3M MCl or 3M NH_4NO_3. The tip potentials were always less negative than -5 mV.

The resting membrane potential was found to vary inversely approximately with the logarithm of the extracellular potassium concentration, but the slope was very small (about 6 mV per lo-fold increase in potassium concentration). Substituting lithium for sodium did not change the resting potential. However, substituting tetraethylammonia for sodium increased the potential. A similar effect was obtained by substituting sulphate for chloride, whereas substituting nitrate for chloride did not change the membrane potential significantly.

It is concluded that both potassium, sodium, and possibly chloride contribute to the maintenance of the resting membrane potential. Similar results and conclusions were reached by Douglas, W.W., T. Kanno, and S.R. Sampson, J.Physiol. 1967 191.1o7. in studies on the adrenal chromaffin cells.

16 Petersen, O.H. (Institute of Medical Physiology C, University of Copenhagen, Denmark): THE MECHANISM OF THE LOSS OF POTASSIUM FROM SALIVARY GLANDS AFTER STIMULATION WITH ACETYLCHOLINE.

When salivary glands are stimulated to secrete, their cells lose potassium (K^+) to both the saliva and the blood. This loss is followed by a reuptake of K^+ from the blood to the gland cells (Burgen, A.S.V., J.Physiol., 1956. 132. 2o). Little is known about the mechanisms underlying these transports.

In the present study the K^+ transport between perfused cat submandibular glands and the perfusion fluid was investigated. The flow of perfusion fluid from a cannula in the gland vein was recorded and the concentration of K^+ in the perfusion fluid coming from the gland vein cannula was measured by flame photometry. Injections of lo µg acetylcholine (ACh) were given intraarterially and the relationship between the secretion (number of drops of saliva coming from a cannula inserted into the submandibular duct) and the loss of potassium to the perfusion fluid was studied.

During perfusion with sodium-free (Na^+-free) lithium (Li^+) Locke's solution the secretion was much more reduced than was the loss of K^+, while the gland was unable to take up K^+ from the perfusion fluid. After having returned to Na^+ Locke's solution the secretory ability was only partially restored while the loss of K^+ on stimulation was of the same size as before the perfusion with Li^+ Locke's solution. The ability to take up K^+ from the perfusion fluid was immediately restored by returning from Li^+ to Na^+ Locke's solution.

lo min after start of perfusion with Na^+ Locke's solution containing dinitrophenol (DNP) (10^{-4}M) the loss of K^+ on stimulation was uninhibited while the secretion was reduced. To secure that this apparently lacking effect on the K^+ loss was not due to simultaneous effects on K^+ loss and uptake, obscuring an effect on the K^+ loss, the effect of perfusion with DNP for 15 min was investigated after 2 min of perfusion with K^+-free Locke's solution. Also in this case DNP had a much smaller effect on the K^+ loss after stimulation than on the secretion.

Generally the effect of ACh on cell membranes is to increase the permeability to ions such as K^+. As K^+ is not in thermodynamic equilibrium across the acinar cell membranes of the salivary glands, but has a marked tendency to escape from the cells, this effect of ACh could explain the K^+ loss from salivary glands after stimulation with ACh.

Frederiksen,O. & P.P.Leyssac. (Inst.f. exper.Medicine, University of Copenhagen. Denmark). ISOSMOTIC TRANSPORT ACROSS THE GALL BLADDER EPITHELIUM. 17

It is well established that the in vitro gall bladder preparation from the lumen absorbs NaCl and water in isosmotic proportions between identical bathing solutions in the absence of impermeant solutes. Net transport of Na and Cl are accomplished by an active electrically neutral transfer process.

Taking advantage of the high rates of solute-and water transfer and energy consumption characteristic for the gall bladder epithelium some general assumptions regarding the mechanism of solute transfer could be investigated. Net fluid absorption was measured by weighing the bladder; net Na-transport was calculated from the water transport and the Na-concentration of the bathing media, and oxygen consumption was measured with an oxygen electrode.

The acute effects resulting from abrupt changes in NaCl concentration of the bathing media indicated that fluid volume transfer remained unaffected while Na-transport changed abruptly in direct proportion to the NaCl concentration. Transport-linked oxygen consumption was linearly related to net fluid volume transfer and oxygen uptake per eqv. Na transported varied in inverse proportion to the NaCl concentration of the media.

It is concluded that the range of absorption rates of isosmotic fluid represents a range of energy-requiring capacities for transcellular transfer of fluid volume units.

18 Uvnäs, B. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): INTRODUCTION.

Storage in subcellular elements is a common way by which living organisms harbour biologically-active substances in an inactive form. From such intracellular depots the substances can be rapidly released in an active form. Several biogenic amines are localized to granules or vesicles in adrenal medullary cells, in mast cells, in thrombocytes, in enterochromaffin cells, in peripheral and central neurones and nerve terminals etc. From their stores the biogenic amines can be released by chemical and physical stimuli under physiological and pathological conditions, as well as by various drugs. It was thought that a comparative analysis of the morphological and chemical features of the subcellular depots, the mechanisms of uptake, storage and release of the active substances from these depots into the extracellular milieux should contribute to a wider understanding of these release processes. Today's symposium is designed to give various specialists in the Scandinavian countries the possibility of presenting and collating their knowledge and experience within this field which is of the utmost importance to both physiologists and pharmacologists. I hope their contributions will stimulate a lively and constructive discussion.

19 Hökfelt, T. (Department of Histology, Karolinska Institutet, Stockholm, Sweden): ULTRASTRUCTURAL STUDIES ON MONOAMINE STORAGE VESICLES.

Using various types of fixatives (e.g. potassium permanganate) the ultrastructural localization of certain monoamines in peripheral and central neurons has been studied. Evidence was obtained that two types of storage vesicles exist in peripheral noradrenaline as well as in central dopamine, noradrenaline and 5-hydroxytryptamine neurons. The first type, the small granular vesicles, have a diameter of about 500 Å and the second type, the large granular vesicles, have a diameter of about 1000 Å. Both types are limited by a triple-layered membrane and contain an electron dense core or granule, which probably represents the reaction product between the amine and the fixative. The small and large granular vesicles are found in all parts of the neurons, although the highest numbers occur in the terminal parts of the axons, mainly localized to axonal enlargements often called varicosities. The small granular vesicles are mostly more numerous than the large ones. Thus, in certain peripheral adrenergic neurons about 98 per cent of all vesicles are of the small type. Results obtained after electric stimulation and the intraneuronal localization of the vesicles may suggest that the small granular vesicles are of immediate importance for the release of monoamines at the synaptic cleft.

Bloom, G.D. and Ö. Hägermark (Department of Histology, University of Umeå, Umeå and Department of Dermatology, Karolinska Institutet, Stockholm, Sweden): ON THE ULTRASTRUCTURE OF MAST CELL GRANULES. **20**

The ultrastructure of mast cells is well preserved after fixation in glutaraldehyde and osmium tetroxide. In electron micrographs of thin sections stained with uranyl acetate and lead citrate mast cells are filled with electron dense granules, about 0.5 μ in diameter. The fine structure of the granules varies in different animal species. The granules are surrounded by a closely adhering unit membrane; sometimes an electron lucid space separates the granular matrix from the surrounding membrane.

Histamine release and the concomitant morphological changes were studied in rat mast cells under various conditions. Some liberators, e.g. compound 48/80, seem to trigger an active cell process with extrusion of mast granules as a final result. After treatment with such liberators the number of altered, less dense granules increases in the cells. The granular extrusion seems to occur by exocytosis, whereby the perigranular membrane is left behind in the cell. Thus the released granules are devoid of a membrane. Surface active agents and hyposmosis bring about histamine release by affecting the integrity of mast cell structure resulting in a breakdown of plasma membrane and cellular compartments.

Helle, Karen B. (Institute of Physiology, University of Bergen, Norway): THE CHEMICAL COMPOSITION OF THE CHROMAFFIN GRANULE. **21**

Chromaffin granules of bovine adrenal medulla have been shown to contain 35% protein, 22% lipid, 20.5% catecholamines and 15% ATP (Hillarp, N.-Å., Acta physiol. scand. 1959.47.271). The lipid fraction consists mainly of phospholipids and cholesterol (Winkler, H. et al. Arch. exp. Path. Pharmak. 1967.256.407). Chromogranin, the major protein of the chromaffin granule, has been shown to be present in the membrane as well as in the lysate fraction of the granules (Helle, K.B. and Serck-Hanssen, G., Pharmacol. Res. Comm. 1969. 1). Chromogranin has been isolated as a lipoprotein of very high density, containing 0.25μmoles lipid phosphate/mg protein (Helle, K.B., Biochem. J., 1968.109.43P), particularly rich in glutamyl and prolyl residues but low in cysteine and cystine (Helle, K.B., Mol. Pharmacol. 2. 298. 1966). Associated with the granule membrane are the enzymes dopamine-β-hydroxylase (Kirshner, N., Pharmacol. Rev. 11.350. 1959) and ATP-ase, plus a cytochrome of the b-type (Banks, P., Biochem.J. 1965.95.490.

Chromaffin granules of splenic nerves have been shown to contain in addition to noradrenaline and ATP (Euler, U.S.v. and Hillarp, N.-Å., Nature (Lond.) 1956.177.44) also the specific granule protein, chromogranin (Banks, P. et al., Mol. Pharmacol. 1969.5.210) as well as the enzyme dopamine-β-hydroxylase (Livett, G.B. et al., Biochem. Pharm. 1969. 18.923).

22 Bergqvist, Ulla (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): *CHEMISTRY OF MAST CELL GRANULES.*

In rat peritoneal mast cells histamine is stored in intracellular granules consisting mainly of a protein-heparin complex. Since it has been proposed (Åborg, C.-H., J. Novotný and B. Uvnäs, Acta physiol. scand. 1967, 69, 276-283) that the amine is bound electrostatically to carboxyl groups in the protein part of the complex we have attempted to isolate and identify this protein.

Most of the protein-heparin linkage appears be ionic and mast cell granules may be dissolved in M NaCl. The major part of the protein can then be separated from heparin by running such a solution through a Dowex 1-X2 column. Subsequent elution with 2 M NaCl yields a fraction containing heparin and a small amount of protein which is probably covalently bound to it.

The free protein can be separated into water-soluble and water-insoluble fractions. Both are homogenous on disc electrophoresis. Their amino acid compositions are similar, each containing 16 different amino acids. The proteins are both basic with an IP on Cellogel strips of 10.5-11.0. The percentages of the dicarboxylic acids Glu. and Asp. are high enough to account for the amine binding capacity of the granules if it is assumed that the amines are bound to free carboxyl groups in the protein.

The molecular weight of the soluble protein, determined by equilibrium centrifugation was 5,600. The two proteins have high chymase activities, which is rather surprising considering their low molecular weights.

23 Björklund, A. (Institute of Anatomy and Histology, University of Lund, Lund, Sweden) HISTOCHEMICAL DEMONSTRATION OF TRYPTAMINE.

A sensitive fluorescence method has been devised for the demonstration of tryptamine on the cellular level by formaldehyde condensation. This gives a 13-18 fold increase in the fluorescence yield of tryptamine compared with the conventional Falck-Hillarp method. The conditions of the conventional procedure were modified in one of two ways: (1) A gaseous oxidant (ozone) was introduced into the reaction vessel. Up to a certain concentration of ozone, the yield of the formaldehyde-induced tryptamine fluorescence was markedly increased, probably because of an increased oxidative dehydrogenation of the initial condensation product. In the combined formaldehyde-ozon procedure, the fluorescence yields of catecholamines and 5-HT were reduced to about 20% compared with the yields in the conventional formaldehyde treatment. (2) Acidification after conventional formaldehyde treatment produced a similar high fluorescence yield.

The histochemical and microspectrofluorimetric characteristics of the fluorophores formed from tryptamine under these conditions differ clearly from those of the fluorophores formed from catecholamines, 5-HT, and other indole compounds tested. These procedures, which were worked out on histochemical models, have successfully been applied also on tissues incubated with tryptamine. Thus, the findings seem to offer the possibility of demonstrating tissue tryptamine with high specificity and sensitivity. A substance behaving like tryptamine, according to the above-mentioned criteria, has been found in cells of the pars intermedia and pars distalis of the pituitary gland.

Owman, Ch. and Håkanson, R. (Departments of Histology and Pharmacology, University of Lund, Sweden): FLUORESCENCE MICROSCOPY OF NON-MAST CELL HISTAMINE IN MURINE GASTRIC MUCOSA. 24

Histamine in freeze-dried cryostat sections (Håkanson and Owman, Life Sci, 1967, 6, 759; Thunberg, Exp. Cell Res. 1967, 47, 108) or paraffin sections (Ehinger, Håkanson, Owman and Sporrong, Biochem. Pharmacol. 1968, 17, 1997) forms fluorophores with o-phthaldialdehyde vapours. Microspectrographic analysis of the fluorophores from authentic histamine on thin-layer silica gel chromatoplates (Håkanson, Juhlin, Owman and Sporrong, to be published) shows activation peaks at 365 mμ and 405 mμ. The emisson maximum changes with the concentration of histamine, from yellow (about 550 mμ) at high concentrations towards a blue fluorescence at low concentrations.

The bulk of gastric histamine in mouse and rat is stored in a large system of blue-fluorescent, enterochromaffin-like cells in the mucosa of the oxyntic gland area; the cells are argyrophilic but non-argentaffin (Håkanson and Owman, Experientia, in press). Histamine also occurs in the mast cells, which are the only storage site for gastric histamine in all other mammalian species analyzed. Gastric histamine is resistant towards 48/80 (Aures, Håkanson, Owman and Sporrong, Life Sci, 1968, 17, 1147).

The epithelial histamine cells in rat gastric mucosa are probably endocrine. Their distribution agrees with that of vitamin B_{12}-binding protein; they may thus be the storage site of the antipernicious principle (Håkanson, Lindstrand, Nordgren and Owman, to be published).

von Euler, U.S. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden): FACTORS INFLUENCING UPTAKE AND RELEASE OF TRANSMITTER IN ADRENERGIC NERVE GRANULES. 25

Isolated adrenergic nerve granules suspended in phosphate buffer or sucrose give off noradrenaline (NA) at a rate which is dependent on pH, temperature and the NA concentration in the medium. Concomitantly with the release, reuptake occurs, beginning at about 10^{-7} M NA. At 10^{-4} M NA reuptake balances release and no net change of NA occurs. In the presence of ATP in the medium, release is balanced by uptake even at 10^{-6} M NA.

Characteristic changes in the release rate and uptake power are observed with various groups of drugs. Indirectly acting amines (tyramine, phenethylamine, amphetamine) enhance the release and inhibit the uptake of NA. Only part of this effect is due to exchange.

Adrenergic blocking agents, particularly of the α-type, inhibit both release and uptake of NA. The possible analogy of the uptake processes in granules and in effector cell receptors has been suggested (Euler and Lishajko 1967).

Various metabolic inhibitors influence the release and uptake of NA in granules. Oligomycin inhibits both processes, while antimycin A in 10^{-5} M blocks uptake almost completely. Uncouplers of various kinds (DNP, CCP, pentachlorphenol and desaspidin) all enhance the release. It is suggested that uptake and binding require the presence of ATP, and that release ensues in the absence of ATP or during increased ATP-ase action.

26 Lishajko, F. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden): RELEASE AND REUPTAKE OF CATECHOLAMINES IN ISOLATED ADRENAL MEDULLARY GRANULES.

Isolated granules from sheep and bovine adrenal medullary cells release dopamine (DA), noradrenaline (NA) and adrenaline (A) at characteristically different rates. Thus DA and A follow an exponential course, while NA is initially more rapidly released and thereafter exponentially at a slower rate in 0.13 M K-phosphate pH 7.5 at 37°C. The rapidly released NA was localized in the low speed sediment, while in microsome fractions NA and A are released exponentially. Addition of DA to the incubation fluid decreases the net loss of DA in the sediment after incubation, owing to reuptake.

Addition of ATP-Mg^{2+} inhibits the release of DA as well as that of A and NA, presumably owing to inhibition of release and increased reuptake. However, in the presence of chloride ions above 40 mM in the incubation media, ATP-Mg^{2+} accelerates the release of NA and A. The influence of Cl^- ions on release of catecholamines will be discussed. No net uptake of NA and A was observed in partially depleted granules in the presence of ATP-Mg^{2+}, while the granules take up DA up to the original amount. Addition of ATP-Mg^{2+} also inhibits the release of soluble proteins in parallel with the catecholamines. The increased release of catecholamines caused by prenylamine is also accompanied by a release of soluble protein.

27 Uvnäs, B. and Åborg, C.-H. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): STORAGE AND RELEASE OF HISTAMINE IN ISOLATED MAST CELL GRANULES.

Granules isolated from water-lysed mast cells retain their histamine when suspended in distilled water. The histamine is released on suspension of the granules in sodium chloride solutions, the release occurring as an equivalent ionic exchange between Na^+ and Hi^+. The influence of pH on the histamine storage indicates an ionic linkage to COO^- groups. The uptake capacity is around 1000 mμeq/mg granules (dry weight). Titrations of the granules between pHs 3 and 7 indicate the presence of weakly acid (COO^-) groups capable of binding around 1000 mμeq. of cations per mg. in the protein part of the granule heparin protein complex.

The cation binding properties of the granules are similar to those of a weak cation exchange resin. On exposure to cations in concentrations normally present in intra- and extra-cellular milieux they will release all their histamine.

Hamberger, B. and G. Jonsson (Department of Histology, Karolinska Institutet, Stockholm, Sweden). UPTAKE OF NORADRENALINE IN ADRENERGIC NERVES. **28**
Adrenergic nerve terminals have a great ability to take up and accumulate catecholamines. It is now generally accepted from histochemical and biochemical experiments that at least two mechanisms exist for this uptake and storage in the isolated rat iris. The membrane pump seems to be the most important mechanism for the initial uptake while the granular uptake mechanism is important for the storage and retention intraneuronally. Reserpine pretreatment does not affect the initial uptake rate and noradrenaline can accumulate intraneuronally outside the usual storage sites provided that the action of monoamine oxidase has eliminated. After pretreatment with the catecholamine synthesis inhibitor H 44/68, the initial uptake is not influenced and the total storage capacity is only increased 10-20% compared to the untreated and the intraneuronal localization seems to be the same. The results indicate that the depleted noradrenaline stores cannot be completely refilled with exogenous noradrenaline after depletion with a synthesis inhibitor. Uptake of noradrenaline to any significant degree outside the adrenergic nerves only occurs with high concentrations (10^{-3}M or more) of the amine in the medium and can in these cases be located both diffusely and to special cells.

Stjärne, L. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden): RELEASE OF CATECHOLAMINES FROM ADRENAL MEDULLA AS COMPARED TO THAT FROM SYMPATHETIC NERVES. **29**

Hormone secretion from the adrenal medulla seems to occur by exocytosis. Secretion is initiated by acetylcholine (Ach) released from the secretory nerve terminals, which exhibit both temporal and spatial summation. Ach causes partial local depolarization of the adrenal medullary cells accompanied, but not necessarily causally related to, increased Ca^{++} influx, which in its turn mediates secretion of all the soluble components of the amine storage vesicles directly into the extracellular space. There is good experimental support that this sequence of events can take place. However, final proof that this is the physiological mechanism for catecholamine (CA) secretion from the medulla is still lacking.

Concerning neurotransmitter release from sympathetic nerves theoretical considerations as well as available experimental data rather contradict the probability for exocytosis. Thus CA turnover in the nerves is much more rapid than in adrenal medulla. It seems unlikely that protein turnover could be equally fast, as required by the exocytosis hypothesis. Moreover, the half life of nerve granules is considerably longer than that of the granular amines. Experimentally, there is so far no indication that the noradrenaline (NA) released by nerve impulses is accompanied by other soluble constituents of the nerve granules. Results recently obtained at this laboratory give no indication that adenine nucleotide material is released concomitantly with NA from the sympathetic nerves of the cat spleen. The evidence thus points towards basic differences in mechanisms of hormone secretion and neurotransmitter release.

30 Paasonen, M. K. and Solatunturi, E. (Department of Pharmacology, University of Helsinki, Finland): RELEASE OF 5-HYDROXYTRYPTAMINE (5HT) FROM BLOOD PLATELETS.

5HT is stored in mammalian blood platelets in highly osmiophilic organelles, which also contain ATP and, in the platelets of rabbit, histamine. The uptake of 5HT by platelets against a concentration gradient can be inhibited at the platelet membrane by, e.g., imipramine, and at the intracellular stores by reserpine-like drugs.

The release of 5HT from platelets is induced by reserpine and, at high concentrations, by many drugs, which, at lower concentrations inhibit the uptake of 5HT. Chlorpromazine (CPZ) and other related phenothiazine derivatives cause a depletion of 5HT, histamine, potassium and ATP from rabbit platelets in vitro. When platelets were incubated with $3x10^{-4}M$ or higher concentration of CPZ in plasma containing ^{3}H-methoxyinulin the amount of inulin in the subsequently separated platelet pellet was about doubled when compared with inulin in the control pellet. This indicates that CPZ causes membrane damage allowing inulin to penetrate into platelets. Desmonomethyl--CPZ, a more potent 5HT releaser than CPZ, was more potent in this experiment, too, but reserpine had no effect. The membrane damage seems not to be necessary for the 5HT release induced by CPZ-sulphoxide. This phenothiazine has only weak central action, and, unlike CPZ and other related drugs, it neither inhibits glucose oxidation nor decreases ATP content in platelets.

(Supported by grants from The Sigrid Jusélius Foundation and The National Research Council for Medical Sciences, Finland.)

31 Slorach, S.A. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): RELEASE OF HISTAMINE FROM MAST CELLS INDUCED BY DEGRANULATING AGENTS.

Histamine in mast cells is stored in discrete intracellular granules, consisting of a protein-heparin complex, and may be released by suspending the granules in cation-containing media. It is probable that histamine release from such cells involves a cation exchange, either extra- or intra-cellular, at some stage.

A study of the amounts of histamine, heparin and granule protein released on exposure of the cells to the degranulating agent compound 48/80 showed that there was a good correlation between the three release curves. From these results and further studies on the uptake of sodium by compound 48/80-treated cells it is concluded that the principal mechanism of histamine release induced by this degranulating agent involves an initial extrusion of histamine-containing granules. This is followed by an exchange of histamine in the extruded granules for cations in the extracellular medium.

Diamant, B.(Dept. of Pharmacology, Karolinska Institutet, Stockholm, Sweden): HISTAMINE RELEASE FROM MAST CELLS INDUCED BY ATP. 32

ATP induces histamine release from mast cells by a non-degranulating mechanism. A 1:1 molar relationship has been established between histamine release and hydrolysis of extracellular ATP by an ATP-hydrolysing enzyme in the mast cell membrane. The difference in morphology of mast cells after local application of ATP and compound 48/80 to the cell membrane will be demonstrated. The two mechanisms also differ in regard to time course and effects of divalent cations. Common features of the two mechanisms are their dependence on pH and temperature as well as on endogenous ATP. With antimycin and oligomycin (10^{-7}M) histamine release is inhibited concomitantly with a decrease of intracellular ATP; in the presence of glucose the decrease of endogenous ATP is counteracted and at the same time the effect of antimycin on histamine release is reversed in the case of 48/80 but not in the case of ATP. This indicates that 48/80-induced histamine release can utilize endogenous ATP derived from glycolysis whereas ATP-induced histamine release depends on oxidative phosphorylation. Due to differences in the time course of the two release mechanisms, mast cells need preincubation with antimycin for inhibition of 48/80-induced histamine release whereas this is not necessary for release induced by ATP.

The results indicate the existence of two different mechanisms by which histamine can be released from mast cells.

Häggendal, J.(Dept. of Pharmacology, University of Göteborg, Sweden): ON RELEASE OF TRANSMITTER FROM ADRENERGIC NERVE TERMINALS AT NERVE ACTIVITY. 33

Transmitters are generally assumed to be released in the form of "quantal packets" (cf. Eccles, J.C., The physiol. of synapses. Springer-Verlag. 1964). The transmitter content in one vesicle or granule is suggested to correspond to one quantal packet which can produce a subthreshold miniature potential. - Since the amine storage granules have a life-span of several weeks (Dahlström, A. and Häggendal, J., Acta physiol. scand. 1966. 67. 278), whereas the nerve terminal turnover of noradrenaline (NA) appears to be at most a few days, it seems improbable that whole granules would be released. - Considering the inactivating mechanisms at the nerve terminal-effector cell level of adrenergic vasoconstrictor nerves, the amount of NA, released to the blood stream, was found rather low per nerve impulse as compared to the tissue NA content (Folkow, B., Häggendal, J. and Lisander, B., Acta physiol. scand. 1967. Suppl. 307). Assuming that one nerve impulse may release NA from almost every varicosity along the nerve terminals, the figure for NA release was calculated to about 400 molecules/varicosity/stimulus, corresponding to only a few per cent of the estimated NA content in one granule. Obviously this appears to contradict the view that one transmitter quantum corresponds to the NA content in one granule. - The concept of "quantal release" appears, however, to be compatible with the release of a small NA pool of the granule content, or release from a hypothetical NA pool attached to sites on the nerve terminal membrane. - On the other hand recent results together with B. Folkow may suggest that the amount of released NA to some extent also depends on the reactive state of the effector cell. Therefore, a hypothetical feed back mechanism, operating via the synaptic gap may be considered.

34 Andén, N.-E. (Department of Pharmacology, University of Göteborg, Sweden): MONOAMINE RELEASE FROM NERVE TERMINALS.

Noradrenaline (NA) is released from the postganglionic sympathetic nerve terminals by nerve impulses (electrical stimulation, ganglionic stimulating drugs) or by indirectly acting sympathomimetics (tyramine and amphetamine).

After reserpine treatment the granules are gradually depleted of NA. The functional effect of nerve stimulation is not impaired until the NA is lowered by approximately 90 per cent. The responses to nerve stimulation recover when NA levels still are very low. The uptake of NA in the granules is, however, partially restored at the time of functional recovery indicating that the release by the nerve impulses is dependent on the ability of the granules to incorporate NA in a small fraction immediately important for the function: This fraction may consist of granules synthetized in the cell body after the reserpine treatment and transported to the nerve terminals.

Reserpine treatment also abolishes the functional effects of indirectly acting sympathomimetics. The responses to tyramine and amphetamine are easily restored by administration of NA. These drugs probably act by release of NA from extragranular stores.

The NA in the granules can be replaced by analogs like α-methyl NA and metaraminol which also can be released by nerve impulses ("false transmitters"). Though these amines have a somewhat weaker action on the receptors, they do not produce a pronounced impairment of the adrenergic transmission. The NA may be released normally due to weak inhibition of the granular uptake mechanism.

35 Cedergren, E. and Thornell, L.E. (Department of Anatomy, University of Umeå, Umeå, Sweden): ULTRASTRUCTURE OF MUSCLE COMPONENTS INVOLVED IN EXCITATION-CONTRACTION COUPLING.

It will be necessary to limit the subject considerably as almost any structure in the muscle cells can be said to be more or less involved in the excitation-contraction coupling process. The plasmamembranes and intracellular membranes belonging to the sarcotubular system - sarcoplasmic reticulum - or analogous structures are the main components which will be concerned about. The organization and ultrastructure of the sarcotubules and the triad and diad configurations appearing in different kinds of striated muscle, heart muscle and smooth muscle will be described. Experiments concerning the influence of different ionic and enzymatic conditions on the membranous structures will be related. Special attention will be given to the T-tubule and the relation of the plasmamembranes to the intracellular membranes.

The cellular membrane at contacts in ordinary and specialized heart muscle cells will be described and recent observations on the complexity of these structures will be reported as well as changes at the cell attachments induced by different enzymes.

Frankenhaeuser, B. (Nobel Institute for Neurophysiology, Karolinska Institutet, S-104 01 Stockholm 60, Sweden): **36** THE EFFECT OF CALCIUM AND OF LOCAL CURRENTS ON TWITCH MUSCLE FIBRES.

It is commonly held that calcium, released inside the fibre, during membrane excitation, causes the fibre to contract (e.g. Ebashi, S. & Endo, M., Progr. Biophys. Mol. Biol. 1968. 18). Calcium, however, also acts on the muscle fibre membrane. It shifts the curve relating contraction and relaxation to membrane potential along the potential axis. These effects have striking similarities with the effects of calcium on the specific sodium permeability mechanism in nerve. A consequence of the membrane effects is that a muscle fibre in Ca-free solution does not contract. Magnesium mimics the actions of calcium on the muscle membrane.

The whole cross-section of a fibre is activated in a shorter time than that required by an activating substance to move by free diffusion from the surface to the centre of the fibre. Experimental findings indicate that the contraction activating substance is released from the sarcoplasmic reticulum and that it is released during activity from a store firmly bound in the reticulum since: (a) a muscle contracts for a considerable time in a Ca-free medium; (b) caffeine causes a contraction even when it is applied to a muscle held so long a time in Ca-free medium that it does not respond mechanically to polarization.

Release of an activator for the mechanical system is associated with positive membrane polarizations. The contracture during lasting polarization is transient but during caffeine application and during calcium injection it is lasting. Therefore it is evident that the release of activator during polarization is transient. The polarization of the membrane (including the transverse tubular system) may either control the calcium permeability of the membrane, or the polarization may activate a transport system in which the transport itself is independent of potential as driving force. In the former case the transport is by free diffusion in the electric field through the membrane, and the net transport changes direction from inward to outward at the equilibrium potential for calcium.

Experiments were made with the aim to decide whether or not Ca^{++} moves passively through the polarized membrane during excitation. The sarcomeres were measured cinephotographically during local polarization of the fibre by current through an external electrode (5-20 μm diameter) applied close to the fibre. Large positive step polarizations were associated with contractions also very close to the electrode. Since these potential steps were large ($>$ 200 mV) they exclude a passive inward movement of free calcium through the membrane in the vicinity of the electrode. A similar polarizing current efficiently blocked calcium entry through a ruptured membrane and the fibre remained in a relaxed state. It is consequently concluded that the idea is excluded that Ca^{++} moves passively through a membrane in which the calcium permeability is controlled by the membrane potential.

37 Lännergren, J. (Nobel Institute for Neurophysiology, Karolinska Institutet, S-104 01 Stockholm 60, Sweden): MECHANICAL PROPERTIES OF ISOLATED AMPHIBIAN SLOW MUSCLE FIBRES.

On account of differences both in morphology, innervation pattern, membrane response and contractile properties one type of skeletal muscle fibre can be discerned - the slow muscle fibre (s.m.f.) which differs from the more familiar twitch fibre in several respects: small diameter, scanty and irregularly arranged sarcoplasmic reticulum, small capacity for energy production, multiple innervation distributed along the length of fibre, lack of regenerative membrane activity. The mechanical response is characterized by slow development of tension on stimulation and ability to maintain a high level of tension for long periods of time (Kuffler, S. W. & Vaughan Williams, E. M., J. Physiol. (Lond.) 1953. 121. 318).

Even in Amphibia, where s.m.f. are relatively numerous, they are by far outnumbered by twitch fibres which makes results obtained on whole muscles difficult to interpret. This difficulty is circumvented by the use of single fibres. Single s.m.f.:s from the iliofibularis muscle of the clawed toad, Xenopus laevis, have been shown to give long-lasting contractures in response to KCl, ACh and choline. The relation between membrane potential and tension production is very steep (Lännergren, J. Acta physiol. scand., 1967. 69. 362). That the 'slowness' of the s.m.f. is a property of the contractile system itself has been demonstrated by Costatin et al. (J. Physiol. (Lond.) 1967. 188. 261) who showed that local Ca application to skinned twitch and slow m.f. resulted in a much slower sarcomere shortening in the latter.

Previous experiments on Xenopus s.m.f.:s showed that the tension response to local electrical stimulation was much larger at a just subthreshold [K] than in Ringer solution. This indicated that the stiffness of the fibre increased as a result of depolarization even if there was no active tension. Results from experiments on twitch fibres have also been claimed to show that stiffness may vary independently of active tension (Frank, G. B. Acta physiol. scand. 1965. 65. 1). The experiments to be presented were undertaken to test this assumption.

Small ($< 1\%$ of L_o), constant-speed extensions of isolated Xenopus s.m.f.:s in Ringer solution gave a small tension response consisting of a steep initial phase (up to 50 Å extension/sarcomere = elastic limit) and a second phase of much lower slope, just as for a whole sartorius muscle (Hill, D. K., J. Physiol. (Lond.) 1969. 199. 637) or a single tw. m.f. The values for the elastic modulus (E) and the elastic limit were about the same for the two types ($E \simeq 0.7$ kg/cm^2; el. limit $\simeq 2$ g/cm^2). This response was little changed at subthreshold [K].

Long extensions (up to $L = 140\%$ L_o) at subthreshold [K] gave rise to large tension responses. A tension level, close to that which the fibre would reach when fully activated, could be attained. This is not a simple 'passive' tension, however, but more likely the combined result of a moderate stretch activation and the great change of slope of the force-velocity curve when forced lengthening is compared to active shortening (Katz, B., J. Physiol. (Lond.) 1939. 96. 45).

Edman, K.A.P.(Department of Pharmacology, University of Lund, Lund, Sweden): 38
ASPECTS UPON THE EXCITATION-CONTRACTION COUPLING IN CARDIAC MUSCLE.

A great number of observations support the view that the contractile process in cardiac muscle, similar to the situation in skeletal muscle, is governed by means of an activator agent, probably calcium, which is released into the myofibrillar space in consequence of excitation of the plasma membrane (for references, e.g. Edman, K.A.P., Ann. Rev. Pharmacol. 1965. 5. 99-118 and Langer, G.A., Physiol. Rev. 1968. 48. 708-757). Only recently, however, has it become possible, by analysis of the active state of the myocardium, to evaluate the kinetics of the activation of cardiac muscle, and hence the kinetics of the hypothetical activator in the myofibrillar space(Edman, K.A.P., D.W. Grieve and E.Nilsson, Pflügers Arch. 1966. 290. 320-334; Brady, A.J., J. Physiol. 1966. 184. 560-580; Sonnenblick, E.H., J.gen. Physiol. 1967. 50. 661) As demonstrated in these studies the capacity of the heart muscle to produce tension and the capacity to produce motion undergo parallel changes during the course of contraction. These findings are fully consistent with the view that the two parameters of myocardial activity, force and shortening velocity, are governed by a common control function in the excitation-contraction coupling (Edman, K.A.P. and E. Nilsson, Acta physiol. scand. 1968. 72. 205-219).

The time course of the active state in myocardium is markedly different from that in skeletal muscle. Thus whilst the rising phase of the active state in skeletal muscle is a matter of a few milliseconds, there is a slow development of the activity in cardiac muscle, 1/3-1/2 of the total active state time being required for attainment of maximum. Furthermore, in contrast to the situation in skeletal muscle, the maximal intensity of the myocardial active state is a variable. These differences would seem to imply that the rate of release (or inflow) and the rate of elimination of the activator agent are different in the two types of muscle. The data from skeletal muscle suggest that there is a very rapid increase of the activator concentration and that, furthermore, the amount of activator calcium released is greater than needed for complete activation of the contractile system. In the myocardial fibre, on the other hand, there is probably a relatively slow inflow of activator, and the concentration of activator does not, under ordinary conditions, reach the level for mechanical saturation of the contractile element. The implication of these facts is that every change in concentration of the activator around the myofibrils (above a certain threshold concentration) will manifest itself as a mechanical response in the myocardium. In accordance, the analysis of the active state provides strong support for the idea that the inotropic changes produced by altered stimulation frequency, digitalis, adrenaline and calcium are due to altered kinetics of the activator mechanism in the excitation-contraction coupling (Edman, K.A.P. and E. Nilsson, Acta physiol. scand. 1969, in press). The origin of the calcium which activates the contractile system is not yet defined. An inward calcium current across the plasma membrane appears to take place during excitation of the myocardial fibre. Most of the evidence would seem to indicate, however, that the calcium immediately involved in the excitation-contraction coupling is released from an intracellular site, most likely the sarcoplasmic reticulum. The same structures are also, conceivably, responsible for the sequestration of calcium from the myofibrillar space (for references, see Langer, G.A., Physiol. Rev. 1968. 48. 708-757).

39 Axelsson, J. (Dept. of Physiology, University of Iceland): POTENTIAL CHANGE AND CONTRACTION.

Investigations of the activation of the contractile mechanism in polarized muscles have shown that there is, contrary to what was commonly believed, no certain correlation between transmembrane potential changes and mechanical activity. This has recently become obvious in several types of smooth muscle. Thus simultaneous records of electrical and mechanical activity in the portal vein have been digitized and the transfer function between them studied with the result that great dissociation between electrical and mechanical activity can now be clearly demonstrated. For example, the increase in tension in response to noradrenaline is not accompanied by a corresponding increase in measurable electrical activity.

In the portal vein as elsewhere, calcium appears to be an indispensable link in the chains of events leading from the stimulation of the muscle to eventual contraction. This suggests the hypothesis with regard to activation of the contractile mechanism by means of noradrenaline without corresponding changes in transmembrane potential that the action of this drug is mediated by an increased influx of calcium ions and/or liberation of inactive or bound calcium in intracellular or membrane comportments.

In some types of smooth muscle activation of the contractile mechanism not correlated to transmembrane potential changes may play a physiological role.

Landgren, S. (Department of Physiology, University of Umeå, Sweden): PROJECTION OF GROUP I MUSCLE AFFERENTS TO THE CEREBRAL CORTEX. 40

A study of afferent and efferent connections has been one of the approaches to an understanding of the function of the cerebral cortex. The classical outlining of the somatosensory projection areas (SI and SII) and the cortical motor areas (M_1 and M_2) is an example of a functional framework resulting from this approach. These homologues are, however, too simple to accommodate the present knowledge of the cortical distribution of afferent inflow. Recent investigations have revealed a detailed organisation of the skin, joint and muscle afferent projections. This report shall be restricted to the projections of group I muscle afferents to the cat's sensorimotor cortex. Such projections are found in the cytoarchitectonic areas 3a and 3b, which form an interesting zone along the border of the motor cortex (4 γ).

The group I muscle afferents from the forelimb ascend in the dorsal columns, relay in the cuneate nucleus and in the contralateral nucleus ventralis posterolateralis of the thalamus and reach at least 4 separate cortical projection fields. The most well known of these is the one located near the postcruciate dimple (Pcd), which was originally described by Amassian and Berlin (J. Physiol. 1958. 143. 61P) and by Oscarsson and Rosén (J. Physiol. 1963. 169. 924). Later another projection area was found in the lower bank of the anterior suprasylvian sulcus. Still another group I area was localized in the ansate sulcus by Silfvenius (Acta physiol. scand. 1968. 74. 25A), who also described a separate locus in area 4 γ at the lateral end of the cruciate sulcus.

The group I path from the hindlimb ascends in the dorsolateral fascicle of the spinal cord. The location of the segmental relay is unknown, but evidence of a medullary synapse in nucleus Z of Brodal has been reported to this congress by Landgren and Silfvenius (Acta physiol. scand. 1969. in press). The location of the thalamic relay was so far not established, but cortical projections were found in two places, one rostromedial to Pcd and another near the cruiate sulcus on the medial surface of the hemisphere. Both these fields are located in areas 3a and 3b and overlap with the motor cortex (4 γ).

These cortical group I loci are consistently found in all investigated animals. Their size is of the order of 2-3 mm in diameter and thus slightly too large to match the size of a functional cortical column. They seem to depend on branching axons from the same thalamic relay neurone. The conduction time in the group I path to the cortex is short (forelimb: 5 msec, hindlimb: 10 msec) and comparable to that of the primary projections from the skin.

Many efferent paths take their origin in the region of the cortical group I loci. Some of the cortical cells, that are discharged by the group I afferents, send their axons into the pyramidal tract, but appart from this fact very little is known about the destinations of the efferent paths. Electrical stimulation of the motor cortex affects the motoneurone, spinal interneurones, primary afferents and neurones in ascending tracts. More experimental work is, however, required to elucidate the possible relations between the cortical group I neurones and these efferent channels.

41 Silfvenius, H. (Department of Physiology, University of Göteborg, Sweden): PROJECTIONS OF PACINIAN AFFERENTS TO THE CORTICAL GROUP I LOCI.

Muscle spindles and pacinian receptors are sensitive mechanoreceptors located in deep tissues. They respond to vibration and have rapidly conducting afferents. Their adaptation rate differs and therefore their response to continuous stimulation. The spindle records length of muscle and functions in motor control. The pacinian receptor subserves sensation of vibration. Both do, however, contribute to the dynamic component of the response to movements. The role of pacinian afferents in motor mechanisms should be considered.

The projections of pacinian afferents to the motor cortex and its border zones were investigated in cats anesthetized with chloralose. Electrical stimulation of the fore- and hindlimb interosseous nerves was used, as was natural stimulation of interosseous pacinian receptors with a mechanical pulse. Cortical surface- and depth potentials were recorded with ball- and microelectrodes.

The pacinian projections overlap with the Group I projections. Responses to activation of pacinian afferents were observed in all Group I loci. The pacinian projections differed, however, from those of the Group I afferents. The former were larger and extended into primary projections of skin afferents. Pacinian afferents also project to the motor cortex, 4γ. The pacinian receptors thus contribute to the information which is made available to the motor cortex and they may therefore influence the control of movements.

42 Körner, L. (Department of Physiology, University of Göteborg, Sweden): THE PROJECTIONS OF LOW THRESHOLD JOINT AFFERENTS TO THE CEREBRAL CORTEX OF THE CAT.

Low threshold joint afferents are considered to subserve kinesthesis. They take origin in the Golgi endings of the joint ligaments and in the Ruffini endings of the joint capsulae. Their discharge is slowly adapting and its adapted frequency is a function of the joint angle. The cortical projections of these afferents has recently been investigated in cats anaesthetized with chloralose (Körner, L. and S. Landgren, Acta physiol. scand. 1969, in press). Primary projection areas were found near the primary SI projection fields of the low threshold cutaneous afferents. In addition, however, other projection fields were localized to the cortical loci of the low threshold muscle afferents. These last mentioned projections should be functionally related to the projections of the group I muscle afferents and are therefore probably not involved in kinesthesis but in motor control.

Oscarsson, O., Rosén, I. and Sjölund, B. (Institute of Physiology, University of Lund, Sweden): INFORMATION CARRIED BY THE FORELIMB GROUP I PATH TO THE CEREBRAL CORTEX. 43

Stimulation of group I muscle afferents evokes activity in the sensorimotor cortex of the cat (see Landgren, S., this symposium) and monkey (Albe-Fessard, D., Liebeskind, J. and Lamarre, Y., C. R. Acad., Paris 1965. 261. 3891). However, stimulation of these afferents in the cat does not influence its general behaviour or EEG, neither will volleys evoked in these afferents serve as a discriminative stimulus (Giaquinto, S., Pompeiano, O. and Swett, J.E., Arch. ital. Biol. 1963. 101. 133; Swett, J.E. and Bourassa, C.M., J. Neurophysiol. 1967. 30. 530). Stretch of muscle in man does not result in conscious perception and cannot serve as a basis for "position sense" (see Gelfan, S. and Carter, S., Exp. Neurol. 1967. 18. 469). It has been suggested that the forelimb group I path to the cerebral cortex is a feedback system used for adjusting the motor output from the cortex (Oscarsson, O. and Rosén, I., J. Physiol., Lond., 1963. 169. 924).

The information carried by the forelimb group I path to the cat cerebral cortex has been investigated in some detail. Observations reported at this congress (Rosén, I. and Sjölund, B.) suggest that this path is activated from muscle spindle but not tendon organ afferents. The second order neurones in the cuneate nucleus are usually activated from one muscle only, wheras the third order neurones in the thalamus are usually activated from a group of synergistic muscles (Rosén, I., Acta physiol. scand. 1968. 73. Suppl. 310. 13A). Some neurones at both levels are also activated from group II muscle afferents suggesting a highly specific convergence of the two types of afferents from muscle spindles. No excitation is evoked by stimulation of group III muscle afferents (Rosén, I., in preparation).

The fourth order neurones in the cortex are usually activated not only from synergists but also from antagonists and muscles acting at different joints. These neurones receive also strong excitation from cutaneous afferents through unknown thalamocortical or corticocortical paths (Oscarsson, O., Rosén, I. and Sulg, I., J. Physiol., Lond., 1966. 183. 189).

Fifth order neurones have been identified in the cortex. They show the same convergence pattern as the fourth order neurones but are inhibited instead of excited (Grampp, W. and Oscarsson, O., In "Structure and Function of Inhibitory Neuronal Mechanisms", Ed. Euler, C. von, Skoglund, S. and Söderberg, U., Pergamon Press 1968, p.351). This suggests that many of the fourth order neurones are local inhibitory cells but some send their axons into the pyramidal tract and are presumably excitatory (Swett, J.E. and Bourassa, C.M., J. Physiol., Lond., 1967. 189. 101).

14 Laursen, A. Mosfeldt (Institute of Neurophysiology, University of Copenhagen, Denmark): QUANTITATIVE ANALYSIS OF THE BEHAVIORAL DEFICIT PRODUCED BY INTERRUPTION OF A PYRAMIDAL TRACT IN MONKEYS.

Although the pyramidal tract is the largest efferent tract in the brain stem of higher mammals lesions to it produce little lasting deficit. The pyramidal syndrome of clinical neurology is absent after surgical interruption of the tract in man and after seven months movements of the fingers were only slightly less well executed on the affected than on the normal side (Bucy, P.C., Keplinger, J.E., and Siqueira, E.B., J.Neurosurg. 1964. 21. 385). In cat pyramidotomy eliminates placing and flexion reflexes and contralateral extremities become weak; two to three weeks after the operation, however, neurological examination reveals nothing abnormal apart from some slowness of motion (Marshall, C. Quart.Rev.Biol. 1933. 31. 68). Cats trained to press a lever under the brighter of two lights could, after pyramidotomy, not be trained to respond rapidly though their ability to execute fast movements was unchanged (Laursen, A.M., and Wiesendanger, M., Brain Research 1967. 5. 207). In addition to this motor deficit a sensory impairment is to be expected. Pyramidal fibers end in sensory relay nuclei of the medulla oblongata and spinal cord and corticofugal inhibition of transmission through primary afferents in the spinal cord is exerted in part through the pyramidal tract (Lindblom, U.F., and Ottosson, J.O., Acta physiol.scand. 1957. 38. 309).

The functional significance of pyramidal control of afferent transmission is unknown. I have tested the hypothesis that two different sensory tasks are associated with two different "settings" of the neurons in the dorsal horn and that the pyramidal tract does the setting. That the modality of dorsal horn neurons may change was observed in acute experiments by Wall (J.Physiol.1967. 188. 403). We trained monkeys to reach into a dark box with the right hand, grasp a silver plated handle and turn it 30 degrees right or left depending on whether its temperature was 29 or 25°C; the two temperatures were presented in a random sequence. In this way two difficult discriminations were performed rapidly one after the other and the postulated switching of the modality of dorsal horn neurons should occur. In control trials a red or a green light indicated the required direction of turning.

The number of errors made in turning the handle 30 degrees (kinesthetic errors) and the time it took to turn it was compared in 1000 preoperative and 1000 trials about 3 months after the lesion. Control and experimental trials were similarly affected and thus the hypothesis was not confirmed. Decision time in warm trials was selectively increased indicating, possibly, a deficient "range setting" for temperature after the lesion. This new hypothesis is currently being investigated.

Kernell, D. (The Nobel Institute for Neurophysiology, Karolinska Institutet, 104 01 Stockholm 60, Sweden): 45 THE PYRAMIDAL PROJECTION TO THE SPINAL CORD.

The present communication will mainly deal with studies on primates, and it will largely be restricted to that portion of the motor cortex efferents which consists of large (i.e. fast conducting) fibres running in the pyramidal tract (PT). There is much to suggest that the function of these fast PT units is different from that of the more numerous PT units with slower axonal conduction velocities. Recordings from discharging PT units in conscious primates suggest that it is predominantly the fast PT units that are primarily engaged in the control of rapid and distinct movements (Evarts, E. V., J. Neurophysiol. 1966. 29. 1011). In the primate (but not in the cat) there is a monosynaptic excitatory connexion between fast PT units and spinal alpha motoneurones (Bernhard, C. G., Bohm, E. & Petersén, I., Acta physiol. scand., 1953. 29. suppl. 106. 79). These monosynaptic effects from fast PT units are more powerful in motoneurones of distal limb muscles (e.g. for hands and fingers) than in those of more proximal muscles (Phillips, C. G. & Porter, R., Progr. Brain Res., 1964. 12. 222; Clough, J. F. M., Kernell, D. & Phillips, C. G., J. Physiol. (Lond.) 1968. 198. 145). The direct connexion between fast PT units and alpha motoneurones would seem to be especially advantageous for the fine control of 'skilled' hand and finger movements. Among the alpha motoneurones of a given nerve, the cells which receive a strong monosynaptic input from fast PT units also tend to receive a comparatively powerful monosynaptic excitation from primary afferents of muscle spindles (Clough et al., 1968). This arrangement is of interest with respect to the possible role of gamma motoneurones and muscle spindles for the control of phasic movements initiated by fast PT units.

In addition to their monosynaptic excitatory effects, the fast PT units give rise to a disynaptically mediated inhibition in many motoneurones (Preston, J. B. & Whitlock, D. G., J. Neurophysiol. 1960. 23. 154). This disynaptic projection might perhaps serve to inhibit the antagonists to movements initiated by fast PT units. Such a reciprocal pattern of innervation is, however, probably difficult to establish with the aid of electrical stimulation to the cortex, because the cell bodies of PT units innervating motoneurones of different muscles are likely to be intermingled. PT cells which lie very close together in the motor cortex may show a reciprocal discharge pattern during voluntary movements (Evarts, E. V., J. Neurophysiol., 1965. 28. 216).

For an interpretation of experiments concerning the long-latency effects (excitatory and inhibitory) which may be elicited in motoneurones by cortical stimulation, it has to be taken into account that a strong cortical stimulus pulse will elicit a rapid repetitive discharge of fast PT units (Kernell, D. & Wu Chien-Ping, J. Physiol. (Lond.) 1967. 191. 653 & 673).

In the cat the PT fibres have functional connexions with interneurones of various spinal reflex arcs (Lundberg, A. & Voorhoeve, P., Acta physiol. scand., 1962. 56. 201). It would be surprising if comparable projections did not exist in primates as well.

Jansen, J.K.S. (Institute of Physiology, University of Oslo, Norway): TRANSFER OF SIGNALS FROM MUSCLE STRETCH RECEPTORS. 46

So far, two groups of second order neurones activated by primary afferents from muscle stretch receptors have been investigated in particular detail. The motoneurones are in many respects the commonly accepted model of synaptic activation of nerve cells. The second group is the cells of origin of the dorsal spino-cerebellar tract (DSCT). Our own studies concern the latter group. In several ways their behaviour is simpler and more completely understood.

The transfer of signals to DSCT neurones are characterized by:

1. A high degree of specificity.
2. A high degree of linearity within their functional range.
3. A high efficiency of signal transfer.
4. A characteristic firing pattern of the second order neurones.

These points are explained: 1. By the anatomical coupling. 2. By the properties of the neurones. 3. By the properties of the synapsis and 4 by the properties of the input activity, the synaptic and neuronal properties.

Simplified models have been formulated which account quantitatively for the behaviour of the DSCT neurones. The synaptic transfer to the DSCT neurones can be inhibited by inputs from neighbouring muscles or by descending activity through the pyramidel tract. Such inhibition may reduce the "gain" of synaptic transfer, and may affect the firing pattern of the second order neurones. These observations can be explained by the same model.

The properties of the motoneurones are matched to the mechanical properties of skeletal muscles. Their afferent input from muscle stretch receptors is differently organized and in most respects motoneuronal behaviour is more complex than that of the DSCT neurones.

47 Euler, C.v. (Nobel Institute for Neurophysiology, Karolinska Institutet, Stockholm, Sweden): NEURAL CONTROL MECHANISMS DETERMINING PACE AND DEPTH OF RESPIRATORY MOVEMENTS.

It is now almost generally accepted that rhythmic breathing represents a recurring inhibition of a 'drive' for ventilation which is continously computed on the basis of information from peripheral and central chemoreceptors and other central and peripheral neural inputs.

Two interacting mechanisms are known to operate the rhythmic inhibition: 1) the internal bulbo-pontine pacemaker mechanisms and 2) the mechanisms governed by the pulmonary mechanoreceptors. The latter feed back information on volume , rate of expansion and transmural pressure of the lungs. A quantitative knowledge has not been available about how this information is used centrally to modify inspiratory and expiratory times or the depth of the breaths. To what extent the volume dependent feed-back mechanism constitutets an oscillating mechanism in its own right or whether it operates primarily by modifying the internal pacemaker is the matter under investigation.

The internal bulbo-pontine pacemaker seems to be the dominating frequency governor in eupnoeic breating in man (Guz, A. et al. Resp. Physiol. 1966. 1. 206) and in thermal polypnoea and panting in animal. It has been shown both in intact and vagotomized cats (Euler, C.v., F. Herrero & I. Wexler. Resp. Physiol 1969 in press) that as in man (Hey, E.N. et al. Resp. Physiol 1966. 1. 193), increased body temperature is unique among respiratory stimuli in that it alone will change the slope constant of the linear relation between pulmonary ventilation and tidal volume thus affecting mainly the frequency parameter. After vagotomy an increase in hypercapnic or hypoxic 'drive' causes virtually no change in respiratory frequency. The vagal mechanisms alone are responsible for the increase in frequency when 'drive' is increased both in man and animal.

In our attempt to gain further insight in the mode of operation of the control mechanisms determining rate and depth of breathing the analysis has taken the form of a dialogue between animal experiments (on cat) on one hand and analog modeling of the respiratory control mechanisms on the other.

This work by F. Clark, C.v. Euler & B. Roos (unpublished) has so far given the following results. Respiratory timing is governed by neural activity during inspiration. The duration of this inspiratory activity sets the duration of the phase of expiration. Volume information during inspiration serves to shorten the duration of the inspiratory phase without changing the linear expiratory to inspiratory time relation. The responsiveness to volume pulses,, which is low at the onset of inspiration increases steeply with time during that phase This explains i. a. how , in case of increasing 'drive' tidal volume can increase as inspiratory time shortens and why the high rate of breathing in panting is but little influenced by the vagal input. Volume information during the expiratory phase lengthens the duration of that phase but has no apparent effect on the following inspiration. Thus under corditions of constant drive and temperature each cycle, beginning with inspiration is an independent event.

Larsson, S. (Physiological Institute, Odense University, Odense, Denmark): **48**
ETIOLOGICAL AND CURATIVE ASPECTS ON OBESITY.

In recent years more knowledge of the etiology of obesity has been gained. Thus, we can now divide in large obesity into the following groups:

1. Hereditary obesity. This type of obesity will express itself differently. On the whole, however, endocrinological disturbances are not so common in man in the etiology of obesity.

2. Inactivity obesity. This type of obesity is probably the most common in the present human society. In this case the etiology is quite clear. I will refer to the nomenclature given by Dr. Passmore, who calls the present average human being Homo Sedentarius, instead of Homo Sapiens.

3. Dietary obesity. This group we can divide into two subunits, namely:

   a. Overeating. Naturally this overeating is a specific overeating in relation to energy expenditure.

   b. Dietary imbalance. In this case the energy expenditure is low and the diet usually too high in fats and carbohydrates. At the same time the individual has an extremely low muscular activity.

As to the treatment of obesity it is in most cases completely wrong to suggest decrease in caloric consumption. Experiments have shown that on the whole the best effect to cure obesity is to increase muscular exercise. In this respect one has to take into consideration two aspects, namely weight reduction and fat decrease of the body. Generally in human patients the desire is to decrease in weight fairly rapidly. Many of the fundamental experiments have been made in rather small animals where the life span is short. Unfortunately many of the weight reducing programmes given in the weekly magazines particularly directed to ladies guarantee an extremely rapid weight reduction, usually without any scientific background.

For the majority of the obese people the cure ought to be based upon dietary anamnesis and correction of food intake supplemented with a program of increased muscular activity. The conclusion for this statement will be discussed by referring to experiments upon both animals and man.

49 Donner, K.O. (Department of Physiological Zoology, University of Helsinki, Finland): PHOTOCHEMICAL ASPECTS OF THE RECEPTOR PROCESS IN VISION.

The absorption of photons by the visual pigment situated in the lamellar structure of the outer limb of vertebrate photoreceptors, triggers excitation. Such quantum absorptions initiate a series of changes in the molecules, the first step being the isomerization of the chromophore from the 11-cis to the all-trans form. This is followed by a series of relatively long-lasting thermal reactions that are fairly well known for rhodopsin in solution (Wald, G., Nature 1968. 219. 800). With certain differences these reactions can also be shown to occur in situ, for instance, in the rods of the isolated frog retina. Here the rhodopsin molecules are highly oriented so that they mainly absorb light incident parallel to the long axis of the rods. This mode of orientation is preserved by the photoproducts until the separation between the chromophore and the specific protein, opsin, occurs. Much before this visual excitation takes place and must then be mediated by some molecular change not associated with any change in the orientation of the chromophore.

Evidence from parallel investigations of the thermal decay of the photoproducts and sensitivity measurements with electrophysiological methods on single ganglion cells (Donner, K.O. & Reuter, T., J. Physiol. 1968. 199. 59) suggests that these products have an important function in the adaptation process. It thus appears that small amounts of metarhodopsin II present in the rods exert a negative feed-back on the excitation produced and thus reduce the sensitivity of the receptors to an extent depending on the rhodopsin bleached by the prevailing illumination or by immediately preceding exposures of the retina to light. This effect is, however, not identical with the reduction of sensitivity directly caused by a background of light. The relation between the amounts of metarhodopsin II and threshold can be quantitatively measured. It closely agrees with the properties of the parametric feed-back postulated in studies of the Limulus photoreceptor (Fuortes, M.G.F. & Hodgkin, A.L., J. Physiol. 1964. 172. 239). A sufficient amount of metarhodopsin II finally saturates the rods and makes them practically inexcitable.

It further appears that the regeneration of rhodopsin in the rods also affects their sensitivity to light, but in a different way. The rate of synthesis of new molecules has a sensitivity-reducing effect similar to that produced by backgrounds of real light, and the relation between threshold and rate of regeneration thus follows Weber's law. However, this effect is much weaker than that produced by a background. Thus a background light of an intensity that gives an absorption of about 1 quantum per rod per sec has an effect equivalent to that produced by the synthesis of about 3000 molecules per rod per sec in darkness.

Skou, J. C. (Institute of Physiology, University of Aarhus, Denmark): THE MOLECULAR BASIS FOR THE ACTIVE TRANSPORT OF Na^+ AND K^+. 50

The main problem in relation to active transport of Na^+ and K^+ is how the energy from the hydrolysis of ATP is converted into a movement of ions against an electrochemical gradient. A step on the way to solve this problem is the isolation of an enzyme system from cell membranes which fulfil a number of requirements to a transport system: the substrate for the system is ATP; it is asymmetric in the sense that it has a site with an apparent affinity for Na^+ higher than for K^+ which when the system is located in the cell membrane is facing the inside of the membrane and another site which has an apparent affinity for K^+ higher than for Na^+ and which is facing the outside of the membrane; Na^+ is required at the "Na site" and K^+ at the "K site" for activation; the system has the same quantitative relationship to Na^+ and K^+ as the transport system in the intact cell membrane; it can be isolated from all cells which have been shown to have a K^+ coupled Na^+ transport; G-strophanthin which is a specific inhibitor of active transport of Na^+ and K^+ inhibits the enzyme system. This suggest that the system is part of or the transport system.

There is indirect evidence that the system under the influence of Mg^{++}, ATP, Na^+ and K^+ undergo a change in structural configuration and it is possible to distinguish between two different states of the system. The one is characterized by being insensitive to G-strophanthin while the other is sensitive to G-strophanthin. MgATP turn the system into the G-strophanthin sensitive state; this is due to an effect of ATP as such and not to a hydrolysis of ATP. With Na^+ at the "Na site" and K^+ at the "K site" the system in the G-strophanthin sensitive state has the catalytic activity and the hydrolysis of ATP turn the system into the G-strophanthin insensitive state. It seems likely that it is a cycling between these two states which leads to the transport of the cations.

On the basis of the ability of Mg^{++}, ATP, Na^+ and K^+ to influence the two different states of the enzyme system it is possible to set up a hypothetical model for the transport system which operates with four different forms of the system. One which gives a Na^+: Na^+ exchange, another which gives a K^+: K^+ exchange, a third which gives a K^+ coupled Na^+ transport and which due to the exchange of Na^+ for K^+ leads to the fourth of the forms. They all exist at the same time in the cell and the ratio between them is determined by the ratio of Na^+ and K^+ in the internal and in the external solutions.

51 Hartiala, K. (Department of Physiology, University of Turku, Turku, Finland): THE ROLE OF GASTROINTESTINAL WALL IN DRUG METABOLISM.

Whole animal, tissue slice and isolated subcellular particle experiments have demonstrated that the mucous membrane of the whole alimentary tract takes an active part in the so-called phase I (oxidation, reduction, hydrolysis) and phase II (synthetic) reactions. (Ann.Med.exp.Fenn.1955. 33.239; Biochem.Pharmac.1961.6.82; Nature 1964.201.1036 and 1965.205.809). Also the enzymes and the nucleotides responsible for these syntheses have been located in the mucosal specimens. The type and capacity of these reactions in the gastrointestinal tract are species dependent and are obviously the same as those carried by the liver of the same animal species. Substrates for these reactions involve compounds produced by the body itself (e.g. steroids) and foreign compounds widely used for therapeutic purposes. The amount of metabolites produced by these reactions during the absorption processes can be large. This has been demonstrated in dogs by using 4-C^{14} marked steroids (progesterone, androstenedione, testosterone or 17α-methyl-testosterone) and placing them into isolated intestinal segments. The first metabolites could be detected within few minutes after the application of the sample. After half an hour about 40 different polar metabolic products were found in the portal blood. Sterilization of the gut lumen does not alter these metabolic patterns. The sequence of these reactions can be followed and it possibly reflects the metabolic arrangements within the endoplasmic reticulum.

The upper part of the duodenum possesses the highest capacity for the synthetic reactions. The distribution patterns of the enzymes and nucleotides responsible e.g. for glucuronide conjugation as well as those involved in oxidative phosphorylation processes are not linear and reveal specific differences.

The fetal development of these functions in the liver, intestine or kidney reveals species differences. In general they are far from the adult level at the time of birth and practically absent during the first half of the fetal period.

The gastrointestinal mucous membrane thus, exerts a great variety of metabolic effects on foreign substances. These reactions change the chemical and biological nature of the absorbed substrates although they operate mainly on trace levels. Part of the nucleotide-bound energy sources of these reactions are the same necessary for the local synthesis of epithelial and connective tissue glycoproteins.

Bill, A. (The Wallenberg Laboratory and the Institute of Pharmacology, University of Uppsala, Sweden): 52 THE DYNAMICS OF AQUEOUS HUMOR.

The continuous formation and drainage of aqueous humor contributes to maintain the intraocular volume and pressure within narrow limits which is a prerequisite for precise function of the optical apparatus. A second task is to nutriate the avascular intraocular tissues.

Results from several laboratories indicate that in the ciliary processes there is active transport of Na^+, Cl^- and ascorbic acid into the posterior chamber and transport of I^- and some organic anions in the other direction. The movement of water into the posterior chamber seems to be secondary to the net transport of ions. Mechanisms for facilitated diffusion contribute to give rapid movement of amino acids into the aqueous humor of the posterior chamber. The low concentration of plasma proteins in the aqueous humor and the high concentration in the tissue fluid of the ciliary processes, about 60-70 percent of that in plasma, make it seem unlikely that ultrafiltration of tissue fluid contributes to the formation of the aqueous humor; a tendency to reabsorption of freshly secreted aqueous humor seems more likely.

The aqueous humor flows from the posterior chamber into the anterior chamber via the pupil. Exchange of matter with the vitreous humor and the lens changes the composition of the fluid and possibly also its volume. Recent experiments show that if there is normally any flow of aqueous humor into the vitreous humor it is not appreciably influenced by a moderate rise in the intraocular pressure.

In the anterior chamber there is exchange between the aqueous humor and the cornea, the chamber angle tissue, the iris and part of the lens. Experiments with myoglobin, albumin and gammaglobulin have shown that the three proteins leave the anterior chamber at almost exactly the same rates in spite of differences in size. The proteins thus seem to be drained by bulk flow. In vervet monkeys (Cercopithecus ethiops) part of the bulk flow, about 1.1 µl/min, occurs through a trabecular meshwork into the canal of Schlemm and from there into intra- and episcleral veins. The rate of flow is proportional to the driving pressure. Another part of the aqueous humor about 0.6 µl/min is drained into the interstitial tissue spaces of the ciliary muscle, where it mixes with the tissue fluid and is drained with such fluid into the space beneath the sclera and out through the sclera. Part of this fluid is resorbed into the conjunctival lymph vessels. This flow is very little influenced by moderate changes in eye pressure. Low molecular weight substances like diodrast and iodoantipyrine leave the anterior chamber both by bulk flow and diffusion. Data for iodoantipyrine elimination indicate that the blood flow through the iris vessels that exchange matter with the anterior chamber is very low, about 4 µl/min.

A rise in eye pressure tends to lower the rate of aqueous formation most probably by interfering with the circulation of blood in the ciliary processes. Adrenergic drugs and sympathetic stimulation tend to increase the rate of formation of aqueous humor, pilocarpine and acetazolamide reduce the secretion rate. There is no clearcut evidence indicating an extraocular center for regulation of intraocular pressure or rate of aqueous formation according to information derived from receptors sensing intraocular pressure or rate of flow of aqueous humor.

53 Fuxe, K. and Hökfelt, T. (Department of Histology, Karolinska Institutet, Stockholm, Sverige): ON THE ROLE OF CENTRAL MONOAMINE NEURONS IN NEUROENDOCRINE MECHANISMS.

Many areas of the hypothalamus, the preoptic area and the limbic system are known to receive a large number of 5-HT and NA nerve terminals, which arise from fibres mainly ascending in the lateral hypothalamic area and which in turn originate from cell bodies in the lower brain stem. Furthermore, there exists a tubero-infundibular DA neuron system which innervates the external layer of the median eminence. Here the DA nerve terminals probably establish axo-axonic contacts with "peptidergic" neurons involved in the central gonadotrophin secretion. Using amine synthesis inhibitors and labelled monoamines the turnover of the various monoamine nerve terminal systems have been studied under various endocrinological states by way of a histochemical and biochemical monoamine analysis. The turnover will give an indication of the state of activity in the monoamine nerve terminals and therefore an indication of their role in neuro-endocrine mechanisms can be obtained.
Tubero-infundibular DA neurons. The turnover is markedly increased in pregnancy, pseudopregnancy and lactation but not significantly changed after adrenalectomy, stress or thyroxine treatment as shown in the male rat. This strongly suggests that these DA neurons are involved in the control of gonadotrophin secretion. In agreement with this it has been found that the activity varies during the ovarian cycle, being somewhat lower in proestrus; that the activity is low after castration and very low after hypophysectomy and relatively high after androgen-sterilization and exposure to constant light; that estrogen and testosteron but not progesteron and hydrocortison cause a marked activation of the system particularly in the castrated state. Furthermore, prolactine in low amounts but not FSH, LH, ACTH or vasopressin is capable of causing a marked activation of the system. Certain antifertility steroids such as mestranol and ethynodiol diacetate also cause a marked activation of the DA neurons. Under these various conditions the turnover in the nigro-neostriatal DA neurons is not significantly changed, demonstrating the specificity in the response of the tubero-infundibular DA system. To explain the present results the working hypothesis is given that the DA released in the median eminence at least partly acts to inhibit the synthesis and/or release of LRF from the neurons storing this factor. A direct action on the anterior pituitary can be excluded, since DA even in high concentrations in the incubation medium does not influence the secretion of LH from the anterior pituitary. - The role of central NA and 5-HT neurons in neuroendocrine functions will also be discussed.

Waaler, B.A. (Institute of Physiology, University of Oslo): 54
PLASMA KININS IN PHYSIOLOGY AND PATHOPHYSIOLOGY.

A variety of enzymes can release peptide material with profound circulatory effects from proteins in mammalian plasma. Two linear peptides: bradykinin and kallidin (9 and 10 amino acids) have been identified as active substances - plasma kinins - resulting from such reactions. Interest in the plasma kinins stems mainly from their great potency as vasodilator and hypotensive agents. In addition they can cause increased permeability of small vessels, pain sensation, contraction of several types of smooth muscles, and possibly leucocyte emigration and accumulation.

Biochemical work has revealed interesting information about kinin structure and specificity, kinin formation and kinin inactivation. The biological activity of plasma kinins depends on specific characteristics of the amino acid chain, and further knowledge here may lead to a much wanted concept of the receptor mechanisms involved. - Plasma kinins can develop from several plasma protein precursors, kininogens. One or more of these have molecular weights in the region of 50 000, and will be relatively well represented in interstitial fluid. Another kininogen, with a molecular weight of about 197 000, will be much more confined to the intravascular space (Jacobsen and Kriz, Br.J.Pharmac. Chemother. 1967, 29, 25). Various kinin-forming enzymes act on one or both kininogens and kinin formation may occur intravascularly as well as extravascularly.

It has been claimed that plasma kinins play a dominant role in the functional vasodilatation in active glandular tissue (Hilton, S.M., Physiol.Rev.1962, 42, 265). The submandibulary gland of the cat is the best analyzed structure in this connection. Antagonists maintain that vasodilator nerves are responsible for such dilatation (Schachter, M. and Beilenson, S., Gastroenterology 1967,52,401). The intermediate view that both mechanisms play an important role has received support from investigations by Gautvik (personal communication), indicating that on chorda thympani stimulation there is an initial, marked decrease in vascular resistance in the cat submandibulary gland, probably mediated directly via vasodilator nerves. Formation of plasma kinins increased and prolonged the vasodilator effect.

Plasma kinins have been considered as mediators in the inflammatory response, and they have also been discussed as being involved in a variety of pathophysiological situations: shocks of various types, asthmatic attacks, foreign body granulomas and pneumoconioses, hereditary angioneurotic edema, carcinoid syndrome etc. In these and other connections the participation of plasma kinins have been difficult to prove or disprove. If participating, plasma kinins do probably act together with other agents or mechanisms. As long as there are no specific antikinins available, a more exact evaluation of the possible contribution of kinins seems difficult.

55 Enger, Per S. (Institute of Physiology, University of Oslo, Norway): RECEPTION OF SOUND AND VIBRATIONS BY THE FISH EAR.

The sound frequencies that can be perceived by the fish ear range from less than 30 Hz to above 5000 Hz in Ostariophysine species (teleosts which posess a chain of ossicles connecting the swimbladder directly to the inner ear). In most non-Ostariophysids the upper limit of pitch perception is less than 1000 Hz, but can be as high as 3000-4000 Hz in some species with air-filled cavities in close proximity to the labyrinth (Mormyridae, Clupeidae).

The physical stimulus for the auditory (as well as the lateral line) receptors appears to be particle displacement rather than acoustic pressure. An underwater sound source, however, produces both a progagated sound pressure wave and a local water displacement (vibration). The sound pressure amplitude decreases linearly with distance, whereas the local displacement (the socalled near-field effect) decreases with distance to the second or third power. The local water displacement can stimulate auditory receptors directly and will at close range interfere with determinations of sound pressure thresholds. Perception of propagated sound is accomplished by air bladders or vesicles in teleosts. A swimbladder will undergo volume changes in response to pressure changes. These volume changes produce local particle displacements which in turn stimulate the auditory receptors.

Sound pressure thresholds are known for a few species and range from above 1 μbar in the least sensitive non-Ostariophysids to -45 dB ref. 1 μbar in the goldfish (Ostariophysi). In order to compare these values with measurements of sound and noise in the sea, the frequency band width over which the acoustic pressure is integrated must be known. From recent experiments it appears that the response of auditory neurones is the same to pure tones as to noise of 1/3 and 1 octave bandwidths centered at the frequency of the pure tone.

Wiesel, T. (Department of Neurobiology, Harvard Medical School, U.S.A.) **56**

FUNCTIONAL ORGANIZATION OF THE MONKEY VISUAL CORTEX.

Classical anatomical and physiological studies have shown that the contralateral visual field projects onto the primary visual (striate) cortex in an orderly and topographical way. The precise topography is observed also on a cellular level; in microelectrode penetrations through the striate cortex, receptive fields of successively recorded cells are always close together and indeed overlap to a large extent. In a penetration perpendicular to the surface the fields stay in more or less the same position on the retina. In an oblique penetration there is a slight gradual shift of field position after a traverse of many mm.

Besides having practically the same field positions, neighboring cells are similar in a number of other ways. Two cells near each other usually have the same receptive field orientation and the same eye preference. As the cortex is traversed these two variables change not gradually, but in sudden jumps. Orientation, for example, remains constant during a vertical penetration from surface to white matter, but in oblique penetrations it stays constant for a small distance, and then shifts abruptly to a new value. Cells having the same receptive field orientation are aggregated into small discrete column-like regions extending through the cortex with walls perpendicular to the cortical surface. There are as many as 15-17 kinds of orientation columns. Regions defined by eye preference are similarly columnar in shape; these columns are of just two types, and they seem to be larger than the orientation columns. In these two systems the walls separating columns seem to be quite independent.

Cutting across these systems of vertical columns are the cortical layers. Cells in the striate cortex differ in the relative complexity of their stimulus requirements and can be subdivided into 'simple', 'complex', and 'hypercomplex' cells. Cells in the upper and lower layers are mostly complex and hypercomplex, cells in layer 4, roughly midway between surface and white matter, are most often simple. Some units (which may be afferent fibers from the lateral geniculate body) have concentric fields. Furthermore, cells in layer 4, unlike cells in other layers, are seldom driven by both eyes; instead some are driven by one eye, some by the other. The fourth layer receives direct geniculate input and the cells in this layer would therefore be expected to have the least elaborate properties of any cells in the striate cortex. It is therefore perhaps not surprising to find 'simple' cells driven monocularly in this layer.

In summary, the cortex can be looked upon as a system organized vertically and horizontally in entirely different ways. In the vertical system (in which cells encountered in a vertical penetration through the cortex have common features) stimulus dimensions such as line orientation and ocular dominance are mapped in sets of superimposed but independent mosaics. The horizontal system segregates cells in layers by hierarchical orders, the lowest orders located in layer IV, the higher orders in the upper and lower layers.

57 Crone, C. (Institute of Medical Physiology A, University of Copenhagen, Denmark). THE BLOOD-BRAIN BARRIER.

The ability of a molecule to pass from plasma into brain tissue is determined by the presence of lipophilic groups rather than by the size of the molecule. This was demonstrated in experiments where the uptake in brain of a homologous series: propanol, 1,2-propanediol and glycerol was determined during a single passage (Crone 1964). It was found that Collander's general findings with respect to cell permeability of non-electrolytes applies to the brain.

As is the case in many cells glucose constitutes an exception. It is rapidly transferred across the blood-brain barrier. The mechanism shows saturation kinetics and stereospecificity (Crone 1965). The transport can be inhibited by the presence of similar compounds (methyl-O-Glucose).

Anatomists have claimed that the transport of glucose into the brain takes place via the glial cells covering the cerebral capillaries. The view is probably wrong as demonstrated by Wolfe and Nicholls (1967) who could find no preferential uptake of glucose by glial cells using autoradiographic techniques.

It still remains unsettled what is the morphological substrate of the blood-brain barrier. Several proposals have been made: 1) a special structure of the capillary endothelium, 2) a virtual non-existing interstitial space in the brain, 3) glial cell covering. The concept of a vanishingly small interstitial space at least seems to be wrong (Rall, Oppelt & Patlak, 1962).

Morphological studies of the fate of protein markers injected either into the blood or into the cerebral ventricles show that the individual endothelial cells in the brain capillaries are connected by "tight junctions" through which protein cannot pass (Brightman and Reese, 1969).

Capillaries from various organs present different permeabilities due to widely different morphology of the endothelial cells, ranging from fenestrated capillaries with wide interendothelial gaps (liver and intestine) to brain with no fenestrations and tight junctions between the endothelial cells.

It is tempting to speculate that the blood-brain barrier is a reflection of a special morphology of the brain capillaries.

Ehinger, B., Falck, B., Persson, H., Rosengren, E. and Sporrong, B. (The Institute of Anatomy and Histology and the Department of Pharmacology, University of Lund, and the Research Laboratories, AB Draco, Lund, Sweden): LOCALIZATION OF ACETYLCHOLINE IN THE FELINE IRIS. **58**

Acetylcholine was bioassayed in the normal cat iris, and also after selective sympathetic or parasympathetic denervations. Sympathetic denervation caused no significant change in the acetylcholine content of the cat iris, whereas selective parasympathetic denervation reduced the acetylcholine content below the level of detectability, which on the average was at about 5 per cent of the acetylcholine content of the normal iris. It is concluded that if adrenergic terminals contain any acetylcholine, it is less than what is detectable with the methods available at present, most certainly less than 6 per cent of the acetylcholine content of cholinergic neurons. On the basis of these and other recently obtained observations the hypothesis of Burn and Rand of a cholinergic link in the adrenergic transmission is discussed. It is proposed that it is more reasonable to suppose an interaction between peripheral adrenergic and cholinergic terminals than to presume a cholinergic mechanism within adrenergic nerves.

Klinge, E., O. Penttilä and P. Pohto (Department of Pharmacology, University of Helsinki, Finland): CELLS EXHIBITING MONOAMINE FLUORESCENCE IN URETHRAL TISSUE OF BULL AND RABBIT. **59**

Pieces of tissue were freeze dried in vacuo and exposed to formaldehyde vapour. Numerous non-neuronal cells exhibiting intense greenish-yellow or yellow fluorescence were observed in or in close vicinity to the urethral mucosa of bulls and rabbits. In bulls the surrounding cavernous tissue was practically devoid of adrenergic nerve fibres, whereas they were readily detectable in this tissue of rabbits. Using a modified thiocholine method no acetylcholinesterase activity was detected in the monoamine cells. No nerve fibres entered the urethral mucosa of either animal. It is likely that the fluorescent amine in the cells of both animals is 5-hydroxytryptamine, but in the bulls there also might be some dopamine. This is indicated by the monoamine contents observed in the respective tissues (Penttilä, O. and A. Vartiainen, Acta pharmacol. (Kbh.) 1964, 21, 145). In the urethral mucosa of the bull the 5-hydroxytryptamine content is about three times as high as in the surrounding cavernous tissue. Incubation experiments also showed that the 5-hydroxytryptophan decarboxylase activity in the bull urethral tissue exceeds by far that of the surrounding cavernous tissue, whereas the monoamine oxidase activity is about equal. The functional role of the monoamine cells is undefined.

60 Ericson, Lars E. (Dept. of Anatomy, University of Göteborg, Sweden): SUBCELLULAR LOCALIZATION OF 5-HYDROXYTRYPTAMINE IN MOUSE THYROID PARAFOLLICULAR CELLS.

It is now well established that the thyroid parafollicular cells (P.F. cells) secrete calcitonin. Like several other cell types elaborating polypeptide hormones the P.F. cells have monoaminergic mechanisms. Light microscopic studies have demonstrated that 5-HT is a naturally occurring compound in these cells in goat and sheep. In most other species, however the presence of monoamines in P.F. cells can only be demonstrated after injection of monoamine precursors (5-HTP and DOPA) which are decarboxylated within the cells to the corresponding amines. These are stored in the cytoplasm by a mechanism sensitive to reserpine.

In the present study, which was performed to elucidate the intracellular localization of the monoamines, mice were injected with tritiated 5-HTP. The thyroids were fixed by perfusion with glutaraldehyde and prepared for light and electron microscopic autoradiography.

In light microscopic sections autoradiographic grains were recovered exclusively over P.F. cells. In electron microscopic autoradiographs the close association between silver grains and the specific granules of the P.F. cells, confirmed by quantitative analysis, was very evident. Grains were seldom encountered over cytoplasmic parts devoid of granules.

Thus the present study clearly demonstrates that a monoamine is localized to the granules which are the most distinctive cytoplasmic components of the P.F. cells (Ekholm and Ericson, J. Ultrastruct. Res. 23, 253, 1968) and which in all probality also contain calcitonin (Ericson, J. Ultrastruct. Res. 24, 145, 1968).

61 Bygdeman, S. and Stjärne, L. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden): THE ROLE OF CALCIUM UPTAKE IN COLLAGEN INDUCED PLATELET AGGREGATION.

Platelet aggregation induced by a collagen fibril suspension is calcium dependent and involves a release of adenine nucleotides, 5-hydroxy-tryptamine and other compounds stored in granules within the platelets. Stormorken (Acta physiol. scand. 1969. 75. 38) has recently argued that the platelets should be regarded as secretory cells and has put forward the hypothesis that the release reactions, involved in platelet aggregation was similar or identical with that observed in some other cell types i. e. adrenal medullary cells. To test this hypothesis and since it is known that uptake of calcium is a necessary step in the release of catecholamines adrenal medullary cells we have thought it to be of interest to study if an uptake of calcium occurred also in the platelets during the aggregation reaction.

In a first series of experiment it was found that guanethidin, which is reported to inhibit calcium uptake, in concentrations from 10^{-6} to 10^{-4} M did not significantly influence the aggregation response to a subsequent addition of collagen in human platelet rich plasma. In a second series of experiments human platelet rich plasma was incubated with tracer amounts of Ca^{45} and the uptake of the isotope after aggregation was determined. No difference in uptake was observed between these experiments and control experiments in which no aggregation was induced.

The results do not support the view that the release reaction involved in platelet aggregation is of the same nature as that observed in adrenal medullary cells.

Håkanson, R., Lindstrand, K., Nordgren, L. and Owman, Ch. (Departments of Pharmacology, Biochemistry and Histology, University of Lund, Sweden): **62**
GASTRIC ARGYROPHIL (ENTEROCHROMAFFIN-LIKE) CELLS: A POSSIBLE STORAGE SITE FOR THE ANTIPERNICIOUS PRINCIPLE (INTRINSIC FACTOR).

Two systems of cells with a possibly endocrine function occur in gastric mucosa. One is the enterochromaffin cell system, which is the major storage site for gastrointestinal 5-hydroxytryptamine. These cells are argyrophil as well as argentaffin. The other system consists of cells which are morphologically similar to the enterochromaffin cells but devoid of 5-hydroxytryptamine (Håkanson, Lilja and Owman, European J. Pharmacol. 1967.1.188). These enterochromaffin-like cells stain argyrophil but not argentaffin. In some species these cells contain histamine (Håkanson and Owman, Life Sci. 1967.6.759). It has been suggested that these two cell systems are active in the formation of gastrointestinal polypeptide hormones (Aures and Håkanson, European J. Pharmacol. 1968.3.316; Pearse, Nature 1969.221.1210). Recently, the system of enterochromaffin-like cells has been implicated as the source of the antipernicious principle (intrinsic factor) (Håkanson et al. in press). This assumption is based on the excellent correlation between the distribution of this cell system and of the intrinsic factor in a number of species. It is also supported by evidence indicating a close parallelism between the development of this cell system and of the intrinsic factor in neonatal animals.

Serck-Hanssen, Guldborg.(Dept. of Biochem., University of Bergen, Norway): **63**
CHROMOGRANIN, A CONSTITUENT OF THE CHROMAFFIN GRANULE MEMBRANE.

The catecholamines, CA, of the chromaffin cells of the adrenal medulla are released on stimulation together with ATP and the soluble protein (Banks, P. & Helle, K., Biochem. J.1965. 97. 40c). The mechanism of release is probably by exocytosis (Schneider, F.H. et al., Br. J. Pharmacol. 1967. 31.94). The granule membrane is not incorporated in the plasma membrane after release of CA but exists as discrete particles within the cell (Poisner, A.M. et al., Biochem. Pharmacol. 1967. 16. 2101, Malamed, S. et al., Ibid. 1968. 17. 241). It has been shown that chromogranin, the main soluble protein of the chromaffin granule, also is a major component of the granule membrane obtained after lysis of isolated granules by osmotic shock or ultrasonic vibration (Helle, K.B. & Serck-Hanssen, G., Pharmacol. Res. Comm. 1969. 1).

The chromogranin of the membrane has now been studied in adrenals perfused in vitro and stimulated by acetylcholine. The results show that the large granule fraction from stimulated and control glands contain 15-20 % chromogranin based on mg protein. On further resolution of the large granule fraction on sucrose gradient, chromogranin can be recovered in two fractions corresponding to that of free membranes and intact granules. In stimulated glands the amount of CA found in the large granule fraction and the membrane fraction from the gradient is only 1/2-1/3 of that obtained for control glands. The higher loss of CA to that of chromogranin indicates that on stimulation a major part of the chromogranin is retained within the cell. This is in agreement with it being bound to the granule membrane.

64 Sachs, Ch. (Department of Histology, Karolinska Institutet, Stockholm, Sweden). EFFECTS OF 6-HYDROXYDOPAMINE ON SYMPATHETIC ADRENERGIC NEURONS.

6-hydroxydopamine (6-OH-DA) has been shown to produce a long lasting depletion of noradrenaline (NA) from various peripheral organs (Porter et al., J. Pharmacol. 1963. 140.308; Laverty et al., Brit. J. Pharmacol. 1965. 24. 549; Thoenen and Tranzer, N-S's Arch. exp. Path. Pharmak., 1968. 261. 271). Electron microscopic and fluorescence histochemical studies have revealed that 6-OH-DA induces a selective destruction of adrenergic nerve terminals (Tranzer and Thoenen, N-S's Arch. exp. Path. Pharmak., 1967. 257. 342; Malmfors and Sachs, Europ.J.Pharmacol. 1968. 3. 89). The present investigation is concearned with the time-course of 6-OH-DA induced disappearance of endogenous NA, its reappearance and changes in uptake-storage properties of NA in adrenergic nerves. 6-OH-DA (20 mg/kg i.v.) causes a general reduction of formaldehyde-induced fluorescence of NA in the adrenergic nerves of mouse atria within 15-20 minutes whereas after 1 hr only a few nerve terminals generally can be observed. The NA content as found by chemical assay, are at these time-intervals 60-80% and 20% respectively of untreated. A restoration of the adrenergic ground-plexus can be observed histochemically after 3-4 weeks, while the NA content is not restored completely until 8 weeks after the 6-OH-DA injection. Desmethylimipramine or NA in high concentrations can partially prevent the depleting action of 6-OH-DA. The uptake of ^{3}H-6-OH-DA is considerably reduced after sympathetic denervation. These data speak in favour of the view that 6-OH-DA or some metabolite has to be taken up by the adrenergic nerve endings to produce its effect.

65 Malmfors, T., and Olson, L. (Dept. of Histology, Karolinska Institutet, Stockholm, Sweden): FUNCTIONAL REINNERVATION BY ADRENERGIC NERVE TERMINALS IN TRANSPLANTED INTESTINAL SMOOTH MUSCLE.

Sympathetic adrenergic neurons have been shown to possess great regenerative capacity both as regards their non-terminal axons (Olson, L., Histochemie 1969. 17. 349) and their terminal parts (Malmfors, T. and L. Olson, Acta Physiol. Scand. 1967. 71. 401). The present investigation concerns the return of neuromuscular transmission after regeneration of adrenergic nerves. Longitudinal strips were prepared from the muscle layer of the rat ileum, thus interrupting the normal supply of adrenergic nerves to the muscle layer without any damage to the nerve cells of the plexus of Auerbach. The strips were homologeously transplanted to the anterior chamber of the eye. Transplants survived well and could be readily observed through the cornea. Vascular contacts were established between the transplant and host iris and spontaneous rythmic contractions were soon observed in the transplants (typically 1 per 2 sec. often in bursts). These spontaneous contractions could be promptly and completely inhibited by electrical stimulation of the cervical sympathetic trunc (10/sec. 6v., dur. 1 msec). The inhibition could be repeated after periods of rest during which the spontaneous contractions reappeared. Fluorescence histochemical investigation revealed a growth of adrenergic nerves from the normally present plexus in the iris of the host eye to the transplant, where varicose nerve terminals were found to reinnervate the plexus of Auerbach surrounding the non-fluorescent cell bodies to an almost normal extent.

Lundberg,D.(Institute of Pharmacology,University of Uppsala,Sweden): 66
EFFECTS OF SOME DRUGS ON THE BRETYLIUM-INDUCED DELAY OF THE DEGENERATION RELEASE OF SYMPATHETIC TRANSMITTER.

It is known that bretylium delays the depletion of the noradrenaline stores which follows division of sympathetic axons (Benmiloud,M. and U.S.v.Euler,Acta physiol.scand.1963.59.34) and that bretylium among four potent neurone-blockers studied causes the greatest delay of a degeneration contraction in the rat (Lundberg,D.,Acta physiol.scand.1969.75.415).To study the delaying effect of bretylium further some drugs active at the adrenergic nerve terminals were tested for bretylium-antagonizing action.

The degeneration contraction of periorbital smooth muscles produced by high cervical ganglionectomy was measured intermittently in conscious rats.Drugs were given s.c. within 1-3 hrs before the expected start of the contraction.- Injected after bretylium Lu 3-010, desmethylimipramine (DMI) and protriptyline at 10 mg/kg and metaraminol and dexamphetamine at 2 and 4 mg/kg,respectively,significantly shortened the bretylium-induced delay,whereas trimipramine and cocaine at 10 and 10-20 mg/kg,respectively,had no reversing effect. Given before bretylium DMI and dexamphetamine but not metaraminol or cocaine reduced the delay.In fact cocaine significantly prolonged the delay.

The results are still hard to interpret. Interference with the amine pump of the axon membrane does not seem to be sufficient to explain the antagonism to bretylium in the situation studied.

Palmer, B., and K.-A. Norberg. (Department of Histology, Karolinska Institutet, and Research Laboratory of the Thorax Clinic, Karolinska Hospital, Stockholm, Sweden): IMPROVEMENT OF BLOOD FLOW IN EXPERIMENTAL SKIN FLAPS BY PHENTOLAMINE. 67

Cutaneous blood vessels in a three-sided skin flap become sympathetically denervated within 24-48 hours (Jurell, G., K.-A. Norberg and B. Palmer, Acta physiol. scand. 1968. 74. 511). Within this period the uptake mechanism in the neuronal cell membrane is destroyed (Malmfors,T., and Ch. Sachs, Acta physiol. scand. 1965. 64. 211). This probably can explain the early supersensitivity for catecholamines. A supersensitivity of the blood vessels in the apex of a flap would create conditions for vasoconstriction leading to tissue necrosis. With the aim to elucidate some of the reasons for failure of the flap surgery technique, the blood flow in experimental flaps in rats was analyzed during ether anesthesia by means of the ^{133}Xe clearance method, according to Lassen et al.(Lancet 1964. 1.686). The flow was expressed as the quotient between the clearance values for the flap and contralateral control side, expressed in per cent. The flow in the apex raised from about 15 per cent initially to about 65 per cent on the 7th day. Blocking of the adrenergic α-receptors by phentolamine (Regitine® 1 mg/kg b.w. i.m.) caused an improvement in blood flow in the apex up to about 70 per cent already on the 3rd day. The possibility thus arises that denervation supersensitivity may be of major importance for the blood flow in flaps during the first critical days postoperatively.

68 Johansson, B., B. Ljung, T. Malmfors and L. Olson (Dept. of Physiology, Univ. of Göteborg and Dept. of Histology, Karolinska Inst., Stockholm, Sweden): DENERVATION SUPERSENSITIVITY IN THE SPARSELY INNERVATED SMOOTH MUSCLE OF THE PORTAL VEIN.

The propagating smooth muscle of the rat portal vein was shown by the fluorescence technique to receive a sparse adrenergic nerve supply organized as a continuous two-dimensional plexus between the heavy longitudinal and the inner circular muscle layers. Scattered nerve terminals were found at the adventitio-medial border. In view of this sparse innervation it was considered of interest to study the degree of "supersensitivity after denervation". Mechanical responses of isolated portal veins from sham-operated and ganglionectomized (coeliac +mesenteric) rats were studied. NA dose-response curves for six successfully denervated preparations, examined 3 to 17 days after operation, were parallelly displaced to the left, corresponding to a mean change of ED_{50} from 1.0×10^{-6}M to 1.3×10^{-7}M. After blockade of neural NA uptake by cocaine the ED_{50} of innervated preparations was 3.7×10^{-8}. Excitatory responses to Ach were not affected by chronic denervation. The results indicate that the supersensitivity to NA after denervation is due to elimination of the neural NA uptake. It appears that the "innervated" smooth muscle cells play a major role not only in the neural response but also in the response to exogenous NA.

69 Anggård, E. and R. Sjöström (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): SEPARATION OF ACIDIC AND NEUTRAL CATECHOLAMINE METABOLITES ON LIPOPHILIC SEPHADEX.

Methylated and hydroxypropionylated Sephadex has recently become available for chromatography of lipophilic substances such as steroids and bile acids (Nyström and Sjövall 1964, 1965). In the present study vanillylmandelic acid, homovanillic acid, 3,4-dihydroxymandelic acid, 3,4-dihydroxyphenylacetic acid, 3-methoxy-4-hydroxyphenylethylene glycol and 3,4-dihydroxyphenylethylene glycol were separated on hydroxypropionylated Sephadex (Sephadex LH-20), Pharmacia, Uppsala, Sweden). Ethylene chloride and methanol were used as solvents. The acids were run as the methyl esters.

Separation of the abovementioned compounds was obtained in a single analysis. The method is fast (4-6 hours), efficient (600-800 theoretical plates/foot) and the column can be used repeatedly without repackning. It appears to be useful for purification prior to gaschromatographic analysis.

Farnebo, L.-O. (Department of Histology, Karolinska institutet, Stockholm, Sweden): RELEASE OF ^{3}H-NORADRENALINE FROM ISOLATED RAT IRIS BY FIELD STIMULATION. 70

Field stimulation, which is known to cause depolarization of nerve membranes, markedly increase the efflux of ^{3}H-noradrenaline (^{3}H-NA) from nervous tissues previously incubated in ^{3}H-NA (Baldessarini and Kopin, J. Pharmacol. exp. Ther. 1967. 156. 31-38).

Isolated rat irides were incubated in ^{3}H-NA and then stimulated by an electrical field (biphasic pulses, 10/sec, 2 msec, 5 V/cm). Stimulation caused a marked increase in the efflux of total ^{3}H. The stimulus induced release was the same in irides from untreated rats and rats pretreated with a tyrosine hydroxylase inhibitor (H 44/68, 1 h). The efflux of ^{3}H per minute was high during the first 15 min of stimulation but then declined. In irides from untreated rats, stimulation for 60 min caused a slight reduction in fluorescence intensity of the adrenergic nerves, while after H 44/68 pretreatment the reduction was more pronounced. No stimulation induced ^{3}H efflux was found in irides from rats pretreated with reserpine (16 hrs) and nialamid (1 h). Irides (from untreated rats) which were incubated in reserpine phosphate 10^{-7} M after incubation in ^{3}H-NA showed a high spontaneous ^{3}H efflux. This efflux was further increased by stimulation. The stimulus induced release was considerably higher than that from irides not incubated in reserpine.

The technique used presents new possibilities for the study of release mechanisms in adrenergic nerves.

Hedqvist, P. (Department of Physiology, Karolinska Institutet, Stockholm, Sweden): PROSTAGLANDIN E AS A MODULATOR OF NORADRENALINE RELEASE FROM SYMPATHETIC NERVES. 71

Prostaglandin E (PGE), which is known to be released by sympathetic nerve stimulation, lowers the arterial blood pressure and counteracts the increase of blood pressure caused by noradrenaline (NA) (c.f. Bergström, Carlson and Weeks, Pharmacol. Rev. 1968. 20. 1). This indicates that PGE may play a modulatory role on the sympathetic neuro-effector system. The present experiments were performed to study wether PGE may modify the release of NA from sympathetic nerves.

Isolated cat spleens were perfused at a constant rate with salinic medium. Close arterial infusion of PGE_1, 10^{-6} - 4 10^{-6} M, was found occasionally to reduce the outflow of NA in response to stimulation of the splenic nerves. When PGE_2, within the same concentration range, was infused instead, the NA overflow response consistently fell, often to less than 50 per cent of that of the preceding control stimulation. Addition to the perfusion medium of phenoxybenzamine (PBA), which has been shown to inhibit the release of PGE, resulted in a several-fold increase of the NA overflow response to nerve stimulation. Simultaneous infusion of PGE_2 strongly counteracted this effect of PBA, leading to NA output figures close to those from the preceding control stimulation.

It is suggested that PGE, locally mobilized by sympathetic nerve stimulation, may counteract further release of NA from the nerves by a negative feed back mechanism.

2 Sjöstrand, N.O. and G.Swedin. (Dept. of Physiology, Karolinska Institutet, Stockholm, Sweden): POTENTIATION BY SMOOTH MUSCLE STIMULANTS OF AN HYPOGASTRIC-NERVE-SEMINAL VESICLE PREPARATION FROM THE GUINEA-PIG.

Potentiation by smooth muscle stimulants of the hypogastric nerve-vas deferans preparation has previously been described (Sjöstrand, N.O., Nature 1961. 192.1190; c.f. Sjöstrand, N.O. and G. Swedin, Acta physiol scand. 1968. 74. 472).

The contractions of the seminal vesicle were recorded with a balloon inserted in the lumen of the seminal vesicle.

Adrenaline, noradrenaline, acetylcholine, histamine, serotonine, bradykinin, prostaglandin E_1 and bariumchloride were found to potentiate the responses of the seminal vesicle to hypogastric nerve stimulation. This potentiation occurred with doses much smaller than those giving a direct contraction of the organ.

It is suggested that in vivo such a potentiation can occur and be of importance for the emission.

73 Lundborg, P.G. (Department of Pharmacology, University of Göteborg, Sweden): EFFECT OF (+)-AMPHETAMINE ON THE SUBCELLULAR DISTRIBUTION OF α-METHYLATED AMINES.

In in vivo experiments on mouse hearts the releasing effect of (+)amphetamine on previously administered racemic ^{3}H-metaraminol or ^{3}H-α-methyl-noradrenaline was studied. Also the effect of previously administered (+)amphetamine on the uptake and subcellular distribution of ^{3}H-metaraminol and ^{3}H-α-methyl-noradrenaline was investigated.

The dose used of (+)amphetamine was of importance for the subcellular site of attack of the drug.

30 min after the administration of ^{3}H-metaraminol 5 mg/kg of (+)amphetamine caused a release of the labelled amine predominantly from the particulate (granular) fraction, 0.2 mg/kg of (+)amphetamine, however, caused a release exclusively from the supernatant fraction.

24 hrs after the administration of ^{3}H-metaraminol (+)amphetamine caused a release of ^{3}H-metaraminol only from the supernatant fraction.

If the animals were pretreated with reserpine before administration of ^{3}H-metaraminol (+)amphetamine caused a pronounced release of the amine from all fractions.

The affinity of ^{3}H-α-methyl-noradrenaline for granular binding sites is higher than that of ^{3}H-metaraminol. Thus the extragranular pool of ^{3}H-α-methyl-noradrenaline is small. Therefore it was hard to demonstrate a release of this amine from the supernatant fraction. After reserpine treatment, however, (+)amphetamine caused considerable release of ^{3}H-α-methyl-noradrenaline and this release was more pronounced from the supernatant than from the particulate fraction.

Peterson, C. and Diamant, B. Dept. of Pharmacology, Karolinska institutet, Stockholm 60, Sweden): THE EFFECT OF SOME HEXOSES AND PENTOSES ON HISTAMINE RELEASE FROM ISOLATED RAT MAST CELLS INDUCED BY ATP. 74

Histamine release from isolated rat mast cells is induced by ATP in the presence of Ca^{++} (Diamant, B. and Krüger, P-G., Acta physiol. scand. 1967. 71. 291). Peritoneal rat mast cells were isolated in the absence of glucose. Incubation of the cells with ATP (4.5×10^{-5}M) at 37° for 15 min released about 20 % of their histamine content. Preincubation with glucose and mannose (5.6×10^{-4}M) at 37°for 10 min increased the histamine liberation to about 50 % while the sugars alone had no releasing activity. Other hexoses investigated, such as fructose, galactose, L(-) glucose and the pentoses ribose and 2-deoxyribose had no enhancing effect on the histamine release. Incubations of mast cells with glucose and mannose at 37° for 15 min induced a significantly higher production of lactate as compared to controls or incubations with the other sugars.

It is concluded that glucose and mannose potentiate histamine release by ATP and that these sugars give rise to the production of lactate in the mast cells.

Dahlquist, R. and Diamant, B. (Dept. of Pharmacology, Karolinska institutet, Stockholm 60, Sweden): INFLUENCE OF ATP UPON SODIUM FLUXES ACROSS THE MAST CELL MEMBRANE. 75

Searching for a mechanism by which ATP induces histamine release from isolated rat mast cells, $^{22}NaCl$ was used to investigate whether ATP would induce sodium uptake into the cells from the medium. Histamine might then be released by intracellular ion exchange.

The presence of ATP (0.5mM) in the incubation medium increased sodium uptake 2.5 times, compared to controls without ATP. This effect was independent of the presence of Ca^{++} (1mM). In the presence of 1 mM of Mg^{++} the stimulatory effect of ATP on sodium uptake was 7 times that in controls without ATP. In contrast, ATP-induced histamine release does not occur in the absence of Ca^{++}, and Mg^{++} exerts an inhibitory effect (Diamant and Krüger, Acta physiol. scand. 1967. 71. 291). ITP, CTP, GTP, TTP and UTP could not be substituted for ATP.

The mast cells accumulated sodium during the first 20 min of incubation. Calculations indicate that within this time ATP had disappeared due to hydrolysis by an ATP-splitting enzyme in the cell membrane. The ATP-Mg-stimulated sodium uptake was completely inhibited by oligomycin (10^{-8}M), while ouabain (1mM) was without inhibitory effects. On prolonged incubation, the sodium content of the cells decreased. This decrease was counteracted by ouabain (1mM) and glucose (5.6mM) when added to cells which had accumulated sodium for 20 min.

It is concluded that the mechanism by which ATP induces histamine release from rat mast cells is not through an exchange of sodium taken up from the extracellular medium for intracellular histamine.

76 Fredholm, B.[1] and Hägermark, Ö. (Departments of Pharmacology and Dermatology, Karolinska Institutet, Stockholm, Sweden): STUDIES ON HEAT-INDUCED HISTAMINE RELEASE FROM SKIN AND FROM PERITONEAL MAST CELLS OF THE RAT.

Thermal injury evokes an inflammatory reaction in the exposed tissue. There are several indications that mast cells and substances released from these cells are involved in the reaction. In the present work the degranulating and histamine releasing effects of moderate heat were studied on rat skin and peritoneal mast cells.

The cutaneous mast cells were degranulated in vivo by immersing the animals in water at 60-80°C for 20 sec. In vitro, histamine was released from minced skin and from peritoneal mast cells exposed to temperatures above 52°C. The rate of release was markedly increased by raising the temperature from 56°C to 60°C. The metabolic inhibitors 2,4-dinitrophenol and potassium cyanide did not inhibit the release process. The kinetics of the heat-induced release differed from that caused by compound 48/80. It is concluded that the histamine release induced by heat does not involve the energy-requiring mechanisms concerned in the release caused by e.g. antigen and compound 48/80.

1) Present address: Department of Pharmacology, Research Laboratories, AB Leo, Hälsingborg, Sweden.

77 Strandberg, K. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): PURIFICATION AND PROPERTIES OF A LIPID-SOLUBLE SMOOTH-MUSCLE STIMULATING PRINCIPLE, SRS, APPEARING ON HISTAMINE RELEASE IN CAT PAWS.

Lipid-soluble smooth-muscle stimulating material appears in the effluents from cat paws perfused with the histamine releasing agent compound 48/80 (Chakravarty et al. Acta.physiol. scand. 1959. 45. 255). This material has been designated "slow reacting substance", SRS, since it elicits slow, sustained, non-tachyphylactic contractions of the isolated guinea-pig ileum. It has been shown, however, that this SRS actually consists of several principles with different biological and chemical properties (Änggård et al. Acta physiol. scand. 1963. 59. 97).

In the present investigation cat paws were perfused for 90 min with a modified Tyrode solution (pH 7) containing compound 48/80 (1 µg/ml) at 28-32°C. The lyophilized effluents were extracted with 80 per cent aqueous ethanol and the principle producing the slow contraction of the guinea-pig ileum was purified by solvent partition (water/ether), silicic acid and anion exchange chromatography. The overall recovery was 10-20 per cent, calculated from the non-histamine smooth-muscle activity of the ethanolic extract. The purified material was dialysable, soluble in polar solvents, acid-labile, heat-stable and it behaved homogenously on thin layer chromatography in different systems. Studies of the influence of chemicals reactive with certain functional groups on the biological activity of the material indicated that the principle was probably an unsaturated hydroxy-carboxylic acid.

Bergendorff, A. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): UPTAKE OF HISTAMINE AND OTHER BIOGENIC AMINES BY MAST CELL GRANULES AND "ARTIFICIAL GRANULES". 78

Histamine and serotonin are localized to the granule fraction of rat mast cells. The granules consist of a heparin-protein complex.

Histamine containing granules have been isolated from rat mast cells lysed in deionized water. The endogenous histamine is removed by suspending the granules in sodium chloride solution, which results in an exchange of histamine for sodium. By repeated suspension in deionized water the granules are then depleted of sodium.

The uptake and storage of histamine in granules prepared as described above have been shown to be dependent on pH and histamine concentration indicating a linkage of the amine to weakly acid groups in the granule heparin protein complex. The storage of histamine is also influenced by the presence of other cations. The granules can take up and store other biogenic amines than histamine.

"Artificial granules" have been prepared by reacting sodium heparinate with a basic protein having a molecular weight about the same as the granular protein. The cation (various amines and sodium) uptake and storage properties of "artificial granules" are similar to those of granules isolated from mast cells.

Frisk-Holmberg,M. (Department of Pharmacology, Karolinska Institutet Stockholm, Sweden): STUDIES IN THE MECHANISM OF CHLORPROMAZINE INDUCED HISTAMINE RELEASE FROM ISOLATED RAT PERITONEAL MAST CELLS. 79

Mast cells incubated with chlorpromazine in concentrations 3.10^{-5} M to 6.10^{-2} M release 10-70% of their histamine. The release is not accompanied by degranulation.The release is completed within 5 to 10 min., is dependent on ph and increases with decreasing ionization (increased ph) and is considerably reduced at 0°C. After washing, the mast cells respond on a second exposure to chlorpromazine. Metabolic inhibitors slightly stimulate, tetrodotoxin 10 µg/ml reduces release.Chlorpromazine 3.10^{-5}M to 6.10^{-2}M (CPZ-S^{35}) probably enters the mast cells. The cellular content of ^{22}Na is slightly increased after exposure to chlorpromazine of cells, suspended in ^{22}Na containing medium.

It is concluded that the release of histamine occurs intracellullary but that the concentration of chlorpromazine in the cells is too low to explain the release of histamine as due to an ionic exchange between chlorpromazine and histamine in the granules.

80 Lindström, L. (Department of Pharmacology, University of Uppsala, Sweden): INTERACTION BETWEEN CHOLINERGIC AND MONOAMINERGIC MECHANISMS WITH REGARD TO OESTROUS BEHAVIOUR IN FEMALE RATS.

It has previously been demonstrated that psychopharmacological agents that increase the central monoamine level and muscarinic alkaloids inhibit the hormone activated oestrous behaviour in the female rat (Meyerson, B.J., Acta Physiol. Scand. 1964. 63. suppl. 241; Lindström L. and Meyerson B.J., Psychopharmacologia 1967.11.405). The present experiments were performed to study a possible relationship between heat inhibitory monoaminergic and cholinergic mechanisms.

Increased monoaminergic tone in the central nervous system brought about by pargyline (25 mg/kg) or desmethylimipramine (2 mg/kg) prolonged the inhibitory effect of pilocarpine (25 mg/kg), whereas amine depletion by reserpine (1 mg/kg) counteracted the inhibitory effect of pilocarpine (25 mg/kg) and oxotremorine (1 mg/kg). Pilocarpine also lacked an effect after p-chlorophenylalanine (400 mg/kg), a serotonine synthesis inhibitor.

A relationship between cholinergic and monoaminergic central nervous mechanisms inhibiting the oestrous behaviour in the female rat is suggested. It is assumed that the inhibitory effect of pilocarpine is dependent on the monoamine level. The effect of p-chlorophenylalanine indicate that serotonine is important.

81 Meyerson, B.J. and E-B.Nordström (Department of Pharmacology, University of Uppsala, Sweden): SEXUAL MOTIVATION IN THE FEMALE RAT: (I) THE EFFECT OF OESTROGEN AND TESTOSTERONE MEASURED BY AN INCREASING BARRIER METHOD.

Different techniques are employed in this laboratory to study the role of gonadal hormones in the production of sexual motivation. One method is designed to measure the willingness of an animal to pay a painful stimulus to reach a sexually active partner. The subject (S) has to pass from one cage via an electric grid to a second cage which holds the incentive animal. The intensity of the current is stepwise increased every second time S passes. By an electromechanical devise we record the time spent before S passes the grid and the amount of barrier shock (i.e. the number of crossings over the grid) the animal is willing to bear.

S were adult sexually experienced ovariectomized Sprague-Dawley rats. The sexual contact was restricted i.e. contact with stimulus animal (vigorous male) was allowed but the animals separated by a net. The experimentswere performed one run a day for 12 consecutive days, starting one day (day 0) before the hormone treatment. The number of passages over the grid S was willing to perform was significantly increased by oestradiol benzoate 25 and 100 µg/kg s.c. and testosterone proprionate 0.5 and 1.0 mg/kg s.c. at the lower dose levels the maximal response was obtained at day 4. After the higher doses the maximal effect was seen one or two days later.

It is concluded that both oestradiol and testosterone induce in the ovariectomized rat a desire to seek contact with a sexually active male.

Lindström, L. and Meyerson, B. (Department of Pharmacology, University of Uppsala, Sweden): SEXUAL MOTIVATION IN THE FEMALE RAT: (II) THE EFFECT OF OESTROGEN MEASURED BY A T- MAZE CHOICE METHOD. 82

A T-maze choice method has been developed to study sexual motivation in the rat. The subject runs through a runway which brings it to a chamber, the end of which has two exits. One exit leads into a cage with an incentive animal, the other exit to an indifferent animal. We record automatically the running time, the time the animal spends to make up its choice and the specific choise. In the present experiments the contact with the stimuli animals was restricted, i.e. contact was allowed but the animals separated by a net.

Ovariectomized Sprague-Dawley rats were tested during a 12 day period with start on day 0. Oestradiol benzoate 25 or 100 µg/kg s.c. was given at day 1. A sexually active male and a castrated male respectively was used as stimuli animals. Oestrogen treated subjects displayed a clearcut preference to choose the sexually active male. This was not seen in oil treated controls. The maximal response was obtained at day 4-5. A slightly longer latency was seen when the higher dose level of the hormone was used. The time relationship between injection of the oestrogen and the maximal response is in agreement with the data obtained by the increasing barrier method employed in this laboratory.

It seems as if oestrogen induces a goal directed urge to seek contact with a sexually active male.

Kjellberg, B. and Randrup, A. (AB Ferrosan, Malmö, Sweden and St.Hans Hospital, Roskilde, Denmark): VARIOUS FORMS OF STEREOTYPED, ABNORMAL BEHAVIOUR INDUCED BY AMPHETAMINE IN NON-HUMAN PRIMATES. 83

There are to our knowledge relatively few reports dealing with the effects of amphetamine upon the behaviour of non-human primates. We have studied the behavioural effects of one single dose of d-amphetaminesulphate (4 mg/kg s.c.) upon 4 primate monkeys (Cercopithecus aethiops).

As in rats we found selective stimulation of certain behavioural elements and suppression of others resulting in a behaviour with strongly stereotyped character. One monkey raised its right forepaw and looked at it continously for several hours. Another monkey made continous locomotion repeating a certain route covering only a part of the cage and two were sitting at the front wall of the cage seizing continously the bars of the wall while repeating certain movements of the limbs and the head. For periods, movements of the mouth and the tongue were also seen. Grooming was absent in all the monkeys during the period of stereotyped behaviour and then gradually returned. In contrast to rats, however, the behaviour was also abnormal the next day 24-32 hours after amphetamine. The monkey looking at its hand did this much more than normally but not continously, grooming and other normal activities were interspersed. Another monkey performed on the second day new forms of abnormal behaviour, which were not seen during the first day.

It is concluded that when compared to e.g. rats, the behaviour displayed by these primate monkeys after one single dose of amphetamine is highly individual though rather constant for each individual.

84 Jonas, W. (Sct. Hans Hospital, dept. E, Roskilde, Denmark): TETRABENAZINE INDUCED CATACHOLAMINE RELEASE AS IT AFFECTS THE EXCITATORY BEHAVIOUR AF RATS, PRETEATED WITH AMPHETAMINE. The amphetamine (AMPH) excitatory response including stereotyped behaviour seems to depend on the interaction with dopamine. (Randrup, A. and Jonas, W., J. Pham. Pharmac., 19, 483, (1969) and Jonas, W. and Scheel-Krüger, J., Arch. Int. Pharmacodyn. (1969) *in press*). In this paper the mechanism underlying the reappearence of the AMPH excitation induced by tetrabenazine (TBZ) was investigated in rats. All rats recieved AMPH (5 mg/kg). 4 hours later when the excitation had attenuated the rats recieved scopolamine (SCP) (10 mg/kg), aceperone(ACP) (10 mg/kg), spiramide (SPI) (2 mg/kg) or saline. 30 min. later the excitation was reinduced by TBZ (50 mg/kg). A quantitative evaluation of the behaviour features: locomotion, sniffing, gnawing, rearing, eating and drinking was preformed.

SCP significantly prolonged the TBZ reversal effect, ACP, a potent noradrenaline blocking agent, did not have any effect on the reversal, while SPI, a potent and specific dopamine blocking agent, completely antagonized the TBZ reversal.

It is concluded that this AMPH-TBZ excitatory effect depends not on the noradrenaline but on the dopamine release.

85 Scheel-Krüger, J. (Sct. Hans Hospital, Dept. E., Roskilde, Denmark): PHARMACOLOGICAL STUDIES ON A COUNTERBALANCING ADRENERGIC-CHOLINERGIC SYSTEM IN THE BRAIN.

Previous papers have described the behavioural excitation with increased locomotion and stereotyped behaviour induced by amphetamine or apomorphine in rats and mice. Particularly, the stereotyped behaviour seems produced by activating a dopaminergic mechanism in corpus striatum.

The results of this paper show that a cholinergic system exists, which shows antagonism against this adrenergically provoked behaviour, since the stereotypy is potentiated and prolonged by anticholinergica (atropine, scopolamine) and weakly antagonized by cholinergica(physostigmine,oxotremorine) Among the characteristic actions for neuroleptica are the antagonism of amphetamine or apomorphine induced stereotyped behaviour and development of catalepsy, which actions are probably produced by blockade of adrenergic (dopaminergic?) mechanisms in brain. Results of combined drug treatments of neuroleptica and anticholinergica or cholinergica show that the inhibitory activity of a cholinergic system also contributes to the development of these characteristic actions of neuroleptica.

It is concluded that a counterbalancing adrenergic-cholinergic system exists in brain, which involves behavioral features as locomotor activity and stereotyped behavior.

Ahtee, L. & Shillito, E. (A.R.C. Institute of Animal Physiology, Babraham, Cambridge, England): THE BEHAVIOURAL EFFECTS OF BENZODIAZEPINES AND ATROPINE. **86**

The atropine-like drugs are often combined with benzodiazepines in the treatment of gastric ulcer and related disorders. It is possible that the combination of these drugs may produce interesting effects on behaviour and we have investigated this in mice.

Male albino mice were observed in reversed daylight on a tunnel board to test exploration (Shillito, E.,J. Physiol.(Lond.) 1968, 200, 35P) for 5 min ½ hr after i.p. injection of drugs or saline. Following this their motor activity was assessed in an open cage for 3 min. This procedure was repeated on the following day without any injections. The drugs used were atropine 5 or 10 mg/kg, methylatropine 5 or 10 mg/kg, chlordiazepoxide 25 or 50 mg/kg and diazepam 10 or 20 mg/kg.

Atropine or methylatropine did not alter the motor activity of mice, while chlordiazepoxide and diazepam increased the activity especially in the lower doses used. All the compounds used except methylatropine adversely affected the exploratory behaviour. When 10 mg/kg of atropine was given with the benzodiazepines activity of the mice was reduced below normal and exploratory behaviour was further impeded, but this did not occur when methylatropine was used with the benzodiazepines.

The benzodiazepines and atropine may impair exploration by affecting kinaesthesis. It seems that it is a central effect of atropine which modifies the behavioural effects of the benzodiazepines, since methylatropine does not have this effect, although some peripheral anticholinergic effects might be antagonized by these drugs (Ahtee, L. & Pohto, P., Scand.J.clin.Lab.Invest. 1968, 21 Suppl.101, 86).

Lycke, E., Modigh, K. and Roos, B.-E. (Departments of Virology and Pharmacology, University of Göteborg, Sweden): SOME ASPECTS OF MONOAMINE METABOLISM IN MOUSE BRAIN AND AGGRESSIVENESS. **87**

Herpes simplex virus (HSV) encephalitis in mice produces an increased synthesis rate of the monoamines dopamine (DA) and 5-hydroxytryptamine (5-HT) in brain tissue (Lycke, E. and Roos, B.-E., Experientia 1968. 24, 687). In the present investigation HSV inoculated mice were treated with an effective inhibitor of 5-HT synthesis, H 69/17 (the methyl ester hydrochloride of d,l,-p-chlorphenylalanine) in a daily dose of 400 mg/kg i.p. After 4 days the animals showed a marked excitation and an aggressive behavior. In control mice (only inoculated with HSV) a marked excitation but no aggressiveness was observed. If normal mice were treated with H 69/17 followed by L-DOPA (500 mg/kg i.p.) at different time intervals, they developed an immensely aggressive behavior when L-DOPA was given 7 hours or later after the administration of the inhibitor. The same aggressiveness was observed after another effective inhibitor of 5-HT synthesis (H 22/54, α-propyldopacetamide) followed after 1 hour by L-DOPA in a dose of 200 mg/kg or more.

The present study indicates a correlation between the observed aggressive behavior and a low degree of 5-HT receptor stimulation in combination with a high degree of DA receptor stimulation.

88 Malmnäs, C-O. and Meyerson, B.J. (Department of Pharmacology, University of Uppsala, Sweden): THE EFFECT OF ACTH ON COPULATORY BEHAVIOUR IN THE MALE RAT.

The present experiments were conducted to study the effect of adrenocortical stimulation on copulatory behaviour in male rats. The mating behaviour of adult Sprague-Dawley rats, given copulatory experience before castration, was restored by injection of testosterone proprionat once weekly (0,3; 0,5 or 0,7 mg/kg s.c.). The testosterone treatment was chosen to permit a stimulatory or inhibitory effect of further treatments to be discovered. To achiev a sustained adrenocortical stimulatory effect an ACTH zinc chlorid preparation was used (Cortophin prolongat, Pharmacia, Uppsala). ACTH 10 I.E. i.m. was given either (A) at the same time as the testosterone treatment or (B) 6 hours before the tests for mating behaviour. Tests for copulatory behaviour were performed either 3, 5 or 9 days after the testosterone treatment.

No increase of the sexual activity was found in the ACTH treated animals. However, at day 3 (experiment A) the number of animals which ejaculated was decreased and the time from onset of the test to first intromission was increased.

At the concentration and for the length of treatment here employed ACTH could not augment any of the indices of sexual activity tested for. It is concluded, however, that some components of the copulatory behaviour was inhibited either by a direct effect of ACTH or presumably through the liberation of adrenocortical steroids.

89 Rasmussen, Folke (Department of Pharmacology and Toxicology, The Royal Veterinary and Agricultural University, Copenhagen, Denmark): ACTIVE MAMMARY EXCRETION OF N^4-ACETYLATED p-AMINOHIPPURIC ACID.

Different excretion patterns were observed for p-aminohippuric acid and its acetylated metabolite in mammary excretion experiments in goats and cows. The excretion of p-aminohippuric acid conformed to passive diffusion of the non-protein bound and un-ionized fraction. Thus, the p-aminohippuric acid (pK_a 3.8) appeared in ultrafiltrates of milk in concentrations 1/4-1/10 of the concentrations in ultrafiltrates of blood plasma. The concentrations of acetylated p-aminohippuric acid (pK_a 3.9) in ultrafiltrates of milk were on the other hand equal to or higher than in ultrafiltrates of blood plasma.

Further experiments were conducted by intravenous infusion of acetylated p-aminohippuric acid. After acid hydrolysis the concentrations of acetylated p-aminohippuric acid in milk and blood plasma were estimated according to the method described by Bratton & Marshall, J.biol. Chem. 1939, 128, 537. It was found that the concentrations of acetylated p-aminohippuric acid in milk and in ultrafiltrates of milk are equal to or higher than in plasma (ratio M/P) and ultrafiltrates of plasma (ratio M.Ultr./P.Ultr), respectively. It was also found that the milk-to-plasma ratios decrease with increasing concentrations of acetylated p-aminohippuric acid in blood plasma.

It is concluded that an active saturable excretory process is involved in the mammary excretion of acetylated p-aminohippuric acid.

90 Holm, J. & Broen Christensen, C. (Department of Pharmacology, University of Copenhagen, Denmark): DECAMETHONIUH UPTAKE BY SLICES OF MOUSE KIDNEY AND THE INHIBITORY EFFECT OF D-TUBOCURARINE.

Decamethonium is concentrated in the liver and kidneys of mice in vivo (Broen Christensen, C. & Holm, J., Acta Pharmacol. et toxicol. 1969, 27, 17). Slices of mouse liver accumulate decamethonium and the uptake is inhibited by d-tubocurarine (Broen Christensen, C., Acta Pharmacol. et Toxicol. 1967, 25, suppl. 4, 46). The present study was made to investigate the uptake of decamethonium by mouse kidney slices with particular regard to d-tubocurarine inhibition. - Kidney slices were incubated in a medium containing ^{14}C-decamethonium (2×10^{-6} M) and the slice-to-medium concentration ratio (S/M ratio) was measured. - In oxygen atmosphere the S/M ratio, which approximated 9 after 1 hr., continued to increase within 3 hrs. incubation. The S/M ratio decreased when raising the decamethonium concentration. In nitrogen atmosphere the S/M ratio reached a constant value of about 1 within 1/2 hr. When the decamethonium concentration was 2×10^{-6} M, d-tubocurarine (2×10^{-6} M) reduced the S/M ratio by 9%, ten- and hundredfold higher concentrations of d-tubocurarine reduced the S/M ratio by 50 and 80% respectively. - Mouse kidney slices accumulate decamethonium against an apparent concentration gradient and the process, partly depending upon oxygen, shows saturation. The uptake consists of a d-tubocurarine-sensitive part and a part much less sensitive to the inhibitor.

91 Pelkonen,O., Vorne,M., Kärki,N.T. (Department of Pharmacology, University of Oulu, Finland): DRUG-METABOLIZING ACTIVITY IN THE LIVER, INTESTINE AND KIDNEY OF HUMAN FOETUS.

In general foetal and newborn animals show a low level of activity to metabolize drugs. In this study we have determined the capability of human foetal tissues to oxidise (pethidine, hexobarbitone, chlorpromazine), reduce (p-nitrobenzoic acid) and conjugate (p-nitrophenol) drugs.

The age of the foetuses varied from 8 to 22 weeks and the weight ranged from 19 to 280 gr. After homogenisation the tissue preparations were centrifuged at 12000 g and the supernatant was used for enzymatic studies.

No conjugative or pethidine metabolizing activity was present in studied tissues. Low level of hexobarbital metabolizing activity was found in some trials. We were not able with the method used to find cytochrome P-450 in any tissue. Weak but significant enzymatic degradation of chlorpromazine and p-nitrobenzoic acid was found in foetal tissues. The mean metabolic activity for chlorpromazine was in liver 0.09, in kidney 0.04 and in intestine 0.03 µM/g tissue/hr. The Michaelis constant for liver preparation was $6.25\cdot10^{-5}$M. The rate of metabolism for p-nitrobenzoic acid was in liver 0.07 in intestine 0.03 and in kidney 0 µM/g tissue/hr. The drug metabolizing activity of the liver preparation was more stable than that of kidney or intestine.

92 Harri, M.-P. and Nienstedt, W. (Department of Physiology, University of Turku,Finland): THE METABOLISM OF TESTOSTERONE IN THE CANINE INTESTINAL MUCOSA *IN VITRO*.

The metabolism of steroids during absorption from the ileum of dogs has been studied earlier *in vivo* (Nienstedt,W. and Hartiala,K. Acta physiol.scand.1966.Suppl.277.68). The results have shown that the metabolism is chiefly reductive and hydroxylative. In order to investigate the *in vitro* metabolism of the same steroids three different fractions from the mucosal cells of ileum were prepared: homogenate, microsomes and high speed supernatant, each representing 1 g of fresh tissue. After incubating with 4-^{14}C-testosterone and a $NADPH_2$-regenerating system the resulting metabolites were analyzed with different chromatographic systems. The metabolism of testosterone varied greatly in different fractions. The homogenate yielded 5α-androstan-3-ol-17-ones, the microsomes 5α-androstan-17β-ol-3-one, and both yielded diols, mostly 5α-androstan-3β,17β-diol. The supernatant yielded 5β-androstan-3β,17β-diol, possibly *via* androst-4-en-3β,17β-diol. The supernatant metabolites could not be detected among the homogenate metabolites. The findings indicate that the testosterone metabolizing enzyme systems may be located in different parts of the cell. The tentative results obtained with progesterone have revealed similar patterns.

93 Karlog, O. (Department of Pharmacology and Toxicology, The Royal Veterinary and Agricultural University, Copenhagen, Denmark): RATE OF FORMATION OF UNREACTIVATABLE CHOLINESTERASES IN BLOOD OF PIGS INTOXICATED BY DIMETHYL- AND DIETHYLTHIOPHOSPHATES.

Pigs protected by atropine were given intramuscular injections of parathion, methylparathion, malathion or dimethoate resp.. In blood samples the activities of cholinesterases of plasma and erythrocytes were measured before and after reactivation with pralidoxime.

After inhibition with the diethylcompound (parathion) 50% reactivation of the erythrocytcholinesterase was still possible after 40 hours, and for plasma cholinesterase after 16 hours. For methylparathion and the two other dimethylcompounds the corresponding figures were 6 hours and about one hour.

The faster transformation of the dimethyl phosphorylated cholinesterases to the unreactivatable form means that oxime therapy might not be as successful as in intoxications with diethylcompounds.

Wahlström, G. (Department of Pharmacology; University of Uppsala, Sweden): THE EFFECTS OF REPEATED LONG-TERM TREATMENTS WITH BARBITAL OR ALCOHOL ON A HEXOBARBITAL ANAESTHESIA THRESHOLD IN MALE RATS. 94

To determine the threshold dose hexobarbital was infused in a tail vein with a constant rate (0.25 mg/kg/sec) and as threshold was taken the dose needed to obtain a burst suppression of 1 sec or more in the EEG. After treatment with barbital (200 mg/kg/sec) for 6 weeks there is an increase in the threshold dose which has disappeared within a week (Wahlström, G., Acta Pharmacol. Toxicol. 1968, 26, 64).

In the present experiments a first barbital treatment for 6 weeks was followed by a second similar treatment 3 months later. The treshold dose was recorded at weekly intervals after the treatments. In one experiment the second barbital treatment was substituted by alcohol (10 % w/v) administration in the drinking water for 16 weeks. The rats had access to alcohol only for two one-hour periods each day during the activity.

Compared with the first treatment there was still an increase in the hexobarbital thresholds one week after the end of the second treatment. A new increase was seen three weeks after the second treatment. After the first treatment there was only a trace of a similar increase. If alcohol was substituted for barbital an increase three weeks after the end of the alcohol treatment was also seen. The first barbital treatment thus seems to induce a change which makes the increase in threshold dose after the second treatment more marked. An abstinence period of three months has not restituted this change.

This study has been supported by the Tri-Centennial Fund of the Bank of Sweden.

Åberg, G. and B. Wahlström (Department of Zoophysiology, University of Göteborg, Sweden): VASCULAR EFFECTS OF MEPIVACAINE. 95

Isolated vena porta preparations from rats were contracted when mepivacaine (Carbocaine®) was added to the bath fluid. The frequency of action potentials was increased, but there was no depolarization of the membranes. The spasmogenic effect of mepivacaine was not blocked by α-adrenergic blocking drugs. Tetracaine relaxed vena porta preparations and could even relax vessels that were contracted with mepivacaine The vasoconstrictor potency of L(+)-mepivacaine was much stronger than that of D(-)-mepivacaine.

The vascular effects were also studied in vivo using an electromagnetic flow meter and a thermographic method (IR-camera). The vascular tone in the anaesthetized area might be explained as the result of a balance where the dilating effect of a vasomotor nerve block and the constricting action of the local anaesthetic compound are important.

The vascular effects of local anaesthetics are of great importance for the duration of local anaesthesia. Thus there were statistically significant differences between the duration of the local anaesthetic effects of the optial isomers of mepivacaine in vivo although there were no differences between the nerve blocking effects of these compounds in vitro.

96 Elwin, C-E.(Department of Pharmacology,Karolinska institutet,Sweden): ISOLATION OF GASTRIC SECRETORY STIMULANTS IN PEPTONE FRACTIONATED ACCORDING TO MOLECULAR SIZE.

Bathing the pyloric mucosa with protein hydrolysates causes acid secretion from the parietal cells, probably by release of the antral hormone. This was believed to be due to the large molecules of the hydrolysates (Woodward et al., Gastroenterology 1954. 27. 766). However, no evidence of the specific nature of such molecules has been presented. On the other hand, amino acids and peptides may release the antral hormone (Elwin, C-E. & B. Uvnäs, Gastrin, UCLA Forum Med. Sci.1966.No.5.69)

Peptone (Bacto-peptone, Difco) was separated into two fractions by ultrafiltration through a membrane with the cutoff at 1000 mol.w.(Diaflo, UM-2). Tests of stimulatory power on gastric acid secretion were performed by perfusion of the isolated, innervated antral pouch of Pavlov-pouch dogs. Dose-response curves were done at pH 7 with 4, 8 and 16 % solutions of peptone and corresponding proportions of the fractions with molecules larger or less than 1000 mol.w. Antrum perfusion with solutions of the small molecular fraction in amounts corresponding to 4 and 8 % peptone caused an acid secretory response from the fundic pouch equal to 90-100 % of that of peptone alone, whereas solutions of the larger molecules at these concentrations showed almost no effect. Solutions of the large molecular fraction equal to 16 % peptone showed a clear but much less pronounced effect.

Results indicate that molecules of small size in small amounts of proteins are potent gastric secretory stimulants. The small molecular fraction will be further separated.

97 Svensson, S.-O. and Emås, S. (University Clinic of Surgery, Allmänna Sjukhuset, Malmö, Sweden): EFFECT OF SECRETIN ON HISTAMINE AND PENTAGASTRIN STIMULATED ACID SECRETION IN CONSCIOUS CATS.

Intravenous injection of secretin or acidification of the duodenum inhibits gastrin but does not alter histamine stimulated acid secretion in dogs. It has been suggested that the inhibition of acid secretion by duodenal acidification is mediated by released secretin in dogs. The effect of secretin on histamine and pentagastrin stimulated acid secretion has not been studied in conscious cats. Such studies were therefore carried out.

Cats provided with gastric fistulas of the vagally innervated stomach were continuously infused intravenously with histamine or pentagastrin for 7 hours in doses that produced 50 to 75 per cent of the maximal acid response. After 2 hours' infusion 5 or 20 units of natural secretin per kg body weight was given as a rapid intravenous injection; in control experiments secretin was exchanged for saline. Five and 20 units of secretin per kg did not significantly alter histamine but reduced pentagastrin stimulated acid secretion by 30 and 40 per cent, respectively, in the first post-injection 15-minute period. Secretion remained significantly depressed only for an additional 15-minute period. Regurgitation of duodenal contents might have contributed to but does not explain the entire reduction of acid secretion. It is concluded that secretin is a less potent inhibitor of acid secretion in cats than in dogs. While in progress similar results were reported on gastrin stimulated acid secretion in conscious cats with vagally denervated fundic pouches (Stening et al., Personal communication).

This study was supported by Swedish Medical Research Council (Grant no. B68-17X-2324-01).

Jørgen Gliemann and Henrik Sørensen. (Institute of Medical Physiology C, University of Copenhagen, Denmark): 98 THE BIOLOGICAL ACTIVITY OF PROINSULIN.

Shaw and Chance (Diabetes 17, 737, 1968) showed that pancreatic trypsin inhibitor depressed the biological activity of proinsulin on rat epididymal fat tissue. It was suggested that proinsulin exerts its biological effect because it is converted to an active molecule by proteolytic enzymes present in adipose tissue.

We have investigated the biological activity on isolated rat fat cells of beef proinsulin, prepared and purified by Steiner et al. (Diabetes 17, 725, 1968). The findings were: 1: The dose-response relationships for proinsulin and insulin were parallel. 2: The time course of the action of proinsulin and insulin were identical. 3: The biological activity of proinsulin was about 1 per cent of that of insulin. 4: The activity of proinsulin on fat tissue was not significantly different from that on fat cells. 5: Pancreatic trypsin inhibitor failed to exert a specific depression on the activity of proinsulin on either fat cells or fat tissue.

It is concluded that the biological effect of proinsulin is about 1 per cent (or less) of that of insulin, and that there is no evidence for a conversion of proinsulin to a more active molecule by fat tissue in vitro.

Lybeck, H., Leppäluoto, J. and Virkkunen, P. (Institute of Physiology, University of Helsinki, Finland): 99 EXTRATHYROIDAL THYROXINE FORMATION BY RAT TISSUES IN VITRO.

Several approaches have been made to resolve the problem of whether thyroxine is formed outside the thyroid and, although there is an impressive array of indirect evidence to support this idea, the question remains open. The aim of this investigation is to present direct evidence of thyroxine formation by different rat tissues in vitro. In a series of in vitro and vivo experiments with whole rat thyroid lobes, it was shown that when the lobes were preincubated with I-131 or labelled with this isotope during electrophoresis, they released thyroxine on the paper strip after a suitable running time (Lybeck et al. in press). With the same technique a weighed portion of rat thyroid, salivary gland, stomach, liver or abdominal muscle was placed on the paper strip and 15 mm cathodally of them 1 microC of I-131 was pipetted. The tissue was then submitted to electrophoresis for 2 hrs (veronal buffer, 300 V) and thereafter the radioactive proteins, which the tissue had released onto the paper strip were eluted with NH_3 and chromatographed in BAcW and BAmW. Autoradiography of the chromatograms revealed that the thyroid had released I-131 and thyroxine, but that the radioactive proteins from all the different tissue contained some thyroxine although in lesser degree together with origin material and I-131. These results demonstrate that at least when these tissues were offered I-131 they could form radioactive "extrathyroidal" thyroxine.

100 Carstensen,H.,L.Wide,N.Terner and L.Thorén (Department of Physiology,Biological Institute, Umeå University, Umeå; and the Departments of Clinical Chemistry and Surgery, Academic Hospital, University of Uppsala, Uppsala, Sweden): THE INFLUENCE OF SURGICAL STRESS ON PLASMA TESTOSTERONE AND LH IN THE HUMAN MALE.

It was shown previously that gastric resection in human male subjects was followed by decreased levels of testosterone in plasma during the first 3-4 days and by highly increased levels 8-10 days after the operation (Carstensen,H.,N.Terner,L.Thorén and L.Wide, Acta physiol. Scand. 1968.73.24A). These observations were confirmed in new experiments, except that the late increase was not a regular finding. It was speculated whether the early decrease was related to increased cortisol levels, known to occur during the first days after a major operation. This is unlikely since only slight depression of plasma testosterone was observed during voluntary i-m intake of a high dose of cortisone acetate for 3 days in a healthy subject with high normal plasma testosterone values.

After gastrectomy, plasma LH concentrations showed a steady increase to values above normal 8-10 days after the operation, and did not parallel the urinary excretion, which was earlier reported by us to be high during the first days after the operation and low at the time of the late increase in plasma testosterone concentration.

It is concluded that surgical stress activates LH and testosterone secretion considerably slower than it does ACTH and cortisol secretion.

101 Fredholm, B, and Lindskog, M. (Department of Pharmacology, Research Laboratories, AB Leo, Hälsingborg, Sweden): SOME EFFECTS OF A LONG-ACTING ESTRIOL POLYMER, POLYESTRIOL PHOSPHATE.

It has earlier been shown that polymeric phosphates of estradiol and diethylstilbestrol exert prolonged estrogenic activity. This is assumed to be due to the slow release of the monomer in the body (Diczfalusy, E. et al., Acta Chem. Scand. 1958. 12. 1675; ibid 1959. 13. 1011).

During recent years there has been an increasing interest in estriol, since certain evidence suggests that this compound stimulates the cervix, vagina and vulva more efficiently than estradiol or estrone, while the latter are more effective on the corpus uteri (cf Merrill, R., Physiol. Rev. 1958. 38. 463). Recently a polymer of estriol, polyestriol phosphate (SEP) was described (Könyves, I., Tidskr. Kjemi, Bergvesen og Metallurgi 1965. 12. 288).

In the present work the uterine weight and the morphological changes (proliferation) of the vaginal epithelium of mice was followed during 40 days after a single injection of SEP. Other groups of mice received single or repeated injections of estriol. After SEP, 15 mg/kg, the uterine weight increased from 15 to about 100 mg and remained so for 15-20 days. The duration of the cytological changes in the vaginal epithelium was of the same order.

It is concluded that SEP exerts a prolonged estrogenic activity in the mouse.

Ahrén, K. and L. Hamberger (Department of Physiology, University of Göteborg, Sweden): EFFECT OF CYCLIC 3′, 5′-AMP ON OVARIAN AMINO ACID TRANSPORT. **102**

It has recently been found that adenosine 3′, 5′-(cyclic)-monophosphate (cyclic 3′, 5′-AMP) increases the rate of ovarian glycolysis when added to isolated ovaries from prepubertal rats, and it is possible that this nucleotide mediates at least some of the reported effects of gonadotrophins on ovarian carbohydrate metabolism (Ahrén et al., In "The Gonads". Ed. K. McKerns, New York, 1969).

Studies have now been started to analyse whether cyclic 3′, 5′-AMP might be a factor of importance also for the regulation of amino acid transport and protein synthesis in the ovary. Prepubertal rat ovaries were incubated in Krebs bicarbonate buffer containing the non-utilizable amino acid α-aminoisobutyric acid (AIB-^{14}C) or leucine-^{3}H. Distribution ratios between the intracellular compartment and the incubation medium for the two amino acids were determined after 2 hr of incubation. Addition of cyclic 3′, 5′-AMP as a sodium-dibutyryl salt in a concentration of 10 mM increased the distribution ratio for AIB-^{14}C from 13.7 ± 0.8 to 26.3 ± 0.9 and for leucine-^{3}H from 1.52 ± 0.06 to 2.96 ± 0.12, thus indicating a pronounced stimulatory effect of cyclic 3′, 5′-AMP on ovarian amino acid transport. – Studies are now in progress in order to elucidate whether this effect of cyclic 3′, 5′-AMP has a physiological significance particularly in relation to previously reported effects of follicle stimulating hormone (FSH) on ovarian amino acid transport and protein synthesis (e.g. Ahrén et al., Acta physiol. scand. 1967. 71. 211).

Larsen, J. A. (Institute of Physiology, University of Aarhus, Denmark): THE EFFECT OF HYPOTHERMIA ON LIVER FUNCTION. **103**

It was previously observed that slight cooling of cats anesthetized with chloralose caused a reversible decrease in the elimination rate of glycerol of about 40 per cent. The change appeared to be a all or none reaction which, once evoked, was uneffected by a further decrease in temperature.

In the present experiments the elimination rate of glycerol was followed when the body temperature was changed in steps. Each temperature level was kept constant for at least 45 minutes. The temperature was recorded continously by means of a thermistor placed in the right atrium. Furthermore the oxygen uptake was followed.

It was found that the decrease in elimination rate was initiated between temperatures of 36.0 to 37.5 degrees. The oxygen uptake decreased immediatly upon cooling and was reduced by 6-8 per cent for each degree fall in temperature, corresponding to a Q_{10}-value of about 2. The oxygen uptake was often reduced without any change in the elimination rate of glycerol. In accordance with previous experiments there was no change in liver blood flow and plasma free fatty acids.

The results may be explained by assuming that cooling elicits vasoconstriction within the liver accompanied by redistribution of liver blood flow.

104 Karlsson, B.W. & Carlsson, E.I. (Institute of Zoophysiology, University of Lund, Sweden) RELEASE OF LACTIC DEHYDROGENASE (LDH) AND MALIC DEHYDROGENASE (MDH) FROM SLICES OF RAT MAMMARY GLAND, SKELETAL MUSCLE AND LIVER.

The activities of the isoenzymes of LDH (EC 1.1.1.27) in rat mammary gland and mammary gland secretions change in parallel as lactation proceeds, while those of MDH (EC 1.1.1.38) do not (Karlsson B.W. & Carlsson, E.I. Comp. Biochem. Physiol. 1968.25.949) In an attempt to identify factors which may regulate this secretion of enzymes, the release of LDH and MDH from rat mammary gland, skeletal muscle and liver slices has been comparatively studied.

Incubation for 10-180 minutes at 37°C in protein and/or salt solutions revealed successively increasing activities in the media. One factor responsible for this release might be the ratio between intracellular and extracellular concentrations of the enzyme molecules in the original organ, as higher rates of release were noted in slices from organs with higher initial enzyme activities (cf Schmidt, E. et al Enzym. Biol. Chem. 1966. 7. 185) Another factor is the intracellular localization, because enzyme electrophoresis of the incubation media revealed only negligible activities of M-MDH (the MDH form localized in the mitochondria) while activities of S-MDH (the soluble MDH form) and all the five LD isoenzymes were registrable and found to increase during incubation.

Provided that inhibiting or activating processes did not interfere with the enzyme activities, it is concluded that LDH and MDH may be released from mammary gland in vitro in all essentials in the same way as from liver and skeletal muscle. It should be considered whether or not a similar release may occur in vivo.

105 Aitio,A.and Hänninen,O.(Department of Physiology.University of Turku,Finland):STUDIES ON THE FLUX RATE IN THE GLUCURONIC ACID PATHWAY IN NORMAL AND PHENOBARBITAL TREATED RATS.

Phenobarbital administration causes an induction of some enzymes in the glucuronic acid pathway (Hänninen,O.,Ann.Acad. Sci.Fenn.1968.A2. No 142). In order to study the significance in vivo of the enzyme induction, normal and drug treated rats were loaded with pathway metabolites.- D-glucuronic, L-gulonic and D-glucaric acid and their lactones were injected intraperitoneally in different doses before and during the phenobarbital treatment (80mg/kg daily). The urinary excretion of D-glucaric and L-ascorbic acids was determined daily.

The responses in D-glucaric acid excretion were similar in the normal and treated rats with the exception of D-glucuronic acid load: no increase in the normal rats, but a 2-3 - fold increase in the 3 or 4 days treated rats. L-ascorbic acid excretion was insensitive in both states to D-glucaric acid and lactone. With other metabolites a lower response was found in the treated than in the normal rats.

The 2-4-fold increase of liver uronolactonase and glucuronolactonedehydrogenase can explain the D-glucuronic acid stimulated D-glucaric acid excretion in the treated rats. The inability of D-glucaric acid and lactone to reduce urinary L-ascorbic acid excretion speaks against the role of β-glucuronidase in the biosynthesis of L-ascor.ic acid.

Fredholm, B.B. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): INHIBITION OF FATTY ACID RELEASE FROM ADIPOSE TISSUE BY HIGH ARTERIAL LACTATE CONCENTRATIONS. 106

In various conditions following e.g. administration of catecholamines, during exercise and in shock blood lactate levels can increase from a normal of about 1 mM to 10 mM or more.

The possibility that such changes in arterial lactate concentration might interfere with the release of free fatty acids (FFA) and glycerol from adipose tissue (Issekutz, B., Jr. and H.I. Miller, Proc.Soc. exptl. Biol.Med. 1962. 110. 237) was tested in isolated perfused canine subcutaneous adipose tissue (Rosell, S., Acta physiol.scand. 1966. 67. 343). When the arterial lactate concentration was increased by more than 5 mM the FFA release following sympathetic nerve stimulation was significantly reduced. The lipolytic rate, as estimated by the release of glycerol, was not significantly altered, however. Na-L(+)-lactate thus increased the re-esterification of FFA in adipose tissue. On the other hand, Na-pyruvate significantly reduced the re-esterification.

The evidence indicates that high arterial lactate levels, such that might occur e.g. during exercise, can decrease the release of FFA by increasing the re-esterification.

Fredholm, B.B. and Frisk-Holmberg, M. (Department of Pharmacology Karolinska Institutet, Stockholm, Sweden): RELEASE OF HISTAMINE AND PRODUCTS OF LIPOLYSIS FOLLOWING THE ADMINISTRATION OF COMPOUND 48/80 IN CANINE SUBCUTANEOUS ADIPOSE TISSUE. 107

The release of products of lipolysis in subcutaneous adipose tissue, i.e. glycerol and free fatty acids (FFA), following compound 48/80 was reported recently (Fredholm, B.B., H.C. Meng and S. Rosell, Life Sci. 1968. 7. 1209). Since histamine was shown to affect lipolysis similarly it was hypothesisized that compound 48/80 acted indirectly by releasing adipose tissue histamine, and that this was the lipolytic agent proper. The present study lent further credence to this assumption by showing that histamine is indeed released from adipose tissue by compound 48/80. The amounts of histamine recovered in the venous blood following lipolytic amounts of compound 48/80 were found to be 1-20 times higher the minimal effective dose of injected histamine (0.5μg).

Moreover, the threshold dose of compound 48/80 was the same (5-25μg) for vascular, lipolytic and histamine releasing effects. Upon repeated administration of compound 48/80 the vascular and metabolic responses declined in parallell to a diminished release of histamine. In conclusion subcutaneous adipose tissue mast cells may play a role in fatty acid mobilization via the release of its histamine content.

108 Hänninen, O. and Hietanen, E.(Department of Physiology,University of Turku, Finland): EFFECT OF GASTROINTESTINAL SURGERY ON THE METABOLIC GRADIENT IN THE SMALL INTESTINE OF THE RAT.

The metabolic activity decreases greatly from the oral to the aboral end in the small intestine.This is reflected e.g. in the activity of alkaline phosphatase and ATP hydrolyzing enzyme system (Hänninen et al.,Acta Chem. Scand. 1964.18.937; 1965.19.817). In order to study the role of food and gastric chyme in the formation of this gradient the normal anatomy was disturbed by partial resection (20 cm) of jejunum or by pyloric ligation with gastrojejunostomy. - The activity of the enzymes mentioned above was determined as described earlier from the uncentrifuged aqueous extracts of the mucosal samples.

The activity of alkaline phosphatase remained unchanged at least one month in the distal gut after partial jejunal resection. Also the gastrojejunostomy was without an effect on the enzyme activity in the jejunum. But the activity of ATP hydrolyzing enzyme system increased markedly in this area. On the other hand the jejunal resection did not affect on the enzyme activity in the distal small intestine.

The gradient of alkaline phosphatase appears thus to be independent from the normal passage of the chyme, but the response of ATP hydrolyzing enzyme system indicates that the chyme probably contributes to its control.

109 Mollegaard, K.E. (Veterinary Mollegaard Hansens Avlslaboratorier A/S Ejby, pr. 4623 Ll. Skensved, Danmark): SPF BREEDING AND GNOTOBIOTECHNIQUE.

It has proved possible to effect breeding of SPF animals (Special Patogene Free) in a barrier stable without occurence of bacterial infections. SPF animals are derived from gnotobiotians at the Zentralinstitut für Versuchstierzucht in Hannover.

For the SPF breeding is used a barrier stable of 635 sq.metres, built as a house in a larger house. The barrier stable with its passage facilities, autoclave, formalin lock, immerse tank, supply cylinder, staff lock, and technical aids will be described. As the autoclave treatment causes a destruction of protein, indicated by a fall in biological value (B.V.) of the feed from 85,4 to 82,5 (at 110° C for 10 minutes) and 71 (at 133° C for 10 minutes) the necessity of a feed with sufficient content of protein is mentioned. Especially the loss of vitamins A and B_1 is stated. The breeding method, especially the experience with permanent monogamous breeding is stated.

After mention of bacteriological status of the animals as of July 1, 1968 and May the 1., 1969, the necessary microbiological control arrangements are described. Practical advice is given allowing the investigator to use SPF animals without barrier.

The conclusions: 1) It is possible to breed SPF animals indicated by their bacteriological status by use of barrier stable.

2) Use of SPF animals gives the investigator better results even without use of barriere arrangements.

Pruett, E.D.R. (Institute of Work Physiology, Oslo, Norway): INSULIN, FFA AND GLUCOSE DURING AND AFTER LONG-TERM WORK IN MEN. **110**

In order to investigate the relationship between plasma immunoreactive insulin (IRI), blood glucose and plasma FFA during and after heavy muscular exercise, long-term work experiments were carried out at work loads of 20%, 50 % and 70% of the subjects' maximal aerobic work capacity (max V_{O2}) in healthy young men. The subjects, fasting, exercised alternately on a bicycle ergometer and a treadmill for six hours or until exhausted, whichever occurred first. Venous blood samples were drawn while the subject exercised, and an intravenous glucose tolerance test was administered 15 min after the final bout of work.

Blood glucose fell to an average 60% of the pre-exercise value during work at 50% and 70% of max V_{O2}. Plasma IRI fell during all levels of work, and FFA, inorganic phosphorus and potassium levels increased indicating that insulin activity probably had decreased. Thus, the fall in blood glucose concentration during exercise is due to some factor other than an increased plasma insulin.

Glucose tolerance was found to increase 2-2 1/2 times after the exhausting work which had reduced the body's carbohydrate stores. The increase in plasma IRI levels upon glucose infusion was immediate and independent of the preceeding work load, and the IRI levels followed the glucose disappearance curves closely after heavy work. FFA mobilized during the work disappeared rapidly from the blood after the infusion of glucose and the rise in plasma IRI, but the level rose again after the glucose and IRI had returned to the pre-exercise levels.

N.B. IRI assays by Dr. S. Oseid, University Hospital of Oslo, Norway.

Hermansen, L., E.D.R. Pruett, J.-B. Osnes[1] and F.A. Giere[2] (Institute of Work Physiology, Oslo, Norway): CHANGES IN INSULIN AND BLOOD SUGAR CONCENTRATION IN RESPONSE TO MAXIMAL EXERCISE OF SHORT DURATION. **111**

The adrenal medullary hormones are known to increase the blood sugar concentration and to assist in counteracting the hypoglycemic action of insulin. Maximal exercise is known to elicit an increased release of these amines from the adrenals and/or the sympathetic nerves. The aim of this investigation was to study the effect of intermittent maximal exercise on the insulin and blood sugar levels.

5 healthy subjects, 2 female and 3 male, ran on the treadmill at their greatest possible speed for 5-one minute bouts. Each exercise period was followed by a four minute rest period. Blood samples were withdrawn during and after each work bout via indwelling catheters and were analyzed for glucose and plasma immunoreactive insulin (IRI).

The mean blood glucose increased from 90 mg/100 ml at rest to 170 mg/100 ml immediately following the fifth work bout, while the mean plasma IRI increased from 13 μU/ml at rest to 43 μU/ ml after the fifth work bout. The blood glucose concentration began to increase earlier than the plasma IRI indicating that the insulin rise is due to the increase in glucose.

116 Forster, H. and K. Klausen. (Pulmonary Function Laboratory, University Hospital, Madison, Wis., and Laboratory for the Theory of Gymnastics, University of Copenhagen, Denmark): VENTILATION DURING EXERCISE AND DURING CO_2 STIMULATION AT SEA LEVEL AND AT ALTITUDE.

The effect of chronic exposure to hypoxia on ventilatory control was investigated in two independent field studies (Leadville, Colo., 3100 m, 10 subjects, and Barcroft Laboratory, Calif., 3800 m, 12 subjects). Ventilation was measured during exercise at sea level (pre and post altitude) and at intervals during acclimatization to these altitudes. It was found that at all intensities of work the ventilation (BTPS) was greater at altitude than at sea level, when the partial pressure of O_2 in the inspired air was the same at the two altitudes (PIO_2 = 105, 145, 400 mmHg). In addition the ventilatory response to CO_2 stimulation, determined on three subjects at sea level and again periodically at 3100 m altitude, was also found to be markedly elevated at altitude. Of the total increases, a large portion was already present after only 18-24 hours of acclimatization, while the remaining increase occurred more gradually over the first two weeks of acclimatization. It is suggested that part of the increase in ventilation at altitude can be attributed to a reduced bicarbonate concentration and that the rate at which the increase in ventilation occurred is indicative of the rate at which the re-adjustments in buffering capacity are made.

117 Sørensen, Sören C. (Cardiovascular Research Institute and Dept. of Physiology, Univ. of California, San Francisco Medical Center, San Francisco, California, U.S.A.): VENTILATORY ACCLIMATIZATION TO CHRONIC HYPOXIA AFTER TOTAL DENERVATION OF THE PERIPHERAL CHEMORECEPTORS.

We earlier demonstrated that man born at high altitude and goats deprived of their carotid chemoreceptors acclimatized to chronic hypoxia (lowered their $Paco_2$) even though hypoxia caused initially either no ventilatory stimulation or ventilatory depression. We wanted to examine if acclimatization would occur with total absence of peripheral chemoreceptors. Chronic denervation of both carotid and aortic chemoreceptors was performed in rabbits. Completeness of denervation was ascertained by testing the ventilatory response to I.V. NaCN. Ventilatory acclimatization to hypoxia was measured as the decrease in $[HCO_3^-]$ in cerebrospinal fluid after the awake rabbit had been exposed to hypoxia (P_B = 470 mm Hg) for 24 hours. Cerebrospinal fluid (csf) was sampled from the cisterna magna immediately after a lethal dose of barbiturate.

	Denervated rabbits		Intact rabbits	
	$[HCO_3^-]_{csf}$	$[lactate]_{csf}$	$[HCO_3^-]_{csf}$	$[lactate]_{csf}$
control	25.4 ± 1.3 (6)		24.1 ± .9 (6)	3.23 ± .33 (6)
24 hr. hypoxia	20.4 ± 1.1 (6)	4.91 ± 1.90 (6)	19.1 ± .9 (7)	3.64 ± .86 (7)

Concentrations are expressed in meq/L ± standard deviation. ( ) = number of animals. The presence of a peripheral chemoreceptor drive is not essential for acclimatization to occur. We propose that lactic and pyruvic acid efflux from hypoxic cells through brain extracellular fluid (ecf) to blood exceeds HCO_3^- influx to ecf, thereby reducing $[HCO_3^-]$ without imposing a stoichiometric relation between decrease in $[HCO_3^-]$ and increase in [lactate] . Supported by grants HE 06285 and GM 09262 from the National Institutes of Health.

Wilkoff, W.G., B. Rasmussen, and S. Kozlowski. (Laboratory for the Theory of Gymnastics, University of Copenhagen, Denmark): THE EFFECT OF HIGH OXYGEN TENSIONS ON VENTILATION DURING SEVERE EXERCISE. 118

The purpose of this investigation was to study the time course of the ventilatory transients caused by changing the arterial oxygen tension during severe exercise in man. This time course was compared with the changes in Pa_{CO_2}, pH and blood lactate concentration during and after the transient period to see if these parameters could explain the changes in ventilation or whether it was due to altered Pa_{O_2} per se.

The full depressing effect on ventilation was obtained in 10 - 20 sec after the shift from a lower to a higher oxygen tension for all gas mixtures used. When shifting from a higher to a lower tension the rise in ventilation took longer and was of a different character. The changes in lactate concentration were too slow to explain the changes in ventilation. The shifts in Pa_{CO_2} and pH were found to be opposite in direction to those one would expect if these factors were causing the ventilatory changes. It is discussed whether the changes in the ventilation can be explained by: 1) an effect on aortic and carotid chemoreceptors, 2) an interaction with anaerobic processes of the muscles, 3) direct effect on the respiratory center, or by 4) some action on the airways and lungs.

119

Balldin, U. and C. Lundgren (Laboratory of Aviation and Naval Medicine, University of Lund, Sweden): THE EFFECT OF IMMERSION ON INERT GAS ELIMINATION.

The greater risk of decompression sickness in wet than in dry dives induced this work. The effects of submersion itself on nitrogen elimination were studied. Nitrogen elimination from the tissues was measured continuously with an electronic nitrogenmeter during oxygen breathing. In the wet experiments the subjects sat immersed to the chin in water with temperatures between 32° and 37°C. During submersion there was a significantly higher rate of nitrogen elimination than under dry conditions (temperature about 29°C). For instance, the amount of nitrogen eliminated was 15 to 70% larger in a 60 minute period of oxygen breathing sitting in water of 35°C as compared to dry conditions. Apart from the effects of temperature an important factor increasing the nitrogen elimination appears to be the submersion itself.

Submersion might influence the ventilation-perfusion ratio in the lungs, cardiac output and its distribution and the rate of transfer of gas between tissue and blood.

Preliminary experiments performed in collaboration with S. Mellander and J. Lundvall showed that intramuscular deposits of ^{133}Xe were cleared at a faster rate from dependent regions during submersion than in dry conditions. This might at least partly be related to the opening up of capillaries increasing the capillary exchange surface. The submersion leads to decreased vascular transmural pressure which, in turn, may reduce the myogenic precapillary sphincter tone normally prevailing in dependent regions.

120 Rusko, H. (Institute of Physiology of Exercise, University of Jyväskylä, Finland): INDIRECT METHODS IN THE ESTIMATION OF MAXIMAL OXYGEN UPTAKE.

Three extrapolation methods (Andersen, K. and Smith-Sivertsen, J., in Yoshimura, H. and Weiner, J.: Human adaptability and its Methodology, Tokio 1966) were compared with other indirect methods (Åstrand's nomogram and the deltaRQ-method). The subjects were 14 male and 18 female students of physical education and 16 conscripts in military service (mean max. O_2-uptake 3,95, 2,55 and 3,59 l/min respectively).

It was found that the three extrapolation methods underestimated the max. O_2-uptake by 1,5-4,3% (±7,3-8,9%). There were no significant differences between the three methods but each of them tended to be the more accurate the higher the max. O_2-uptake. The correlations between these and the direct method varied between .62-.82. Åstrand's nomogram overestimated the max. O_2-uptake by 8,1% (±12,7%). The maximal heart rate was however only 185,7; when this was taken into account the nomogram underestimated the max. O_2-uptake by 3,3%. The correlation between the nomogram and the direct method was .67. The deltaRQ-method overestimated the max. O_2-uptake by 14,7% (±10,1%), and the method tended to be the more accurate the higher the max. O_2-uptake. The correlation with the direct method was .54.

It is concluded that all the extrapolation methods underestimate the max. O_2-uptake, evidently because of the asymptotic relationship between heart rate and oxygen uptake (work load). This asymptotic error tends to be the smaller the higher the max. O_2-uptake. All the extrapolation methods were found to be more accurate than Åstrand's nomogram or the deltaRQ -method.

121 Areskog, N.-H. (Children's Nutrition Unit, Addis Ababa, Ethiopia and Dept. of Clinical Physiology, University of Uppsala, Sweden): PHYSICAL FITNESS IN ETHIOPIAN YOUNG ADULTS RELATED TO NUTRITIONAL STATUS.

The long-range unfavourable effects of poor nutrition - widespread in developing countries - on the functional performance of the body are still unclear. In the present study from Ethiopia 42 low salary workers (W), age 18-25 years, were compared with an optimally nutriated group of 50 cadets (C), age 18-22 years. Nutritional interviews, anthropometric measurements, bicycle ergometry, muscle dynamometry and spirometry with ventilation tests were performed.

The mean weights and heights were for W 54.0 kg and 1.69 m and for C 58.6 kg and 1.70 m. The cadets had gained on an average 5 kg after one year in the air force, indicating the order of magnitude of the difference in body weight between poorly nourished and well-nourished male Ethiopians. Physical work capacity measured as W_{170} was 717.0 ± 117.8 kpm/min for W and 825.0 ± 153.3 kpm/min for C. Also the muscle force tests showed lower values for W than for C. Vital capacity was 4.3 ± 0.6 l for both groups. Maximal voluntary ventilation (MVV) was 166 ± 39 l/min for W and 178 ± 34 l/min for C.

Compared to Swedish age mates the physical fitness is throughout lower for the two Ethiopian groups also as calculated per kilo body weight.

In spite of often very inadequate diets the achievements were on the whole reasonably good which might be due to adaptational mechanisms.

Thomson, D. (Institute of Physiology, University of Lund, Sweden): CARDIAC OUTPUT DURING POSITIVE AND NEGATIVE WORK. 122

Muscle work in everyday life includes both positive (concentric) and negative (eccentric) muscular movements. On an ordinary bicycle ergometer only positive musclework can be done and thus circulatory parameters has almost exclusively been studied during this kind of work. Earlier investigations by Asmussen (Acta Physiol.Scand. 28:364-382,1953) has shown the oxygen consumption to be much greater during positive leg work than during negative work of the same magnitude.

A study of the central circulation has been done on normal healthy young men doing both positive and negative arm or leg work on a special bicycleergometer. Cardiac output was determined with a CO_2-rebreathing method earlier developed in the laboratory. (Recent investigation by Ferguson, et al. J.Appl.Physiol. 25:450-454,1968 has shown an excellent agreement between this method and the dye-dilution method during work conditions).

The oxygen consumption was 3-4 times greater during positive than during negative work. Positive and negative work with the same oxygen consumption were termed equivalent. Cardiac output and heart rate (with the exception of positive arm work) were greater during negative work compared with an equivalent positive work. Stroke volume was greater during positive work. The results show that during negative work heart rate and cardiac output is not governed solely by the demand for oxygen in the tissues. Other factors such as heat removal may control the central circulation in negative work.

Stensvold, I.[1], and L. Hermansen, (Laboratory of Physiology, Norges Idrettshøgskole, Oslo, Norway): THE RATE OF LACTIC ACID REMOVAL DURING RECOVERY WHILE WORKING AND RESTING. 123

It has been known that lactic acid removal is facilitated during recovery by the performance of light exercise. The purpose of this investagation was to study the relationship between the rate of lactate removal and the metabolic rate during the recovery period.

5 trained subjects (3 female and 2 male) were subjected to 3 bouts of exhausting exercise of 1 min duration with a short rest period (4 min) after each bout. Blood lactic acid concentration was found to increase to 145 ± 7 mg% (mean ± S.E.) in the female, and to 205 ± 4 mg% in the male subjects.

After this severe exercise, lactic acid removal was followed during recovery both at rest and during work. The rate of removal was found to be 3.1 ± 0.1 mg%/min (mean ± S.E.) at rest and 5.6 ± 0.4, 7.8 ± 0.8, 7.5 ± 0.6, and 6.3 ± 0.3 mg%/min during the work at 30, 60, 70 and 80% of the maximal oxygen uptake respectively.

On the basis of these results it appears that the maximal rate of lactic acid removal occurs during recovery exercise representing 60 - 70% of the maximal oxygen uptake.

[1]Institute of Zoophysiology, University of Oslo

124 Karlsson J, Diamant B and Saltin B. (Department of Physiology, GIH and department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): PYRUVATE AND LACTATE CONCENTRATIONS IN MUSCLE TISSUE AND BLOOD DURING EXHAUSTIVE EXERCISE:

Excess lactate (XL) was proposed by Huckabee as being a better indication of anaerobic conditions in the muscle than blood lactate determinations since lactate (HLa) accumulated in the blood, should be due not only to an oxygen deficit but also to an increased lactate production from accumulated pyruvate. To study the changes induced by exercise on the relationships between HPy and HLa in muscle tissue and blood, HPy and HLa were determined in muscle biopsy specimens (M. Quadriceps femoris,L) and blood in 4 subjects before and after heavy bicycle exercise, exhausting the subject within 2-3 min. Biopsies were taken within 5 sec after exhaustion.

In the resting muscle HPy was 0.06 mmoles x kg^{-1} wet muscle and increased only to 0.14 mmoles x kg^{-1} after the exercise, whereas HLa increased from 2.4 to 14.0 mmoles x kg^{-1} wet muscle. In the blood the corresponding values for HPy were 0.14 and 0.53 mmoles x l^{-1} and for HLa 1.4 and 10.2 mmoles x l^{-1} respectively. Thus the HLa/HPy ratio increased from 40 to 100 in the muscle and from 12 to 19 in the blood due to the exercise. The results support that the dominant fraction of the HLa in the muscle tissue after exercise is due to an oxygen deficit. A good correlation has previously been demonstrated between the HLa in the muscle and the oxygen deficit.

125 Greenleaf, J,K-E Olsson and B. Saltin.(Department of Physiology, GIH, Stockholm, Sweden): MUSCLE GLYCOGEN CONTENT AND ITS SIGNIFICANCE FOR THE WATER CONTENT OF THE BODY.

Water is bound to glycogen in the liver of different specimen and values of 2-4 g water x g^{-1} glycogen is given. If the same amount of water is bound to glycogen stored in human muscles a significant change in total body water would occur. In one series of experiments the mean value for the muscle glycogen contents (tigh and shoulder) was increased with 15 g x kg^{-1} wet muscle in 19 subjects which may represent approximately 500 g glycogen. With this storage of glycogen total body water (T_2O-space) increased from 45.8 to 48.0 l ($P<0.001$) and body weight from 73.8 to 76.2 kg.

The results seems to demonstrate that a change in the muscle glycogen content of the body causes the body weight to increase significantly more than the amount of stored glycogen and this "extra" increase in weight is due to an enhanced deposition of water. To test wether this glycogen water may have a role in covering parts of sweat losses 8 subjects twice performed prolonged exercise with no water intake. The first time with a low glycogen content in muscles and the second time with filled glycogen stores. Sweat losses were the same but plasma volume was more reduced when the initial glycogen content was low. It is concluded that the deposition of water with glycogen in the muscle cells is of importance during prolonged exercise to reduce the negative effects of sweating.

Kaijser, L. (Department of Clinical Physiology, Karolinska Hospital, Stockholm, Sweden): THE INFLUENCE OF OXYGEN UNDER HYPERBARIC PRESSURE ON THE CAPACITY FOR DYNAMIC FOREARM WORK. 126

The capacity of the circulatory system to transport oxygen is considered one of the main limiting factors for muscle work. During oxygen breathing at increased ambient pressure, the oxygen content of the arterial blood is increased considerably, and hence the oxygen transport capacity is supposed to be augmented.

Six healthy male volunteers were studied during dynamic forearm work breathing oxygen at 3 atmospheres (3 ata) and as comparison breathing air at 1 ata. Blood was sampled from percutaneous teflon catheters in the brachial artery and a deep vein of the active forearm.

At a low work intensity, the a-v O_2 difference was on the average 19.3 ml/l higher during oxygen than air breathing ($p < 0.01$), suggesting about 15 per cent smaller blood flow at corresponding work intensities. When the work was increased the a-v O_2 difference increased during air but not during oxygen breathing. At exhaustion at the highest work intensity there was no significant difference between oxygen and air breathing ($p > 0.05$). In agreement with this the average performance time to exhaustion was not significantly increased ($p > 0.05$) by oxygen breathing.

It is concluded that under normal circumstances the oxygen transport to the muscle is not the limiting factor for aerobic muscle work.

Banister, E.W., J.E. Taunton, T. Patrick, P. Oforsagd and W.R. Duncan. (Hyperbaric Research Unit, Vancouver, Canada and the Laboratories of Aviation and Naval Medicine, Karolinska Institutet, Stockholm). PHYSIOLOGICAL ADJUSTMENTS TO EXHAUSTIVE EXERCISE AFTER PROLONGED EXPOSURE TO OXYGEN AT HIGH PRESSURE (OHP). 127

The physiological adjustments to severe exercise, before during and after prolonged exposure to hyperbaric oxygen have been studied in two subjects. Standard bicycle ergometer work (1500 kpm/min at 100 rpm) was performed either at 1 ATA (air) or 2 ATA (100% O_2). After a two hour period during which oxygen was breathed at 2 ATA the exercise was repeated under the reversed environmental conditions of the first task. Preoxygenation of at least 1/2 hour preceded any exercise breathing oxygen. Lactic acid accumulation, acid-base balance and respiratory gas exchange were measured.

Lactic acid accumulation was significantly reduced as a result of hyperbaric oxygenation. This reduction appeared time dependent being greater after 2 hours oxygen breathing than after a 1/2 hour. Evidence for the potentiation of exercise tolerance in normoxia after prior, long continued hyperbaric oxygenation was equivocal being observed in one subject but not in the other. Arterial P_{aO_2} values decreased progressively from an initial high value throughout the period of oxygenation while P_{aCO_2} was slightly elevated during exercise in OHP over values for equivalent exercise in normoxia. Ambient ventilation and $\dot{V}_{CO_2}$ STPD were significantly depressed in exercise in OHP and $\dot{V}_{O_2}$ STPD and $\dot{V}_{CO_2}$ during exercise in normoxia after oxygenation also reduced.

128 Iisalo,E., Kanto,J. and Pihlajamäki,K.(Department of Pharmacology,University of Turku,Finland): EFFECTS OF FINNISH SAUNA ON CIRCULATION DURING TREATMENT WITH PROPRANOLOL AND GUANETHIDINE

The effects of Finnish sauna on circulation was studied in healthy young students receiving placebo,propranolol (40 mg one hour before bathing) or guanethidine (20 mg twice a day for 4 days).The sauna temperature ranged between 80-93°C.No differences were observed in the rise of sublingual temperature during the treatments.During a 20 minutes'bathing there was no significant change in systolic blood pressure;after the bath there was an immediate fall in all groups,most markedly in the guanethidine group.All groups recorded a slight fall in diastolic blood pressure which in the guanethidine group continued after the bath. Pulse rate in this group was slightly higher than in the placebo group while being much lower in the propranolol group.

In a cold pressor test immediately after the bathing no significant differences were recorded between the groups.

In a work test with a bicycle ergometer after the bath, the increase in systolic blood pressure was smaller both after guanethidine and propranolol as compared to the placebo. The diastolic blood pressure was lower after guanethidine as compared to the other groups.The increase in pulse rate after propranolol was clearly lower as compared to the other groups.

It is concluded that especially hypertensive patients treated with propranolol or guanethidine should be careful in taking sauna baths.

129 Arvela, P., Huikko, M. (Department of Pharmacology, University of Oulu, Finland): EFFECT OF PROPRANOLOL ON PLASMA FFA-LEVELS AND URINARY EXCRETION OF CATECHOLAMINES DURING FINNISH SAUNA BATH.

Exposing the organism to cold or hot environment causes changes in hormonal balance which aim to maintain homeostasis. It is evident that the sympathetic system is activated by hot environment. (Huikko, M. et al: Acta Physiol. Scand., 68 (1966), 316). In the present study 8 medical students served as test subjects. They were subjected twice to the sauna bath and received either 10 mg of propranolol or placebo. Propranolol was effective in preventing tachycardia produced by staying in sauna, but did not clearly affect the blood pressure. Sauna bath induced an increase in the plasma FFA-level and propranolol prevented this increase effectively. In the present study we were able to confirm our earlier finding, that sauna bath increases the urinary excretion of noradrenaline significantly. This effect was more pronounced after propranolol. There was no change in adrenaline excretion after propranolol.

The increased demand for calories is often attributable to the conditions with sympathetic overactivity. However in the case of hot stress this increase seems unlogical and is apparently to be interpreted as an unavoidable consequence of the sympathetic stimulation.

Hermansen, L. and Osnes, J.-B.[1], (Institute of Work Physiology, Oslo, Norway): MUSCLE AND BLOOD pH BEFORE AND AFTER MAXIMAL WORK OF SHORT DURATION. **130**

The aim of this investigation was to study the relationship between muscle and blood pH before and after exhausting exercise of short duration.

Five healthy young men were subjected to maximal bicycle exercise with a work load which would exhaust the subject within approximately 2 minutes. Needle biopsies of the lateral part of the quadriceps muscle were taken at rest, immediately after work, and during the recovery period. The muscle samples were frozen rapidly in liquid nitrogen, homogenized in a cold isotonic KCl/NaCl solution, and the pH of the homogenates measured with a conventional pH meter (Radiometer). Capillary blood samples were taken simultaneously with the biopsies.

Resting pH values of muscle and blood were 6.98 ± 0.04 (mean ± S.E.) and 7.40 ± 0.01 respectively. After the maximal exercise the muscle pH was 6.46 ± 0.05 and the pH of the blood had decreased to 7.18 ± 0.02.

These observations show that the maximal exercise lowered the pH of the muscle by 0.52 units, while the corresponding reduction in the blood pH was 0.22 units. Measurements during the recovery period (40 min) revealed a more rapid increase in the pH of the muscle than of the blood.

[1]Norwegian Army Medical Service

Høvde, R.[1], and L. Hermansen, (Institute of Work Physiology, Oslo, Norway): BODY TEMPERATURE DURING EXERCISE IN CHILDREN. **131**

It is well established that body temperature increases more rapidly in children than in adults in response to infection. This observation might indicate that there is a difference between the body temperature regulation of children and that of adults. The aim of this investigation was to compare the body temperature response to exercise in children to that previously found in adults.

8 boys, aged 10 - 11 years, worked on the bicycle ergometer at three different work intensities demanding an oxygen uptake of 0.58, 0.97, and 1.36 l/min (approximately 30, 50 and 70% of their maximal oxygen uptake) Rectal temperature increased within 45 min from the resting base level to a new plateau, which level was directly proportional to the work load. Rectal temperature at the end of one hour of work at each of the three work loads was found to be 37.4, 37.9 and 38.4°C respectively. On the basis of these results it appears that there is no difference between children (10 - 11 years) and adults as far as body temperature regulation during exercise is concerned.

[1]Institute of Zoophysiology, University of Oslo.

132 *Oseid, S., R. Høvde*[1], *J.-B. Osnes*[2], *and L. Hermansen,* (Pediatric Research Institute, University Hospital, and Institute of Work Physiology Oslo, Norway): CIRCULATORY RESPONSE TO PROLONGED EXERCISE IN PREPUBERTAL BOYS.

Very few data have been published concerning the capacity for prolonged work in prepubertal children. Recently it has become common practice for children to take part in rather heavy and prolonged physical exercise. On the other hand, children at school are not especially trained for prolonged work in their physical fitness programs. The aim of this study was to investigate the circulatory response to prolonged severe exercise in 11 year old boys.

23 boys, members of one school class in Oslo, were tested on the treadmill. They ran for one hour at a constant speed which demanded an oxygen uptake of 1.45 ± 0.04 l/min (mean ± S.E.), representing on the average 67% of their maximal oxygen uptake. The heart rate increased from 166 beats/min after 5 min of running to 180 beats/min after 25 min and reached 185 beats/min after 60 min. In separate tests, maximal heart rate was found to be 204 ± 1.2 beats/min (mean ± S:E.) The subjects were not exhausted and completed the work in good clinical condition. On the basis of these results it appears that the circulatory adjustments to heavy prolonged work in children do not differ significantly from that previously found in adults.

133 Arfors,K.E., P. Malmberg and K.Pavek (Burn Center, University of Uppsala and Dept. of Experimental Medicine, Pharmacia AB, Uppsala): EVALUATION OF FISHER COMPUTER FOR CARDIAC OUTPUT ESTIMATED BY THERMODILUTION.

Fisher computer allows to obtain direct digital values of cardiac output after injection of thermal indicator into the right atrium or pulmonary artery and detecting the dilution process in the aorta (Slama and Piiper, Z.Kreisl. forsch. 1964. 53. 322). This principle was not, however, verified for very low output values and for left atrial injections of the indicator. Therefore the computer was checked with simultaneous measurements using the Fick O_2 principle and independent recordings of the thermodilution curves, which were integrated and output calculated manually. The experiments were done in anesthetized closed-chest dogs. The values given by computer correlated well with the Fick values in a broad range of flow (1.0 to 6.0 l/min) and, in the mean, there was no significant difference. In the individual dogs, however, the successively recorded values were often systematically different, showing either higher or lower values with one of the methods. Similarly, with manually evaluated thermodilution curves, there was very high correlation (r=0.96). Finally, using the computer after alternative injections into the PA and LA showed no systematic difference and high correlation (r=0.86). The computer may be used with indicator injections both into pulmonary artery and left atrium in the given flow range, however, systematic differences in individual animals have to be expected.

134

Arfors, K.E., P.Malmberg and K.Pavek (Burn Center, University of Uppsala and Dept. of Experimental Medicine, Pharmacia AB, Uppsala): THERMODILUTION TECHNIQUE: LOSS OF THE INDICATOR IN THE LUNG CIRCULATION.

The substantial part of the criticism of the cardiac output estimation by thermodilution method is the possibility of an irreversible exchange of "cold" between the site of injection and detection. This has been studied many times in animals including man by comparing outputs after left and right heart injections. No, or slight difference has been found within the normal range of the cardiac output. However, it seems more probable, that the loss might occur only with low values of the output. To investigate this phenomenon limited to the segment between the pulmonary artery (PA) and left atrium (LA), the indicator has been injected alternatively into these sites in dogs and the dilution was detected in the descending aorta. The paired values showed very high correlation (r=0.978) within the flow range of 1.0-5.0 l/min. The mean output (LA) was 14% higher when compared to the output (PA). One S.D. of differences between the pairs was 8.9% of the mean value. Thus, no loss was observed. The regression line showed that with lower values of output the right site was giving progressively lower values. This might be caused by an increase of the area by unrecognized recirculation. With the flow of approximately 0.7 l/min the pulmonary injections resulted in very prolonged downslope, making the estimation of the area impossible. On the other hand, the curves after LA injections showed a reasonable downslope.

135

Pavek,K. and K.Karovic (Pharmacia AB, Uppsala and the Inst. for Theory of Measurement, Academy of Sciences, Bratislava, Czechoslovakia): EFFECT OF INDICATOR VOLUME ON ESTIMATION OF CARDIAC OUTPUT BY THERMODILUTION.

The injection of thermal indicator either diminishes the inflowing blood flow at the site of injection by the volume of the injectate and we observe that the total flow rate is unchanged downstream, or, in the second extreme case, the volume of the injectate is added to the inflowing blood and downstream we find unchanged blood flow plus the volume of the indicator. In the first case it is appropriate to calculate the output/min - $Q_b = 60\ V_i \cdot (T_b - T_i)/0\int^{\infty} (T_b - T)(t)\,dt$; in the second case the mathematical solution can not be used for the calculation (Pavek, K. et al., Arch Kreisl. forsch. 1969,58. 228), but the situation may be approximated by $Q_b \approx [60\ V_i \cdot (T_b - T_i)/0\int^{\infty} (T_b - T)(t)\,dt] + 60\ V_i\ (\beta - 1)$, where $\beta = 0$. However, in real situation β may be ≥ 1. To estimate this, the thermal indicator was repeatedly injected into the left atrium and dilution detected in descending aorta in dogs with closed and opened chest. The volume of indicator was changed in steps of 4, 8 and 15 ml and was injected in two seconds. The resulting output was calculated using the first equation. The results showed slight increase with increased volume of indicator; thus the value of empirically estimated beta is approximately 0.6 to 0.9.

136 Öberg, P.Å. and U. Sjöstrand (Institute of Physiology and Medical Biophysics, Biomedical Centre, University of Uppsala, Sweden): CONTROL OF SYSTEMIC BLOOD PRESSURE BY CAROTID-SINUS NERVE STIMULATION.

Chronic carotid sinus nerve stimulation as a clinical method for the treatment of essential hypertension has successfully been used in a limited number of patients by Schwartz et al. (Am.J.Surgery 1967.114.5) and also by Bilgutay and Lillehei (J.A.M.A.1965.191.649). However, the studies referred were not based upon studies of the fundamental properties of the regulatory system interfered with.

A method has been worked out by which one of the closed control circuits in the blood-pressure-regulating system of the dog can be reversible opened and closed again with the aid of an on-line analog computer. This makes it possible to study the regulatory properties of the carotid-sinus reflex.

By studies in both time and frequency domains (Öberg, P.Å. and U. Sjöstrand, Acta physiol. scand. 1969.75.287) it is concluded that the electronic analog can be given optimal characteristics producing specified stability and systemic pressure level conditions. These results can be used as direct guidance in both the technical and clinical development of anti-hypertensive therapy by means of electronic pressure-regulating devices.

137 Akre, S. and H. Aars (Institute for Experimental Medical Research, University of Oslo, Norway): SYMPATHETIC RESPONSES TO CHANGES IN SYSTEMIC BLOOD PRESSURE.

Over a wide pressure range arterial baroreceptor activity is linearly related to blood pressure. The associated changes in efferent sympathetic nerve activity have been only incompletely studied. We have quantitatively recorded the activities in left aortic and left renal nerves in anesthetized rabbits. Control diastolic blood pressure ranged from 80 to 100 mmHg. Increasing the systemic blood pressure by noradrenaline infusion (1-6 μg/kg·min) or by inflation of a balloon in the descending aorta sharply reduced the sympathetic activity. Above 120 mm Hg the activity was usually completely abolished. In contrast, sympathetic activity showed only a small rise or remained unchanged in response to a reduction in blood pressure by bleeding. Aortic nerve activity was linearly related to pressure above 60 mm Hg. The small sympathetic response to reduced blood pressures was not due to a high activity at control pressure because sympathetic activity was capable of increasing 100-200 % during hypoxia. It is concluded that the baroreceptor reflex offers a better protection against a rise than a fall in blood pressure.

Hirvonen, L., J. Klossner and E. Länsimies (Cardiorespiratory Research Unit, Department of Physiology, University of Turku, Finland): CIRCULATORY RESPONSE TO HYPOXIA OF NEWBORN LAMB TREATED WITH ATROPINE OR ALPRENOLOL. 138

Nervous regulation of the blood circulation may be of importance for the survival of a newborn in hypoxia. A partial block of the autonomic system was caused by atropine or alprenolol (beta-blocking agent) in anesthetized newborn lambs. The animals were curarized and ventilated with a constant minute volume. Anoxic hypoxia was produced by the use of a low-pressure chamber.

Systemic arterial pressure varied within narrow limits in all groups. Pulmonary arterial pressure increased in control and atropine series. Only insignificant changes were observed in alprenolol-treated animals. Pulse pressure decreased in extreme conditions. Cardiac output remained practically unchanged in all groups. In these experimental conditions the acid-base balance of the blood did not correlate with the cardiac output. Acetylcholine decreased temporarily the systemic arterial pressure in all lamb groups equally at all stages of hypoxia. It decreased the pulmonary arterial pressure if elevated by hypoxia. Pressure changes caused by acetylcholine were not correlated with acid-base balance. The fact that the differences between the various lamb groups were small suggests that the autonomic nervous system has a secondary role in the adaptation of the newborn lamb to hypoxia.

Bolme, P. and J.Novotný (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): ACTIVATION IN THE CONSCIOUS DOG OF THE SYMPATHETIC CHOLINERGIC VASODILATOR NERVES AND A PROPOSAL OF THEIR PHYSIOLOGICAL SIGNIFICANCE: 139

In conscious dogs hind limb blood flow was measured by an electromagnetic flowmeter with a probe fitted on the external iliac artery. Arterial pressure and heart rate were also recorded. Blood flow increase was produced in the hind limb as a conditional reflex response to either electrical skin stimulation or exercise on a treadmill. The blood flow increase was abolished or reduced by atropine ia. In addition a tachycardia, a slight increase in arterial pressure and an alerting reaction were elicited. The response to the conditional stimuli was similar to that observed in conscious dogs following electrical stimulation of sympathetic cholinergic vasodilator pathways in the brain (Bolme et al.Acta physiol.scand. 1967.70.334-346). No habituation to the conditional stimuli was observed.

The results indicate that the sympathetic cholinergic vasodilator nerves are activated in anticipation of situations in which increased skeletal muscle blood flow is suddenly required It is proposed that the role of the vasodilator nerves is not to regulate the local muscular blood flow and the supply of oxygen or substrates to the muscle, but rather to take part in a general homeostatic mechanism working to adjust the arterial pressure when blood is suddenly redistributed from the skin and viscera to the muscles.

140 Karppanen, H., Vapaatalo, H., Lahovaara, S., and Paasonen, M.K. (Department of Pharmacology, University of Helsinki, Finland): PINEALECTOMY-INDUCED HYPERTENSION IN RATS.

It has been demonstrated that pinealectomy (PE) causes hypertension in rats (Zanoboni, A. and Zanoboni-Muciaccia, W., Life Sci. 1967.6.2327). In this study the mechanism of PE induced hypertension and other phenomena were examined. A simplified PE method was developed by using electrocauterization through the skull. The body weight of PE animals increased slower than that of the sham-operated or control animals. The motility of PE rats was higher than that of the controls both in light and dark and their diurnal rhythm was disturbed. The blood pressure of PE rats was increased 1 week after PE and remained elevated up to 7 weeks. There was no consistent correlation between the plasma renin activity and the blood pressure increase. Na^+ and K^+ contents in serum were slightly lowered in PE rats, but their excretion in urine was normal. Angiotensin (20 ng/kg ip) and noradrenaline (20 µg/kg ip) caused smaller pressor effect in PE rats than in the controls. The brain noradrenaline concentration was decreased in PE rats 3 but no more 5 months after operation. The catecholamine contents of heart, spleen, kidney and adrenal glands were not changed. - The possible correlation between the changes observed and the hypertension is not known. (Supported by the P.I. Ahvenainen Foundation, the Heart Association and Sigrid Jusélius Foundation.)

141 Folkow, B., M. Hallbäck, Y. Lundgren and L. Weiss (Dept. of Physiology, University of Göteborg, Göteborg, Sweden): STRUCTURALLY BASED INCREASE OF FLOW RESISTANCE IN SPONTANEOUSLY HYPERTENSIVE RATS.

In essential hypertension in man, flow resistance in forearm or hand is raised largely in proportion to resting arterial pressure, even when the vascular smooth muscles are completely relaxed (e.g. Folkow, B. and R. Sivertsson, Life Sci. 1968. 7. 1283-1289); also the responses to noradrenaline suggest the presence of a morphological vascular adaptation in the form of an increased wall/lumen ratio (Sivertsson, R. and R. Olander, Life Sci. 1968. 7. 1291-1297). - In the present study, the entire systemic circuit (except for the coronaries) of normotensive and spontaneously hypertensive Wistar rats (SH/N strain[x]) was perfused with plasma substitutes. Pressure-flow curves for the maximally dilated vessels were plotted and PRU_{100} for identical pressure levels was calculated. - In the hypertensive rats, systemic flow resistance was increased largely in proportion to the raised arterial pressure even during maximal vasodilatation, the difference to the normotensive rats being highly significant. This suggests that the entire systemic vascular bed is structurally adapted in this type of chronic hypertension to such an extent that the morphological change of the resistance vessels might entirely account for the raised pressure level during rest.

A.Pekkarinen,K.Kätkä and T.Suramo (Department of Pharmacology, Univeraity of Turku,Finland): THE EFFECT OF ANTIHYPERTENSIVE DRUGS AND DIURETICS ON THE DEVELOPMENT OF EXPERIMENTAL COMBINED DESOXYCORTICOSTERONE AND NACL HYPERTENSION OF RATS

Experimental hypertension was developed in rats by daily injections (s.c.) of desoxycorticosterone acetate (DOCA)(Schering) (5 mg/kg) and 2% NaCl in drinking water.The mean blood pressure increased in 6 control groups from 111.0+2.1-116.5+1.3 mmHg in mmHg in 63-118 days with +66-+69 mmHg.(I)This increase was during the combined treatment with furosemide (Hoechst) and phentolamine (Ciba) p.o.(+13 and +28 mmHg),dibenzyline (SKF) and furosemide (+28 mmHg);phentolamine and hydrochlorothiazide (+34,5 mmHg),and with dibenzyline and hydrochlorothiazide(+32) highly significantly less than that of the control group.The combined treatment with hydrochlorothiazide and reserpine,or with furosemide and reserpine prevented the increase of BP (+33 and +31 mmHg) very highly significantly as well as that with phentolamine and α-methyldopa or guanethidine (+34 and +35 mmHg),furosemide with α-methyldopa(+38.5)hydrochlorothiazide with guanethidine or α-methyldopa(+40.5 and +44.5 mmHg).(III) A single diuretic or antihypertensive drugs were not as effective as their combined treatments(hydrochlorothiazide +47,furosemide +47 and +55,Hygroton® +55,dibenzyline +44,phentolamine +47,reserpine +37 add +51,guanethidine +51,guanoxane +45,bethanidine +50,phentolamine +47, α-methyldopa +43,hydralazine +57,Catapresan® +58 and chlorprothixene +58 mmHg.)

143

A.Pekkarinen,K.Kätkä and T.Suramo (Department of Pharmacology University of Turku,Finland):THE EFFECT OF ANTIHYPERTENSIVE DRUGS AND DIURETICS ON THE DEVELOPMENT OF EXPERIMENTAL COMBINED NORADRENALINE AND NACL HYPERTENSION OF RATS.

The experimental hypertension was developed in rats by daily adsorbtion of noradrenaline bitartrate (Winthrop 0.5 mg as base/ml glycerol)percutaneously from the tail and 2% NaCl in drinking water. Mean blood pressure increased in 5 NaCl and noradrenaline control groups from 110+1.8-117.5-1.7 mmHg to the maximum +35.0 and +40.0 mmHg above the initial basal level of BP in 110-192 days.With simultaneous daily treatment with hydrochlorothiazide (+13 and +14 mmHg),furosemide (+10, +10,0 and +14.5 mmHg) or reserpine (+9.0,+9.0 and+13.0 mmHg) in drinking water, the mean BP was highly significantly lower, approximately only 1/3 of that of noradrenaline NaCl control groups as well as during the combined treatment with hydrochlorothiazide and reserpine (+10.6 mmHg), or furosemide and reserpine (+10.0 mmHg).

Among other antihypertensives guanethidine (+10.0,+17.0, +22.0 mmHg),bethanidine (+16.0 mmHg),guanoxane (+17.0 mmHg), and α-methyldopa (+13.0, +20.0 and +26.3 mmHg),hydralazine (+21.0 mmHg) a diuretic Hygroton® (+24.0 mmHg), and chlorprothixene (+22 and +24.0 mmHg) showed a smaller final increase of BP than in the control group with hypertension,except in one group of guanethidine, α-methyldopa,phentolamine and chlorprothixene and the Catapresan® group (+27.0 mmHg).

144 A.Pekkarinen,K.Kätkä and T.Suramo (Department of Pharmacology, University of Turku,Finland): THE EFFECT OF ANTIHYPERTENSIVE DRUGS AND DIURETICS ON THE DEVELOPMENT OF EXPERIMENTAL COMBINED ADRENALINE AND NACL HYPERTENSION OF RATS.

Experimental hypertension was developed in rats by daily adsorbtion of adrenaline (0.5 mg/ml glycerol) percutaneously from the tail and 2.0% NaCl in drinking water.Mean blood pressure increased in the two control groups of 10 rats from 116.1±1.4 and 117.2±1.5 to 140.5±1.5 mmHg in 140 days with a slight tendency to decrease later.(I) During simultaneous daily treatment of peroral antihypertensive drugs or diuretics in drinking water,the mean maximum BP was slightly,but very highly significantly lower than in the adrenaline and NaCl control group in the phentolamine (+9.8 mmHg),furosemide(+14.0 mmHg),reserpine (+15.0 mmHg),bethanidine (+14.5 mmHg) groups(= above the initial level), and generally also very highly significantly lower in the guanethidine (+13.5 mmHg) and guanoxane (+13.5 mmHg) groups, except at the one point of maximum (II) BP was only very slightly, but significantly less during the simultaneous hydrochlorothiazide (+18.5 mmHg),α-methyldopa (+19.5 mmHg), and chlorprothixene treatment (+19.5 mmHg). (III) The mean maximum BP was nearly the same as in the control group, in hydralazine (+20.5 mmHg), Hygroton® (+21.8 mmHg), Aptin® (+21.5 mmHg),Aldactone® (+20.5 mmHg) and Cataprese® -groups (+25.0 mmHg).

145 Folkow,B., B.Löfving and B.Öberg (Dept. of Physiology, University of Göteborg, Göteborg, Sweden): FACTORS INFLUENCING BLOOD VISCOSITY IN VIVO AT VERY LOW FLOW RATES.

Recent studies on cats show that blood viscosity in vivo, being throughout much lower than in vitro, increases only moderately with flow reductions and even decreases at the very lowest flow range (Ojosugito et al. Acta physiol. scand. 1969. In press), in contrast to the marked increase of viscosity in vitro at low shear rates. - The mechanism responsible for the decrease of viscosity in vivo at low flows was analyzed in cats, using the maximally dilated calf muscle vessels as biological viscometer. Pressure-flow curves for blood and a Newtonian fluid (dextran-Tyrode) were compared in the lowest flow range, both when vascular passive-elastic recoil occurred with reductions of pressure head and transmural pressure, and when the vessels were maintained distended by keeping transmural pressure high throughout. - While blood viscosity decreased at very low flows when pressure-passive reductions of vascular lumina took place, prevention of such luminal reductions led to marked increases in blood viscosity at corresponding flows, the difference at a given low flow being up to threefold. - The earlier reported viscosity decrease at very low flows therefore seems to be a consequence of the vascular narrowing favouring the appearance of the Fåhraeus-Lindqvist phenomenon and bolus flow. This dependency of blood viscosity on vascular dimensions also at very low flows may have important implications. Thus, some reduction of apparent viscosity may be expected with intense vasoconstriction, while an increase would occur e.g. with severe venous stasis or in dependent limbs with low pressure head due to arterial obstruction.

Håkansson, B.A.S., Östling, S.G. and Zade-Oppen, A.M.M. (Institute of Physiology and Medical Biophysics, University of Uppsala, and Department of Clinical Chemistry, University Hospital, Uppsala, Sweden): THE NON-AFFINITY OF THE RED CELL SURFACE FOR DEXTRAN. 146

The effect of dextran on agglutination of red cells and platelets has been much studied. The associated problem of dextran adsorption by the cells has, however, been somewhat neglected.

A coating material, rendering the cells sticky has been described. (for references see: Swank, R.L., Appl. Physiol. 1958.12.125; Lee, W.H., in: Conference on Evaluation of Low Molecular Weight Dextran in Shock. Nat. Acad. Sci.-Nat. Res. Council, Washington, 1963, p.40) It has been suggested that the material is a dextran-protein complex. An adsorption of 2400 to 8900 dextran molecules per cell, using end-group labelled C-14-dextran, has been reported (Rothman, S. et al., Vox Sanguis. 1957.2.104).

We have measured the recovery of generally labelled C-14-dextran from the supernatant fluid of red cell suspensions in isotonic saline and plasma. Two dextran fractions with molecular weight distributions comparable with clinical dextrans were used. Dextran was added at concentrations ranging between 0.002 and 0.050 g/l. After correction to a standard hematocrit and for the interstitial volume the corrected concentrations after incubation were a linear function of the initial concentrations with a slope greater than 0.93, and the line passed through the origin.

From our results we conclude that dextran adsorption is improbable.

Bø.G. and A. Hauge (Institute of Physiology, University of Oslo, Norway): HYPEROSMOLALITY AND PULMONARY VASCULAR RESISTANCE. 147

It has been demonstrated that venous blood from exercising muscles has an elevated plasma osmolality (Mellander, S. & al. Angiologica 1967.4.310), and several investigators have reported that blood hyperosmolality is a potent pulmonary vasoconstrictor stimulus (Aviado, D.M. The Lung Circulation, Oxford 1965 p.302). This last effect appears to be teleologically disadvantageous. We therefore decided to examine the effect of graded rises in pulmonary arterial osmolality in a lung lobe preparation. In 15 anesthetized openthorax cats ventilated by positive pressure we recorded pulmonary arterial, left atrial and femoral arterial pressures. Left lower lobe arterial blood flow was measured by electromagnetic flowmeter. 2 M solutions of glucose and urea, and 1 M of mannitol and NaCl were infused at varying speed into the lobar artery over periods of 1 min. Knowing pre- and postlobe vascular pressures, lobe flow and hematocrit we calculated lobar vascular resistance (LVR) and changes in plasma osmolality. In all cats the hyperosmolar solutions reversibly reduced LVR (flow increased). The opposite effect was not seen. Reproducible dose-response curves were found. +20 mOsm/l plasma gave a mean LVR fall of 5% and +50 mOsm/l gave a 10% fall. A maximal fall of 30% could be obtained by elevating plasma osmolality by 100 mOsm/l. Bolus injections caused a rapid rise in LVR. This type of response, which may have been caused by sludging of blood, is possibly the one studied by previous investigators.

148 Lundvall, J. (Institute of Physiology, University of Lund, Sweden): FURTHER STUDIES ON REGIONAL HYPEROSMOLALITY IN RELATION TO EXERCISE HYPEREMIA.

The hypothesis that increased osmolality in the interstitial space of exercising muscle contributes to exercise hyperemia (Mellander et al. Angiologica 1967. 4. 310) was further tested in cat and man. I.a. hypertonic infusions to resting cat muscle caused progressive increases of blood flow. Maximal dilatation was reached when venous osmolality, reflecting interstitial tonicity, was raised by 40-100 mOsm/kg.

Similar experiments on the intact human forearm in which venous osmolality could be raised by 15-20 mOsm/kg led to a 3-to 5-fold increase of flow. Since exercise in cat and man results in regional hypertonicity of up to 30-40 mOsm/kg the data indicate a quantitatively important role of hyperosmolality in exercise hyperemia.

During hypertonic infusion arterial osmolality exceeded venous osmolality. Therefore possible transintimal effects on arteriolar smooth muscle would lead to overestimation of the role of hyperosmolality since flow has been related to venous osmolality. To test this possibility the vascular bed of the gut which also dilates during hypertonic infusion, was perfused in retrograde direction. In situations when control resistance was the same with forward and retrograde perfusion, hypertonic infusion gave about equally large dilatations at comparable hypertonicity in the outflows, despite intraluminal osmolality on the arterial side was higher with normal than retrograde perfusion. This seems to refute any significant transintimal effects of hyperosmolality, a conclusion which might be relevant also with regard to the site of action of other blood-borne vasoactive agents.

149 Eriksson, E. and B. Lisander (Depts of Physiology and Anatomy, University of Göteborg, Sweden): INTRAVITAL MICROSCOPY OF MUSCLE BLOOD FLOW IN CATS.

Only few microcirculatory studies of nervous and metabolic blood flow changes in skeletal muscle have been reported. Therefore, a method for intravital study of the tensor muscle of the crural fascia was developed, volume blood flow being judged by simultaneous recordings in adjacent muscles. The total muscle region was exposed to graded constrictor fibre stimulations or intraarterial vasodilator drug administrations during observations of internal arterial diameters, linear flow rates and capillary flow distribution. - Dilatations giving maximal flow increases caused some 50% diameter increases mainly in arteries of 15-100μ with less change in larger ones. No downstream vascular widening, or opening of "sphincters", was seen. - During "rest" the denervated vessels displayed a fairly steady tone; precapillary rhythmicity was not seen though capillary flow patterns changed perpetually, contents being stagnant or flow reversed, sometimes apparently due to cells passing the loops. - Intense vasoconstrictor fibre activations, which lowered flow 6-8fold, reduced diameters in arteries of 15-300μ, with a clear maximum at the 50μ size, where closure could occur; luminal reductions were absent in immediate precapillary sections. However, capillary flow ceased at such stimulations to return after 30 sec at prolonged stimulation, often in a rhythmic pattern. - These microcirculatory events seem to agree well with "macro circulatory" findings, although the sites of precapillary adjustments, leading to changes in resistance and capillary flow distribution, may not be distinctly separated morphologically.

Biber,B., O.Lundgren and J.Svanvik (Dept. of Physiology, University of Göteborg, Sweden): AN INDICATOR-DILUTION TECHNIQUE FOR STUDYING MEAN TRANSIT TIME AND BLOOD FLOW IN THE MUCOSA-SUBMUCOSA OF THE SMALL INTESTINE **150**

The study of blood flow in the mucosa-submucosa of the small intestine by means of diffusible tracers (e.g. krypton, xenon) is complicated by the existence of a counter-current exchange in the intestinal mucosa (Lundgren, O., Acta physiol. scand. 1967.suppl.303). An indicator-dilution technique using nondiffusible (intravascular) tracers has therefore been developed. - A cylindrical Geiger-Müller tube is placed in the intestinal lumen in close contact with the mucosa. The radioactive tracer is administered in a small volume by an "instantaneous", close intra-arterial injection. Mean transit time is calculated from the registered indicator-dilution curve. Regional blood volume is estimated as described by Wolgast (Wolgast, M., Acta physiol. scand. 1968. suppl. 313) from the radioactivity registered by the detector when the tracer has become uniformly distributed in the total blood volume. Total intestinal blood flow is continuously recorded by a drop recorder unit. - Experiments have been performed in which ^{32}P-labelled red blood cells have been used as the intravascular tracer. A 2-3 mm thick tissue layer around the detector is monitored. When total intestinal blood flow amounted to approximately 50 ml/min x 100 g, mean transit time (area under curve divided by height of curve) was estimated to 3-4 sec, relative blood volume to 10-20 % and blood flow to 200-400 ml/min x 100 g. During intense vasodilatation (total intestinal blood flow around 200 ml/min x 100 g) mean transit time was calculated to 1-2 sec and blood flow to 800-1200 ml/min x 100g.

Lundborg, G. (Lab.of exp.biology, Dept.of Anatomy, University of Gothenburg) **151**
STUDIES ON MICROVASCULAR REACTIONS OF RABBIT'S TIBIAL NERVE AFTER PROLONGED ISCHEMIA.

Using vital microscopic observation techniques (Brånemark, Med.Biol.Ill. XVI:2,100,1966; Lundborg and Brånemark, Adv.Microcirc. 1, 66,1968) the microvascular bed of rabbit's Tibial nerve has been studied in vivo under various experimental conditions. By inflating a tourniquet around the thigh one leg was kept ischemic for certain periods of time, and after release the restitution of intrafascicular, nutritive capillary circulation was studied. By stimulating the nerve at the ankle and registrating the elicited compound action potential at knee level the nerve function could be tested. Permeability disturbances were estimated by studying the endoneural distribution of a fluorescing "tracer", intravenously infused. Ultrastructural analyses were performed on endothelial cells and on structures involved in impulse transmission.

After ischemic periods of 6-8 hours there was a complete restitution of the endoneural microcirculation within the first minutes after release. Even after 12 hours ischemia the intraneural circulation was rapidly restored to a considerable extend.

The first visible signs of an endoneural oedema occurred after ischemic periods of 8-10 hours. In case of 2, 4 or 6 hours ischemia the maximum conduction velocity of the nerve was restored to original values within 5, 10 and 30 minutes resp. After 8 hours ischemia nerve activity could be registered only in exceptional cases. Long term studies have been performed in order to analyse the restitution capacity of neuromuscular structures considering the survival and function of the limb.

152 Delin, N.A. (Thoracic Surgery Research Laboratory, Karolinska Sjukhuset, Stockholm, Sweden): INFLUENCE OF EXPERIMENTAL VALVULAR AND SUPRAVALVULAR AORTIC STENOSIS ON INSTANTANEOUS CORONARY ARTERIAL BLOOD FLOW.

Acute supravalvular aortic stenosis (SVAST) was produced in dogs by constriction of the ascending aorta. Valvular aortic stenosis (VAST) was simulated by constriction of the ascending aorta and perfusion of the left coronary artery from a point distal to the constriction. Instantaneous flow was measured by an electromagnetic flowmeter on the circumflex branch of the left coronary artery ($\dot{Q}$ cor). During SVAST or VAST mean $\dot{Q}$ cor and myocardial O_2 consumption were increased while coronary arterio-venous O_2 difference remained unchanged. In VAST the increase in mean $\dot{Q}$ cor consisted in an increase in diastolic $\dot{Q}$ cor, systolic $\dot{Q}$ cor remaining low as in the control state. In SVAST there was a marked increase in systolic $\dot{Q}$ cor, accounting for the whole mean $\dot{Q}$ cor increase, and systolic and diastolic $\dot{Q}$ cor were equal Acute circulatory block by coronary infusion of Lycopodium spores reduced systolic and diastolic $\dot{Q}$ cor equally, leaving the pressure oscillations in the coronary artery unaffected. Thus in SVAST there is a large flow into the microcirculation during systole The low systolic $\dot{Q}$ cor in VAST is expected from the high myocardial tension and the low coronary pressure. The high systolic $\dot{Q}$ cor in SVAST is unexpected, for although the coronary arterial pressure is increased the myocardial tension is equally increased. It is concluded that myocardial contraction may constrict vessel lumina less than commonly believed.

153 HÄggendal, E. and Inger Winsö (Departments of Clinical Physiology and Anesthesiology II, University of Göteborg, Sweden): THE INFLUENCE OF THE ARTERIAL CARBON DIOXIDE TENSION ON THE CEREBROVASCULAR RESPONSE TO HYPOXIA.

It has been shown that cerebral vasoconstriction induced by hypocapnia is counteracted by the tissue hypoxia which exists when the cerebral venous oxygen tension has reached around 20 mm Hg - The purpose of this study was to investigate if the arterial carbon dioxide influences the "threshold" of the hypoxic dilation of the cerebral vessels.

The study was performed in anesthetized dogs. When the animals were normoventilated and the arterial oxygen saturation was lowered cerebral vasodilation occurred when the cerebral venous oxygen tension was about 30 - 35 mm Hg. During pronounced hyperventilation vasodilation consistently occurred at a lower venous oxygen tension (around 20 mm Hg).

It is concluded that the effect of hypoxia on the cerebral vessels is influenced by the carbon dioxide tension. During excessive hyperventilation the oxygen tension will reach significantly lower values until the hypoxic vasodilation appears than during normocapnia. A hypothetical explanation would be that carbon dioxide and oxygen act by similar mechanisms on the vessels (e.g. hydrogen ion concentration of the extracellular fluid around the smooth muscle cells). During respiratory alkalosis there will be needed more metabolic (hypoxic) acidosis in order to reach the same hydrogen ion concentration as in normocapnia and affect vasodilation.

Ekström-Jodal, B., Häggendal, E., Nilsson, N. J., and Norbäck, B. (Departments of Clinical Physiology I and II, Anesthesiology II and Surgery III, University of Göteborg, Sweden): INFLUENCE OF METABOLIC FACTORS ON THE CEREBRAL PRESSURE-FLOW RELATION IN HYPOTENSIVE STATES. **154**

Experimental evidence indicates that the autoregulation of cerebral blood flow is normally effected by non-metabolic factors. On the other hand the cerebral vascular bed is known to be sensitive also to metabolic influences. In the range of low perfusion pressures, below the limit of flow autoregulation, the conditions are less extensively investigated; we have previously found that the vascular resistance can be influenced by changes in oxygen and carbon dioxide tensions to about the same degree here as in the autoregulatory range.

In the present study, performed on anesthetized, artificially ventilated dogs, cerebral vasodilatation was first induced, usually by a continuous infusion of papaverine. By lowering the arterial pressure the flow was then reduced stepwise to normal or slightly subnormal values. In these conditions the pressure-flow relation tended to be curvilinear, convex towards the pressure axis, as seen in pressure-passive vascular beds. In a few animals, where the initial flow increase was brought about by carbon dioxide inhalation, however, the relation had an almost linear course, as demonstrated previously (Häggendal, E., and Johansson, B., Acta Physiol. Scand. 1965. 66. Suppl. 258.27) in hypoxic animals. Our impression is, therefore, that at perfusion pressures below the range of autoregulation a basically pressure-passive relation can be modified by metabolic factors, if these are strong enough.

Ballard, K., C.A. Cobb and S. Rosell. (Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden): THE RELATIONSHIP BETWEEN LIPOLYTIC AND VASOACTIVE EFFECTS OF ADRENALINE AND NORADRENALINE ON CANINE SUBCUTANEOUS ADIPOSE TISSUE. **155**

Adrenaline and noradrenaline are potent lipolytic agents. Since they also have vasoactive properties which may influence the release of free fatty acids, it would be of interest to examine the relationship between the vascular and metabolic effects on adipose tissue.

Adrenaline, or noradrenaline, was added to the arterial blood perfusing canine subcutaneous adipose tissue in situ (Rosell, S., Acta physiol.scand. 1966. 67. 343). Either flow or, alternatively, pressure was constant during the perfusion. Concentrations ranged from .001 to 10µg/ml plasma ($6X10^{-9}$M to $6X10^{-5}$M). The lower concentrations were within ranges reported for resting dogs (Valk, A. de T. and Price, H.L., J.Clin.Invest. 1956. 35. 837). Glycerol release, indicating lipolytic rate, was determined. Adrenaline at concentrations above .01µg/ml plasma caused a net release of glycerol, concomitant with vasoconstriction. Noradrenaline enhanced glycerol release at .005µg/ml plasma but vascular responses were not observed until .01µg/ml plasma was exceeded. Both catecholamines produced only vasoconstriction.

The results indicate that catecholamine plasma levels present in dogs are sufficient to produce lipolysis in subcutaneous adipose tissue. Furthermore, lipolysis may occur without accompanying vasoconstriction.

156 Kovách, A.G.B., S. Rosell, P. Sándor, E. Koltay and N. Tomka. (Dept. of Exp.Res., Univ.Med.School, Budapest, Hungary and Dept. of Pharmacology, Karolinska Institutet, Stockholm, Sweden): BLOOD FLOW AND FREE FATTY ACID (FFA) RELEASE IN CANINE SUBCUTANEOUS ADIPOSE TISSUE IN HEMORRHAGIC SHOCK.

Little is known about vascular and metabolic reactions in adipose tissue in hemorrhagic shock. Therefore, during a procedure, known to cause irreversible shock, blood flow and release of FFA was measured in the subcutaneous adipose tissue (Rosell, S. Acta physiol. scand. 1966. 67. 343), of chloralose anaesthetized dogs. The animals were bled to 55mmHg for 90 min (BI) followed by bleeding to 33 mmHg for an additional 90 min (BII). The shed blood was then reinfused. In BI blood flow diminished from 6 to 0.6 ml/min/100g. In BII flow remained at 10% of control, or ceased. Following reinfusion normal blood flow could not be restored indicating damage to the vascular bed. Arterial FFA conc. fell in BI and BII. There was a small release of FFA.

In phenoxybenzamine pretreated animals blood flow was reduced to about 70% and 50% in BI and BII respectively. Following reinfusion pronounced hyperemia occurred. Arterial FFA increased during BI and BII and there was a definite rise in FFA release.

It is concluded that the vascular bed of canine subcutaneous adipose tissue is especially sensitive to hemorrhage. A pronounced restriction of blood flow results, which will have metabolic consequences. Phenoxybenzamine pretreatment may limit local damage by ensuring adequate blood flow.

157 Nicolaysen, G. (Institute of Physiology, University of Oslo, Norway): Ca^{++}, Mg^{++} AND CAPILLARY PERMEABILITY IN THE LUNG.

Ca^{++} is of importance for various characteristics of cell membranes, and probably also for cell adhesiveness. The exact effect of Ca^{++} in the capillary wall is insufficiently known, but observations indicate a role related to capillary permeability. - An isolated rabbit lung was perfused with plasma at 28°C and changes in preparation weight continuously followed. Addition of EDTA, leaving the calculated sum of ionized Ca and Mg in the perfusate at about 10 µmoles/l or less caused, within 10 to 20 min, an accellerating weight increase, reflecting edema formation. Such a weight increase, was stopped or reduced by addition of $CaCl_2$ or $MgSO_4$. Reduction of ionized Ca plus Mg to a calculated level of about 0.15 mmole/l did not result in edema. With 0.1 mmole/l ionized Ca and 0.4 mmole/l ionized Mg, the capillary filtration coefficient was reversibly increased. A situation with about 1 mmole/l of ionized Ca combined with about 0.1 mmole/l of ionized Mg, as achieved by EGTA-addition, did not result in edema formation, whereas edema developed on further reduction of ionized Mg to micromolar levels. - In order to produce edema in this preparation ionized Ca as well as Mg must be reduced then to very low levels in the perfusate, whereas the water permeability of the capillary wall is reversibly increased during less severe reductions of these ions.

Jonsson, J., K.-E. Arfors and H.H. Hint (Department of Experimental Medicine, Pharmacia AB and Institute of Zoophysiology, University of Uppsala, Sweden): STUDIES ON MICROCIRCULATORY COMMUNICATIONS BETWEEN THE BLOOD AND LYMPHATIC SYSTEMS. 158

Clark and Clark (J.Am.Anatomy, 60, 253, 1937) have by microcirculatory studies described the existence of fenestrations covered by a thin membrane between the postcapillary veins and lymphatic capillaries in rabbit ear chambers. They also observed haemorrhage through such a membrane. We have tried to confirm Clark and Clark's results and have found that the anatomical relationship between postcapillary veins and lymphatic capillaries in rabbit ear chamber are favourable to the existence of direct communications, but we have up to now not been able to demonstrate such communications anatomically. Functionally, we have found indirect evidence for free communication between vascular and lymphatic systems at highly increased central venous pressure after massive dextran infusions to rabbits. - Microcirculatory studies in the rat mesentery showed massive appearance of red cells in lymphatic microcirculatory vessels after reinfusion of blood in the state of haemorrhagic shock. In some cases flowing blood was seen in lymphatics in the same amount as in veins in the same area. These findings are earlier described by Baez (J.Appl.Physiol.21, 299, 1966; S.Baez, Flow prop of blood and other biol. syst., ed. by Copley & Stainsby, 1960, p.398) and can only be explained by haemorrhages directly from blood vessels into lymphatics. The common walls between the postcapillary veins and microcirculatory lymphatic vessels are probably weakened by haemorrhagic shock and by other injuries and a break through special predisposed sites can then be caused by increased venous pressure.

Åberg, B., (Institute of Physiology and Medical Biophysics, Bio-Medical Center, Uppsala, Sweden): MODEL EXPERIMENTS ON TRANSCAPILLARY TRANSPORT. 159

An isolated, perfused intestinal loop with an autodigested mucosa has been used as a model for paracapillary circulation and for studies of passive exchange of electrically neutral molecules over the capillary walls. The intestinal lumen has been regarded as an extracapillary space with free acess to catheters varying and measuring pressure and sampling.

It has been shown, that the velocity and direction of the fluid exchange between intestinal lumen is important to the speed and direction of the transport of raffinose and glucose. Raffinose has to a larger extent appeared to follow a bulk-flow compared with glucose. As the concentrations of the test-molecules are higher in the vessels than in the intestinal lumen, there is, at the venous end of the capillaries, a bulk-flow from the intestinal lumen and a solute counter-diffusion flow into the lumen. This contributes to a separation between the two molecules depending on the magnitude of the linear speed of the capillary resorption flow.

160 Åberg,B and S.-O. Lindahl (Institute of Physiology and Medical Biophysics, Biomedical Center, Uppsala, Sweden): THE SINGLE-INJECTION TECHNIQUE DURING VENOUS CONGESTION.

Earlier studies of transcapillary transport of substances have shown a restriction for penetration either by molecular/porous size (c.f. Grotte, G., Acta chir. Scand. 1956. suppl. 211) in steady-state or by diffusion coefficient in non-steady state (Crone, C., Acta physiol. Scand. 1963. 58. 229).

In penetrating the problem further we have adopted the method of Crone, i.e. given a single injection to the hindlimb of a cat without and with venous congestion. In case of free venous flow we obtained a volume-distribution for glucose somewhat larger than that for raffinose. During congestion the volume-distribution for both molecules was increased but more equal.

At least one explanation for the phenomena studied can be that resorptive flow at the venous end of the capillary might separate the molecules transported from the intracapillary to the extracapillary space on basis of their size. During free venous flow raffinose is transported with a bulk-flow back to the capillary to a greater extent than the smaller glucose molecule. During venous congestion this resorptive flow is disturbed, and the two molecules are transported in a more similar way.

161 Lassen, N.A. and Trap-Jensen, J. (Laboratory of Clinical Physiology and Department of Medicine C, Bispebjerg Hospital, Copenhagen, Denmark): EVIDENCE OF RESTRICTION IN DIFFUSION OF INULIN OVER THE CAPILLARY MEMBRANE IN EXERCISING HUMAN SKELETAL MUSCLE.

The transcapillary passage of hydrophilic molecules show a pattern consistent with simple diffusion through water-filled pores or slits. For larger molecules a restriction in the diffusion must occur since for such molecules the pore dimensions reduces the effective diffusion area. In resting skeletal muscle Crone (Proc.Soc.Exp.Biol.Med. 112:453,1963) found no evidence of restricted diffusion of inulin compared to sucrose, suggesting a much larger pore diameter than hitherto thought. We restudied this problem in rythmically exercising human skeletal muscle in order to minimize interference from flow limitation.

The single injection technique employing a mixture of inulin (or sucrose) and T-1824 was used in 6 normal subjects. The extraction, E, defined as the average fractional loss of diffusible indicator during the initial raising part of the first passage venous time-concentration curves, averaged 0.25 for sucrose and 0.01 for inulin at a blood flow level of 35 ml/100g/min. The capillary diffusion capacity ratios almost equals the ratio of these E values which markedly differ from the ratio of the free diffusion coefficient in water of about 3 (sucrose/inulin) This implies restricted diffusion for inulin compatible with the dimensions of the intercellular slits between the endothelial cells seen by electronmicroscopy.

Garlick, D. and C. Crone. (Institute of Medical Physiology A, University of Copenhagen, Denmark): IS THE INTERSTITIAL SPACE IN MUSCLE WELL-MIXED? 162

It has been suggested (Lassen, N.A. & J. Trap-Jensen, Scand. J. Clin. Lab. Invest. 1968. 21. 108) that capillary permeability can be assessed from the clearance rate of extracellular tracers from the interstitial space. This approach presupposes that the interstitial compartment is well-mixed so that no gradients of the tracers occur outside the capillary wall.

This assumption was tested in experiments where the fractional removal of extracellular markers (mannitol, sucrose, inulin) was studied in resting cat gastrocnemius muscle, perfused with Ringer-colloid, after equilibration with these substances. It was possible to determine extraction from the start of the washout period. The initial value was similar to that found with the indicator dilution technique in the same muscle. However, the extraction fell steadily from this initial value. The most likely explanation is the occurrence of concentration gradients in the interstitial fluid. The fact that the rate of diffusion in the interstitial space becomes a limiting factor in the removal of substances from the tissue, as well as limitations in the capillary wall, means that only extraction values obtained immediately after the start of washout can give information about capillary permeability.

Skadhauge, E. (Institute of Medical Physiology A, University of Copenhagen, Denmark): SOLUTE-LINKED WATER FLOW ACROSS THE CLOACAL EPITHELIUM IN THE NORMAL AND IN THE DEHYDRATED HEN. 163

Several authors have proposed that the water flow from gut lumen to plasma when the lumen has the same osmolality as plasma may be due to an osmotic flow into hypertonic confined regions in or between the cells. The hypertonicity is thought to be created by the active NaCl transport.

If this model is correct the water flow for a constant net NaCl flow should vary with the osmotic permeability of the epithelium.

The large intestine and coprodeum of normal and dehydrated hens was perfused with NaCl solutions of osmolalities varying from 150 mOs below to 300 mOs above the plasma osmolality. The transmural NaCl and water flow were measured. The lumen to plasma Na^+ transport was 220 μeq/kg·h in the normal and 240 μeq/kg·h in the dehydrated fowl. The lumen to plasma net water flow from luminal fluids of plasma osmolality was 180 μl/kg·h in the normal state, 380 μl/kg·h in the dehydrated.

Since the osmotic permeability estimated from the water flow in these experiments when the luminal fluids were far from plasma osmolality and measured in other experiments with impermeant perfusion fluids doubled in the mucosa to serosa direction from the normal state to dehydration, the fact that the solute-linked water flow, too, doubles, provides support for the confined-space-hypertonicity model.

164 Bindslev, N. (Institute of Medical Physiology A, University of Copenhagen, Denmark): HYDRAULIC CONDUCTIVITY, REFLECTION COEFFICIENT, AND SOLUTE MOBILITY OF THE CLOACAL WALL IN THE NORMAL AND THE DEHYDRATED HEN.

To elucidate the physiological changes in the passive transport parameters the hydraulic conductivity Posm, the reflection coefficient σ_s, and the salt mobility ω_s of the cloacal epithelium, the lumen of the coprodeum and large intestine was perfused. The perfusion fluids contained an impermeant solute (raffinose or $MgSO_4$) with osmolalities varying from 200 mOs below to 200 mOs above plasma osmolality. For the determination of Posm and σ_s the infusion rates were 5-9 ml/h. Posm (µl/kg·h·mOs) appears as the slope of the curve relating transmural volume flow to the difference in osmolality between plasma and perfusion fluid. σ_s is found as the ratio of the luminal osmolality and the plasma osmolality at zero volume flow. For the determination of passive salt flow the perfusion rate was varied from 5 to 225 ml/h. The passive salt (NaCl) flow was assessed at zero volume flow. The transmural potential difference was close to zero.

The Posm in the normal birds in the serosa (s) to mucosa (m) direction was 2.0-3.0 and in the m-s direction 4.4-6.1 µl/kg·h·mOs. During dehydration Posm in the s-m direction was unchanged, but in the m-s direction Posm nearly doubled (10.0-10.2 µl/kg·h·mOs). In both states σ_s was unity, and ω_s zero.

165 Persson, E. (Institute of Physiology and Medical Biophysics, University of Uppsala, Sweden): WATER PERMEABILITY IN RAT DISTAL TUBULES IN WATER DIURESIS AND ANTIDIURESIS.

In order to investigate how ADH affected water permeability in rat distal tubules, microperfusion experiments were performed to determine the osmotic water permeability (Lp) and the diffusional water permeability(P_D). The electrolyte concentrations were chosen to give no net electrolyte fluxes.The experiments were performed both in antidiuresis and in water diuresis after waterloading of hypophysectomized animals. In antidiuresis the Lp was $6.1\pm1.2 \times 10^{-8}$ $cm^3/cm^2 \cdot sec \cdot cm\ H_2O$ (mean value, ±1 SD)(n=8) and P_D was $327\pm132 \times 10^{-6}$ cm/sec (n=25). In waterdiuresis Lp was $1.6\pm1.6 \times 10^{-8}$ $cm^3/cm^2 \cdot sec \cdot cm\ H_2O$ (n=7) and P_D was $157\pm32 \times 10^{-5}$ cm/sec. When converted into the same dimension the Lp value was much higher than P_D, a result which cannot be explained by the existence of unstirred layer, but is additional support to the idea of pores through which the water flow at osmotic gradients mainly is a bulk flow and not a diffusional flow.The question of the modification of water structure in microcapillaries may be important for water flow, but yet too little is clarified.The larger ratio(Lp/P_D) in antidiuresis than in water diuresis may indicate that ADH changes the pore area-pore diameter relation so that the bulk flow increase is larger than the diffusional flow increase.

Wieth, J.O., (Institute of Biophysics, University of Copenhagen, Denmark): ANION-INDUCED CHANGES OF ERYTHROCYTE PERMSELECTIVITY. 166

Sodium and potassium permeabilities of human red cells are increased if chloride is replaced by other monovalent anions of the lyotropic series (J.Funder and J.O.Wieth, Acta physiol. scand. 1967.71.1968). Additional information about the permselectivity has been obtained by studying the permeation of ions (Na, K, Cl, SO_4) and of an uncharged molecule (erythritrol).

Anion-induced enhancement of cation permeability was always accompanied by a reduced permeability to negatively charged ions. A maximum effect on permselectivity was found in a 120 mM salicylate medium at 0 °C. The rate of chloride exchange decreased by a factor of 100,000, and chloride and potassium permeabilities were of comparable magnitudes (P-Cl: 2×10^{-9} cm/sec, P-K: 3.5×10^{-9} cm/sec). Passive fluxes of sodium and potassium showed a paradoxical temperature dependence in the presence of the adsorbable anions thiocyanate and salicylate with a minimum at 18 °C, and steep increases both below and above this temperature. Red cell permeability to erythritrol was not affected by the substitution of chloride with other anions. Because the anion-induced effect on permeability is determined by the electric charge of the permeating species, it is concluded that anions interact with fixed positive charges, which control the ionic permeability of the red cell.

Ahlgren, L. and Grampp, W. (Institute of Physiology, University of Lund, Lund, Sweden): MEMBRANE EFFECTS OF OUABAIN IN THE SLOWLY ADAPTING STRETCH RECEPTOR NEURONE OF LOBSTER. 167

Ouabain has previously been shown to cause an immediate and reversible depolarization of the smooth muscle membrane (Casteels, R., J. Physiol. 1966. 184:131). A similar effect was found in the slowly adapting stretch receptor neurone of lobster. Thus, in 5×10^{-4} M concentration ouabain produced a depolarization of 10-25 mV, the higher values obtaining with higher degrees of stretch activation of the cell. This effect which persisted in the presence of tetrodotoxin was abolished by substitution of choline for Na^+. The depolarization was parallelled by a reduction of the membrane resistance which manifested itself particularly after that spike activity had been blocked by tetrodotoxin. During development of the depolarization both amplitude and rates of rise and fall of the action potential diminished at a rate which increased with the firing frequency during the action of the glycoside. The described effects started immediately on arrival of the drug in the experimental chamber and attained a maximum 10-15 min later. Complete reversibility was obtained by washing the preparation for about 40 min. Initially during the washing procedure there was a 20 min long hyperpolarization of maximally 10-15 mV.

The results suggest a dual effect of ouabain on the membrane: 1) The drug causes an unspecific increase in permeability for Na^+ resulting in the depolarization. 2) Ouabain blocks the channels for specific ionic fluxes leading, perhaps in combination with the depolarization, to the decline of the action potential.

172 Poupa, O. and Carlsten, A. (Department of Clinical Physiology, University of Goteborg, Sweden): ANEURYSMS OF FROG HEART OBSERVED IN VIVO.

Almost all frogs (Rana Pipiens) accidentally kept for a few days in the winter period at +28 - +30°C died and at autopsy we observed aneurysms of the ventricle in most of them. This was never observed at +4 - +8°C.

Isoproterenol (150 - 200 mg/kg b.w.) injected twice with 1 day's interval in the lymphatic sac of Rana pipiens causes changes in the heart of frogs at +25°C but not at +4°C. In contrast to the reptiles this frog has only one type of musculature of the heart, the sponge-like, corresponding to the inner part of the reptilian ventricle, supplied by blood from the lacunae. No true coronaries are present. The ventricular lesions of the beating frog heart, provoked by isoproterenol and perfectly studied in 6-40 times magnification, consist of aneurysms and/or blister-like formations of typical localization and certain reversibility. Preliminary microscopy shows no infiltration of polymorphs even in large lesions, neither in the spontaneously dying nor in the isoproterenol group. The cardiac aneurysms produced in this way can be studied for hours and provide us with a living model of heart lesions suitable for hemodynamic and pharmacodynamic research.

The isoproterenol induced aneurysms seem to be very similar to those occurring in the spontaneously dying noninjected frogs kept at +28 - +30°C.

173 Kadefors, R., Magnusson, R., Nilsson, N.J. & Petersen, I. (Chalmers University of Technology, Sahlgren and Vasa Hospitals, Göteborg, Sweden): EFFECTS OF ISCHEMIA ON THE MYOELECTRIC SIGNAL SPECTRUM.

Maximum voluntary muscle contractions are accompanied by an increase of the low-frequency signal components (Kogi, K. & Hakamada, T., Rep. Inst. Sc. Lab. 1962. 60. 27.) and a reduction of the high-frequency signal components, possibly reflecting different sensitivities of different types of motor units (Kaiser, E. & Petersén, I., Electromyography. 1963. 3. 5; Kadefors, R., Kaiser, E. & Petersén, I., Electromyography. 1968. 7. 39.). The present authors have found that this high-frequency decrease is not materially affected by interruption of blood flow through the muscle. Also the reactive hyperemia after the contraction as well as the oxygen saturation, PCO_2, lactic and pyruvic acid concentration of the venous blood from the muscle were of about the same magnitude with arrested blood flow.

On the other hand, in a series of increasing submaximal loads to the biceps brachii muscle of healthy subjects an influence of blood flow arrest was observed. Typical signal spectrum changes were observed under control conditions at wrist loads of about 5 kp and during ischemia of the muscle at about 2 kp. The changes disappeared within a few seconds after restoration of blood circulation.

The results indicate an insufficient blood perfusion of the muscle as a cause of the power spectrum changes.

Molbech, Svend and Sophus H. Johansen (Polioinstitutet, Hellerup and Gentofte Hospital, Danmark): ENDURANCE TIME IN STATIC WORK DURING PARTIAL CURARIZATION. 174

In 3 normal subjects a 50% reduction of normal maximum isometric strength in elbow flexion was produced with (+)-tubocurarine. Under these circumstances the endurance for static work was found relatively much more reduced than strength. Similar experiments with decamethonium in one subject demonstrated no change in the normal relation between endurance and strength. Our findings can be explained by the different sensitivity of the "slow" and "fast" muscle fibers towards the 2 neuromuscular blockers: (+)-tubocurarine attacks mainly the slow fibers, which are fit for sustained contractions, and decamethonium the fast fibers, which are of more importance in maximum isometric strength mobilizations. The sensory feedback from the muscle spindles will be diminished by (+)-tubocurarine (but increased by decamethonium) This difference might contribute to the results, and explain why normal feeling of fatigue was depressed with (+)-tubocurarine, whereas after decamethonium the subject felt an initial increase in strength, subsequently followed by normal fatigue.

Andersson, K.-E. and K.A.P. Edman (Department of Pharmacology, University of Lund, Lund, Sweden): THE MECHANICAL OUTPUT OF SINGLE MUSCLE FIBRES AT DIFFERENT DEGREES OF HYDRATION. 175

According to the sliding-filament model the tension generated by the muscle fibre is dependent upon the number of active links formed and hence to the area of overlap between the A and I filaments of the myofibril. The characteristic relationship between sarcomere length and tetanic tension in single muscle fibres is accordant with this idea. It has previously been reported from this laboratory (Experientia 1968. 24. 134) that the changes in lateral spacing between the filaments that are normally associated with muscle shortening do not affect tension production. In the present study we have analyzed the mechanical output after equilibration of the fibre in different osmotic media. Ordinary Ringer's solution, Ringer + 50 mM sucrose (hypertonic solution) and Ringer containing 80 % of the standard NaCl concentration (hypotonic solution) were compared. The tetanic tension (P_{max}) and the maximal speed of shortening (V_{max}) both increased (by approx. 15 %) when the fibre was equilibrated in the hypotonic medium. The shape of the force-velocity curve was unaffected. A parallel decrease (by approx. 20 %) of P_{max} and V_{max} occurred by immersion of the fibre in the hypertonic solution As the measurements refer to given sarcomere lengths, the results would seem to make clear that the mechanical output per unit overlap area between the A and I filaments can be varied in a tetanically stimulated fibre. This suggests, in terms of the sliding-filament model, that the output of the individual active link, its contribution to fibre shortening as well as to tension production, can be varied by changing the state of hydration of the fibre.

180 Jokinen, Y. (Institute of Physiology, University of Helsinki, Finland): *THE MECHANISM OF ACTIVATION OF NEURONS IN THE RABBIT HYPOTHALAMUS IN* RESPONSE TO LOCAL THERMAL STIMULATION.

Like many other physiologic control systems, the thermoregulatory system receives its principal input from receptors located in hypothalamus. The existence of these receptors was verified at the cellular level by Nakayama et al. (Am.J.Physiol. 204:1122-1126).

To study the properties of the temperaturesensing elements in the preoptic area of adult rabbit, we recorded the single cell responses to the heating of the anterior hypothalamus, using glass capillary microelectrodes under light urethane anesthesia. The stimulus range was 2°C.

Among 210 preoptic neurons examined for temperature sensitivity we found 42 repeatedly responding cells. 24 of these were socalled "warm cells" and 18 "cold cells". 27 of them showed a linear relationship between the mean firing rate and the hypothalamic temperature. The remainder showed a relation which resembled an exponential function. Marked differences in the time structure of interspike interval sequences were found between these categories.

We concluded that the different types of cell cannot be activated by one and the same mechanism. Theoretically, a neuron can be activated by a change either in membrane properties or in synaptic input, and a combination of these components is also possible. Because it was not possible to differentiate the cell types by means of their location, our next step has been to construct a model where the activation mechanisms can be simulated with the aid of digital computer techniques. The output of the model is then subjected to the same procedures as the experimental material.

181 Wiesel, T. and Hubel, D. (Department of Neurobiology, Harvard Medical School, U.S.A.): PERIOD OF SENSITIVITY TO MONOCULAR DEPRIVATION.

A series of neurophysiological experiments were done in monocularly deprived kittens to determine the period of sensitivity to light and form deprivation. Our finding was that kittens were maximally sensitive to monocular deprivation between the 3rd and the 6th week after birth. During this period as little as 3 days of monocular closure was sufficient to produce a clear shift in the normal binocular dominance distribution for cortical cells, and detectable morphological changes in the lateral geniculate body. A closure for 6 days (23-29 day) was enough to cause a complete shift, so that the large majority of recorded cells responded only to the normal eye, just as was seen in kittens deprived for the first 3 months. The sensitivity to monocular deprivation began to decline after the 6th week, disappearing at about 12 weeks of age.

The interruption of normal connections in the visual cortex through monocular deprivation seems to be to a large extent permanent. An animal allowed to recover while still in the sensitive period, for example after a 5-week closure from birth, regained some slight control from the deprived eye over cortical cells over a period of several months or years but the large majority of cells nevertheless remained influenced by that eye. Animals deprived through the entire sensitive period show still less sign of physiological recovery.

Hultborn, H. and M. Udo (Department of Physiology, University of Göteborg, Sweden): SPATIAL CONVERGENCE OF SUPRASPINAL FACILITATION AND RECURRENT INHIBITION IN THE RECIPROCAL IA INHIBITORY PATHWAY. 182

The disynaptic reciprocal Ia inhibition from muscle spindles to antagonistic motoneurones is facilitated at an interneuronal level from many supraspinal structures (cf. Lundberg, Nobel Symposium I, 1966. 275-305). Recent experiments (Hultborn, Jankowska and Lindström, Life Sci. 1968. 7. 337-339) have shown that antidromic stimulation of ventral roots via motor axon collaterals and Renshaw cells causes a depression of the transmission in the Ia inhibitory pathway at an interneuronal level.

The technique of spatial facilitation has now been used to investigate whether the Ia inhibitory interneurones receiving excitatory action from supraspinal centres can be inhibited via recurrent collaterals. Intracellular recording was made from motoneurones. For each motoneurone the stimulation strength was chosen so that separate stimulation of either the supraspinal system or Ia afferents did not evoke an IPSP, while combined stimulation at suitable intervals gave a large IPSP. When preceded by stimulation of ventral roots this test IPSP was abolished or decreased This was found in more than 100 motoneurones belonging to different hindlimb muscles in which an IPSP appeared after facilitation from cortico-, rubro- or vestibulospinal tracts.

We conclude that a convergence from supraspinal and recurrent inhibitory pathways occurs on the same Ia inhibitory interneurones. This indicates that these two pathways are mutually interacting in the control of transmission in the Ia inhibitory pathway

Vallbo, Å.B. (Physiological department, Biological Institute, University of Umeå, Sweden): SINGLE UNIT ANALYSIS OF SLOWLY ADAPTING MUSCLE RECEPTORS IN MAN. 183

Impulses of single afferent fibres in muscle nerves were recorded from human subjects with tungsten electrodes inserted percutaneously. The tip diameters of the electrodes were 5-15 μ and the impedances were 50-150 kohm at 1,000 Hz. General or local anaesthesia was not used. Activities from 72 slowly adapting muscle receptors were studied. The main purpose was to experimentally penetrate the possibilities to define physiological characteristics which would allow an identification of the receptor type, and, second, to determine, in broad, the discharge patterns of the receptors during voluntary contractions without external shortening. For the majority of the endings characteristics of muscle spindles could be demonstrated such as high dynamic sensitivity to passive joint movements, discharge on relaxation after a voluntary contraction or irregular discharge in relaxed muscles indicative of fusimotor activity. During weak voluntary contractions without external shortening the majority of the units responded with a sustained discharge which started and stopped almost simultaneously with the onset and the cessation of the EMG activity. It was concluded that the motor cortex exerts a very powerful control of the intrafusal muscle fibres of the majority of the muscle spindles.

184 Lindquist, Chr. and A. Mårtensson (Department of Physiology, Karolinska Institutet, Stockholm, Sweden): THE POSSIBLE ROLE OF EXTEROCEPTORS IN THE CONTROL OF FACIAL MUSCLES.

It is still a matter of dispute whether muscle spindles are involved in the proprioceptive control of mammalian facial muscles. Morphological and physiological studies have not yielded conclusive data as to the possible presence of such receptors (Hosokawa, H., Texas Rept. Biol. Med. 1961. 19. 405). - Experiments undertaken to study the proprioceptive control of the cat's facial muscles have established that multisynaptic reflex responses of appreciable size are set up in facial muscles on stimulation of the corresponding intact muscle nerve. After section of this nerve no reflex response results when stimulating and recording from the central part of the nerve but is again obtained when the stimulating electrode is shifted to its peripheral part. This latter reflex response cannot be evoked in curarized animals and thus derives from the muscle contraction evoked. Similar reflexes were set up on stimulation of peripheral trigeminal nerve branches. - Afferent discharges induced in trigeminal nerve branches on contraction of facial muscles were analyzed in order to study the physiology and site of the receptors. These were found to respond to a sustained muscle contraction with a rapidly adapting impulse flow. The units studied so far were excited by, respectively, bending of coat hairs or of vibrissae or light touch of the skin. No evidence pointing to the presence of intramuscular contraction-sensitive receptors was found. These findings indicate that contraction-sensitive exteroceptors with afferent fibers in the trigeminal nerve may serve a proprioceptive control of the facial muscles.

185 Järvilehto, T. and Fruhstorfer, H. (Institute of Physiology, University of Helsinki, Finland): CHARACTERISTICS OF SLOW CORTICAL POTENTIALS ASSOCIATED WITH MOTOR AND MENTAL ACTS IN MAN.

The differences between CNV (Walter, W.G. et al., Nature 1964. 203. 380) and readiness potential (Kornhuber, H.H. and Deecke, L., Pflügers Arch. ges. Physiol. 1965. 284. 1) were studied in four situations. In the first situation (A) self-paced movements of the right index finger were used to elicit the readiness potential. The same motor act was timed by an oscilloscope sweep (B). Uncertainty about the quality of the motor act was added by a discrimination task determining the motor response which immediately followed the discrimination (C). In situation D the response followed 15 sec after the discrimination. The EEG was monopolarly recorded from electrodes located at Cz, Fz, and Fpz. Additionally, eye movements were recorded from an electrode situated just below the right eye. The EEG before and during the tasks was selectively summated in a computer omitting EEG epochs contaminated by eye movement, drop-out, or electrode artefacts. Preparation for a motor or mental task was associated with a negative wave maximal at the vertex, that disappeared during the initiation of the task. If uncertainty a[bout] the task was added, a frontal-negative wave appeared, which lasted the readiness potential and disappeared when the task was finished. The CNV seems to be composed of at least two components, one of which is the readiness potential and the o[ther] a frontal-negative wave associated with uncertainty.

Ungerstedt, U. (Dept. of Histology, Karolinska Institutet, Stockholm, Sweden): BEHAVIOURAL REGISTRATION OF DOPAMINE SYNAPTIC ACTIVITY IN THE BRAIN AFTER 6-HYDROXY-DOPAMINE LESIONS.

Several recent studies indicate that 6-hydroxy-dopamine (6-OH-DA) depletes peripheral nerves of noradrenaline by inducing a selective degeneration of the noradrenaline nerve terminals (Tranzer and Thoenen, N-S's Arch. exp. Path. Pharmak. 1967. 257. 74; Malmfors and Sachs, Europ. J. Pharmacol. 1968. 3. 89). In order to induce a degeneration of central monoamine neurons 6-OH-DA was injected stereotaxically in rats into the group of dopamine (DA) cell bodies located in the substantia nigra. The effect was studied with the histochemical fluorescent technique for monoamines. The injection resulted in a rapid degeneration of the whole DA-neuron system to the caudate nucleus with little damage to the brain tissue surrounding the DA cell bodies. Unilateral degeneration of this DA system produced marked turning of the animals to the side ipsilateral to the lesion. The turning could be increased, decreased or reversed by monoaminergic drugs. This was interpreted as an evoked imbalance in DA transmittor activity between left and right side of the brain and a method was worked out for the continous recording of turns per minute. With this method it has been possible to study DA synaptic activity under various pharmacological conditions. Amphetamine has been shown to produce a preferential release of DA from the lesioned neurons during the time of degeneration and the eventual disappearance of DA from the caudate nucleus seems to result in a DA receptor supersensitivity to e.g. apomorphine. The effect of DA release can be modulated by cholinergic drugs.

187

Arbuthnott, G.W. and Ungerstedt, U. (Department of Histology, Karolinska Institutet, Stockholm, Sweden). LOCOMOTOR BEHAVIOUR AFTER ELECTRICAL STIMULATION OF DOPAMINE CONTAINING NEURONES.

Recent experiments in this laboratory (Ungerstedt - this congress) have indicated that an unilateral activation of the dopamine receptors in the caudate nucleus will cause rats to rotate towards the unstimulated side. This result suggested that electrical stimulation of the dopamine neurones to the caudate nucleus should also cause rotation. Rats were prepared with electrodes chronically implanted among the axons of the dopamine neurones at the level of the lateral hypothalamus Electrical stimulation (200-600 μ A, 0.1 - 1.0 msec pulses at 50-100 Hz) through these electrodes did cause the animals to rotate towards the contralateral side. Not unexpectedly, since the electrodes were close to other extrapyramidal structures, other locomotor activity in response to stimulation was also observed: the rats reared up on their hind legs or flexed their contralateral limbs. It is possible to test which of these effects is due to stimulation of the dopamine neurones by pharmacological means, using drugs which have been shown to affect central monoamine transmission. Reduction of the catecholamine stores with tetrabenazine (10 mg/kg 1-2 hrs previously) or blockade of catecholamine receptors with Haloperidol (1 mg/kg 1-10 hrs previously) both reduce the rotation while the other movements associated with stimulation were hardly affected. Thus it seems possible that in this preparation the level of activation of the dopamine receptors can be estimated by measuring the rotation of the animals.

188 Clark, F.J.[x] and C.J. Hoffman (Purdue University, Lafayette. Ind. USA): A HIGH RESOLUTION MICROELECTRODE FOR MEASURING SPECIFIC IMPEDANCE IN THE CEREBRAL CORTEX.

Specific impedance at various depths in the cerebral cortex was measured at 1.6 KH_z using a novel thin film coaxial microelectrode technique which permitted measurement of very small volumes of tissue (0.01 mm^3). Experiments using rats indicated that spreading depression produces increases in specific impedance some 3 to 4 times the resting value, increases which are more than 10 times greater than those previously reported. (Van Harreveld, 1966, Brain Tissue Electrolytes. Washington: Butterworth). These higher values obtained in the present work were attributed to the very high resolution of the microelectrode method used.

Classical models relating specific impedance to extracellular volume were investigated to test their validity in application to suspension of complex insulating structures with high packing density. This investigation coupled with the results of the cortical specific impedance studies suggested that the classical models are indeed valid and that a large extracellular space exists in the cerebral cortex.

189 Rosén, I. and Sjölund, B. (Institute of Physiology, University of Lund, Sweden): NATURAL STIMULATION OF GROUP I ACTIVATED CELLS IN THE CUNEATE NUCLEI OF THE CAT.

This investigation supplements earlier studies of group I activated cuneate cells, which were based on electrical stimulation of nerves. — One forelimb was denervated except for the deep radial nerve which was mounted for stimulation and left in continuity with ext.carp.rad., dig.comm., dig. long. and carp.uln. The muscle tendons could be connected to a strain gauge or loaded with weights. Identification of receptors was based on: (1)Threshold and (2)adaptation on stretch. (3)Discharge pattern on contraction. (4)Effect of succinyl choline. — Out of 44 slowly adapting group I afferents found in the deep radial nerve 20% originated from tendon organs and 72% from muscle spindles. The tendon organ afferents and 86% of the spindle afferents could be antidromically activated from the dorsal funiculus at C3. In the main cuneate nucleus (MCN) 34 cells were activated from group I spindle afferents and 3 from tendon organ afferents. 14 cells could be antidromically activated from the medial lemniscus and were all activated from spindles. In the external cuneate nucleus (ECN) 44 cells were activated from spindle afferents and 4 from tendon organ afferents. About 70% of the cells in both nuclei were activated from only one of the four muscles. 19 of 39 ECN cells but only 2 of 33 MCN cells could be inhibited by stretch in one or more of the muscles not producing excitation. — The results show that (1) tendon organ as well as group I spindle afferents ascend through the dorsal funiculus, (2) the majority of cuneate cells and presumably all cuneothalamic cells are activated from spindles, (3) inhibitory actions from synergists are less common in MCN than in ECN.

Landgren, S. and Silfvenius, H. (Depts. of Physiology, University of Umeå and University of Goteborg, Sweden): THE MEDULLARY RELAY IN THE PATH FROM HINDLIMB MUSCLE SPINDLES TO THE CEREBRAL CORTEX OF THE CAT. **190**

Projections from hindlimb group I muscle afferents to the postsigmoid gyrus of the cat's cerebral cortex were described by Landgren and Silfvenius (J. Physiol. 1968. 200. 353). It was demonstrated that the ascending path travelled in the dorsolateral fascicle, and that it remained intact after removal of the cerebellum. The location of the spinal, medullary and thalamic synapses was unknown. In this series of experiments the rostral part of nucleus gracilis and the caudal part of nucleus vestibularis medialis was explored with penetrating microelectrode tracks in search of responses to electrical stimulation of group I muscle afferents from the quadriceps, posterior biceps semitendinosus, and gastrocnemius-soleus muscles. Cats anaesthetized with chloralose were used.

Focal potentials and action potentials of single neurones were recorded in response to threshold stimulation of the group I afferents. The latency was 4 to 5 msec. Cells responding to stimulation of group I afferents were discharged antidromically from the contralateral thalamus (entrance of the medial lemniscus into the ventrobasal nuclei, latency: 1 msec, frequency following: 800 per sec). The cortical group I response disappeared after a saggittal section in the midline of the IV ventricle. The response in the medulla was abolished by transsection of the dorsolateral fascicle at C 1 and was greatly reduced by transsection of the dorsal columns at L 5 thus just caudal to Clarke's column. The findings suggest that the medullary relay in the group I path from the hindlimb is located in nucleus Z of Brodal and Pompeiano (J. Anat. 1957. 91. 438).

Baldissera, F. and G. ten Bruggencate (Department of Physiology, University of Göteborg, Sweden): RUBROSPINAL EFFECTS ON SPINAL BORDER CELLS. **191**

Spinal border cells (SBC) which belong to the ventral spinocerebellar system (Burke, Lundberg and Weight, Acta physiol. scand. 1968. 74. 16A) receive monosynaptic connexions, both inhibitory and excitatory, from supraspinal pathways descending in the ventral quadrants of the spinal cord (Baldissera and Weight, Acta physiol. scand. 1969, in press). It will be shown here that a dorsal descending pathway, the rubrospinal tract, is also monosynaptically connected with the SBC. In chloralose anesthetized cats the contralateral red nucleus was stimulated with tungsten electrodes while recording intracellularly from SBC in the lumbar cord. In 10 of 56 SBC, monosynaptic EPSPs (segmental latencies of 0.4-0.6 msec) were elicited by red nucleus stimulation; in addition, in most of the cells EPSPs and/or IPSPs with longer latencies, suggesting a di- and/or trisynaptic linkage, have been found. These late effects were often facilitated by volleys in the flexor reflex afferents, mainly from the ipsilateral side. On the other hand the rubrospinal volleys were effective in facilitating the disynaptic IPSP evoked in SBC by group I afferent stimulation. The present and previous results demonstrate that these spinocerebellar neurones are monosynaptically influenced by several descending systems, i.e. vestibulospinal, reticulospinal and rubrospinal tracts, which are known to be the main target of cerebellar output.

196 Przybylski, A. (*Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden; Experimental and Clinical Medical Center, Polish Academy of Sciences, Warsaw, Poland*): SPECIFIC AND UNSPECIFIC STRENGTH OF THE STIMULUS.

It is assumed that every biological stimulus S has two components - specific S_s and unspecific S_n, and that $S = S_s + S_n$, (1)
which with regard to certain values of energy and information of a given receptive channel of the living system would be

$$S_s = I-I_o/E-E_o \approx \Delta I/\Delta E, \quad S_n = E-E_o/I-I_o = \Delta E/\Delta I; \tag{2}$$

where: I and E - the quantity of information and energy of the stimulus percepted by the living system, I_o and E_o - the actual quantity of "steady" information and energy of a given receptive channel of the system. Substituting ΔE by its corresponding change of entropy we have: $S_s = \Delta I/\Delta ST, \quad S_n = \Delta ST/\Delta I.$ (3)
Assuming that the specific strength of the adequate stimulus S_{as} is higher than its unspecific strength S_{an} we can write: $\Delta I_{as}/\Delta S_{as}T > \Delta S_{an}T/\Delta I_{an}$, (4)
from which inequality results - with supposition that $\Delta S_{as}T \leq \Delta S_{an}T$ and $\Delta I_{as} \geq \Delta I_{an}$ - that $\Delta I_{as} > \Delta S_{an}T$. (5)
Putting the value of $\Delta S_{an}T$ from the equation for the whole change of energy of a given receptive channel produced by the adequate stimulus

$$\Delta E_{as} = \Delta S_{as}T + \Delta S_{an}T \tag{6}$$

into the inequality (5) we have: $\Delta I_{as} > \Delta E_{as} - \Delta S_{as}T$ (7)
(phenomenon of gain of information of adequate specific stimulus).
From this inequality results that the informational component of the adequate specific stimulus exceeds its energy component.

obtain a proper fixation of the heavily myelinated motoraxons (see Conradi 1969 c). They nearly always showed splitting of the myelin sheath.

Comparison of the fixation methods

The general ultrastructural appearance of the gray matter with regard to membrane relationships was rather constant, when buffers between 100 mOsm and 500 mOsm were used (cf. Karlsson and Schultz 1965, Johnston and Roots 1967, Westrum 1967). With stronger buffers, however, the outline of the neuron cell bodies and dendrites was often somewhat wrinkled, as compared to the smooth outline, obtained with hypotonic or isotonic buffers. The addition of Rheomacrodex to the fixative did not change the fixation quality markedly, but the fixation of the white matter seemed to be improved.

The quality of the fixations was related to the perfusion method. With the first method mentioned above, in which the aorta was clamped before perfusion, a few experiments resulted in excellent fixation, but usually the result was poor. Insertion of the perfusion catheter directly into the aorta, without previous clamping, produced the following results:

Perfusions performed at a constant pressure, regardless of whether a pressure of 150 or 70 mm Hg was used, resulted in a rapid flow of fixative through the animal and the fixation was very poor. The spinal cord was soft and white, while the spinal muscles were often brown and hard. When, however, the perfusion pressure was varied periodically between about 50 mm Hg and zero, the fixation of the cord was good. In these cases, the deep spinal muscles appeared hard, although the superficial ones seemed nearly unfixed.

Quantitative study

Two animals were used for the quantitative investigation. Equal halves of the material were taken from each of the animals, which were fixed through perfusion at a discontinuous pressure, with 5% purified glutaraldehyde in 300 mOsm Millonig buffer. 2.7% Rheomacrodex was added to the rinsing fluid and fixative. Consecutive semithin transverse sections were cut in cranio-caudal direction, through a specimen from the most cranial millimetre of L 7, in animals in which the size of the lumbosacral roots, on macroscopic examination, seemed to indicate a prefixed lumbosacral plexus (Sherrington 1892).

When a motoneuron was cut through the nucleus, 2—4 grids with ultrathin sections, the depth of some microns apart, were made. About half of the specimens were cut through in this way. The ultrathin sections of each animal included, in total, about 20 motoneuron cell bodies, which were cut roughly through the middle of the nucleus, judging from inspection of the actual profile in the electron microscope. On the fluorescent screen there were, namely, some markings, through which it was possible to control that the profiles of all the motoneuron nuclei had about the same diameter as the profiles of those nuclei which were cut through the nucleolus. The nucleolus was cut through in about half the cases. Profiles of motoneurons, both those in which long profiles of proximal parts of the dendrites were included and those in which no dendrite was seen to project, were chosen from these sections. The profiles of 10 motoneurons were photographed in each animal. Three [illegible] of proximal

SEBASTIAN CONRADI

INTRODUCTION

In order to define the ultrastructural correlate of the monosynaptic connexions of dorsal root origin, Conradi and Skoglund (1968) studied both the normal and the degeneratively-changed boutons on lumbar spinal motoneurons in the cat. The reason for the inconclusive results in that paper is explained by the fact, that such a study requires a thorough knowledge of the bouton types on the motoneurons. This must be obtained by studying serial sections, which were not at hand at that time. A thorough understanding of the ultrastructure of spinal motoneuron synaptology in the adult cat is also of great interest for the neurophysiologist (see Smith *et al.* 1967) and it is furthermore an indispensable prerequisite for a study of the postnatal development of the motoneurons. As pointed out by Mellström and Skoglund (1969), the synaptology of the growing motoneuron poses some special problems. There are thus several reasons for undertaking ultrastructural studies of the spinal motoneurons. The guiding aim of the present investigation has been to obtain morphologic correlates to the postnatal maturation of the spinal reflex system, which shows considerable functional changes during this period of development (for reviews, see Skoglund 1966).

Following this intention, a series of six papers will be presented, dealing with different aspects of the ultrastructure of spinal motoneurons, first in the adult cat, and then in the newborn and growing kitten. In the present paper which is the first in the series, the fixation and sampling methods are de-

scribed. The normal ultrastructure of the neuronal and glial extensions on the motoneurons and in the surrounding neuropile in the adult animal is described. The different types of boutons are presented, and the size of the boutons and the distribution of them on the motoneurons in a restricted part of the ventral horn is studied. In the second paper, (Conradi 1969 b), the proximal part of a motoneuron dendrite, one section of which was included in the quantitative estimation in the first paper, is analyzed through serial sections. The three-dimensional distribution of the boutons on the surface of the dendrite is presented. The third paper (Conradi 1969 c) describes the ultrastructure of the axon hillock and initial motoraxon segment and the distribution of the boutons on these parts of the motoneuron. In the fourth paper (Conradi 1969 d), the changes after dorsal root section are studied. The population of boutons on the motoneurons six weeks after homolateral dorsal root section is studied and the findings compared with the normal state. It is concluded that two types of boutons disappear and the normal structure of these boutons is analyzed through serial sections. The last two papers deal with the postnatal development of the above-mentioned parameters and the results are discussed against the background of earlier physiologic findings. In the fifth paper (Conradi and Skoglund 1969 a), the development of the ultrastructure of the neuronal and glial extensions on the motoneurons is described beginning at the newborn stage. The size and distribution of the boutons of different types on the motoneurons in the newborn and at three weeks are analyzed in the same region of the ventral horn as in the adult. The proximal part of a motoneuron dendrite in the newborn stages is studied through serial sections. In the sixth paper (Conradi and Skoglund 1969 b), the postnatal development of the initial motoraxon segment and the dorsal root boutons is presented.

The lumbosacral motoneurons of the adult cat have been extensively studied with physiologic methods. Many studies with the light microscope have given a rather complete picture of the morphology of these cells. Earlier investigations (v. Lenhossek 1895, Ramon y Cajal 1909, for references, see Bok 1928) have been extended through detailed studies on the size-distribution (Schadé and van Harreveld 1961, Mellström and Skoglund 1969) and arrangement of the dendrites of the motoneurons (Lhermitte and Kraus 1925, Weil 1927, Chu 1954, Aitken and Bridger 1961, Scheibel and Scheibel 1966). The peripheral connexions of different motoneurons (Romanes 1951, Balthasar 1952) and the cytoarchitectonic organization of the ventral horn (Rexed 1954) have been worked out. The boutons on the motoneurons have also been investigated with light microscopy (Held 1897, Auerbach 1898,

Hoff 1932, Gibson 1932, Phalen and Davenport 1937, Lorente de No 1938, Barr 1939, Barnard 1940, Minckler 1940, Schadewald 1941, Haggar and Barr 1950, Aitken and Bridger 1961, Gelfan and Rapisarda 1964, Illis 1964) and with electron microscopy (see for example Wyckoff and Young 1956, Rosenbluth 1962, Gray 1963, Bodian 1964, 1966 a, b, Charlton and Gray 1966, Uchizono 1966, Ralston 1967). From the latter studies on several species, the boutons on the motoneurons have been shown to be of different morphologic types and it has been suggested that the morphologic typing has a physiologic counterpart (Bodian 1966 a, b, Uchizono 1966).

In the present study, the ultrastructure of the boutons and other extensions on the motoneuron cell membrane and in the surrounding neuropile is studied in the lateral motoneuron nucleus in segment L 7 (Peroneus: Romanes 1951, Balthasar 1952), after perfusion with buffered glutar aldehyde. The above-mentioned earlier classification of the boutons is used and somewhat extended. The different bouton types are followed through serial sections, but the types are, as far as possible, defined from the appearance in single sections, so that all bouton profiles in a section could be typed.

The size and distribution on the motoneurons of the boutons of different types is then investigated quantitatively on single sections. The technique and the results are used for the evaluation of the changes after dorsal root section and during the postnatal development. A complete mapping of the number and types of boutons on the motoneurons would require lengthy series of consecutive sections, which work would be too time-consuming at present. Instead, an attempt has been made to estimate the size and distribution of the boutons from single sections. The following factors seem to be of importance for such a study:

a) The work must be performed at a strictly localized region, so that values from different animals can be compared.
b) Neurons with the same morphologic characteristics should be used and the countings made at defined areas of the neurons.
c) The plane of section ought to be the same in all animals used.

The present study was performed on transverse sections through the mid-nucleus level of motoneurons in the lateral motoneuron nucleus in the most cranial millimeter of L 7. This region of the spinal cord was used since direct comparisons with earlier data on the postnatal development of some quantitative parameters (Mellström and Skoglund 1969) can be made, and because the population of cells in the different animals are topographically, thus functionally related.

MATERIAL AND METHODS

33 adult cats of both sexes were used. The fixation method has been published previosuly (Berthold 1968) in an ultrastructural investigation on the spinal roots on roughly the same material as that used here. Briefly, the method was the following:

Fixation method

a) Fixative: 5%, or in a few cases 2.5% glutar aldehyde was used throughout. In most cases, the stock solution, containing 25% glutar aldehyde in water (KEBO, Stockholm) was purified with active charcoal (Fahimi and Drochmans 1965, Anderson 1967) before use. The osmolality of 5% purified glutaraldehyde in distilled water, as determined cryoscopically, was about 500 mOsm.

The purified glutaraldehyde was dissolved either in the buffer system of Millonig (see Karlsson and Schultz 1965), which has an osmolality of 440 mOsm at pH 7.4, or during the earlier experiments, in a phosphate buffer of similar composition. The Millonig buffer was mostly diluted with distilled water so that the osmolality of the buffer in the fixative was 200—300 mOsm, thus isotonic to cat serum (Handbook of Biological Data 1956). Consequently, the total osmolality of the fixative was about 800 mOsm at pH 7.4.

In 4 animals, the buffer was 100 mOsm and 500 mOsm, respectively. In about 2/3 of all animals, 2.7%, or in a few cases, 8.1% Rheomacrodex® (Pharmacia, Sweden) was added to the fixative and rinsing fluid.

b) *Perfusion technique:* The cats were anaesthetized intraperitoneally with pentobarbital, 40 mg/kg body weight, and kept on artificial respiration through a tracheal cannula. The chest was opened and the left lung removed. One of the following two methods was then used:

1) (10 animals). During the earlier part of the study, the aortic arch was clamped, the descending aorta opened, and the perfusion cannula, a teflon tube, was inserted downward. The right auricula was opened and the coeliac, mesenteric and femoral arteries were clamped. Rinsing fluid (Ringer's solution) and the fixative were admin*istered from 50 ml syringes in a manner similar to that described by Osvaldo and* Latta (1966). 50 ml rinsing fluid and 100 ml fixative, both at 37°C, and 400 ml icecold fixative were perfused for 15 min. In this method the ionic strength of the buffer in the fixative was 360 mOsm.

2) In 23 animals, the perfusates were administered from three complete infusion sets, containing Ringer's fluid at 37°, fixative at 37° and icecold fixative, respectively, and connected to the perfusion catheter through a three-way stopcock. Each set was connected *to a blood pressure balloon and a manometer, by which the pressure in the sets could* be changed between zero and 300 mm Hg and continuously controlled. The fluid level in the sets was 10—20 cm above the heart level of the animals. The perfusion catheter, a sharpened teflon tube, was inserted directly downward into the descending aorta *through the arterial wall: the rinsing fluid was immediately delivered. The inferior* v. cava was opened and the coeliac and mesenteric arteries clamped. The perfusion pressure was kept at 100 mm Hg during the rinse (about 15 sec.). During the fixation,

the pressure was either constantly maintained at 150 mm Hg (2 animals) or 70 mm Hg (2 animals) or brought to fluctuate periodically between about 50 mm Hg and zero, 2—3 times per minute (15 animals). 50 ml prerinse at 37°C, 100 ml fixative at 37° and 500—1000 ml icecold fixative were perfused for 20—30 minutes. In these animals, the ionic strength of the buffer was 250 or 300 mOsm. The majority of the operated cats (Conradi 1969 d) were fixed in the same way. Some of the observations refer to the unoperated side of these cats. The above-mentioned procedure was also used with buffers of 500 mOsm and 100 mOsm. Rheomacrodex was used only with this fixation technique.

c) *Postfixation*: Immediately after the perfusion, the spinal canal was opened and the lumbosacral part of the spinal cord excised. Thin transverse slices of the segment L 7 were cut and divided into two symmetric halves, which were postfixed for four hours in a fixative quite similar to the perfusate, but lacking Rheomacrodex. After a rinse (30 min.) in icecold veronal acetate buffer (Andersson-Cedergren 1959) or 300 mOsm Millonig buffer, the blocks were postfixed in icecold 2% OsO_4 in veronal acetate, or 300 mOsm Millonig buffer. After another rinse for 30 min., the tissue blocks were dehydrated in increasing concentrations of acetone for a total of 12 hours, then embedded in Vestopal W.

d) *Sectioning:* On an LKB 4801 Ultrotome, semithin transverse sections of half the spinal cord were prepared; the sections were stained with toluidine blue and examined in the light microscope. The lateral part of the ventral horn was trimmed out and cut into ultrathin sections. In some cases, vertical sections of the lateral motor column were also studied. The ultrathin sections were collected on one-hole grids according to the method of Galey and Nilsson (1966). In most cases, 5—15 consecutive sections were collected on the grids. Longer series, comprising 50—300 consecutive sections, in which a few random single sections were lost, were also studied. Neither in the present nor in the forthcoming papers, were any attempts made to calculate the tissue compression, or errors due to an uneven plane of section, at sectioning. The ultrathin sections were stained with uranyl acetate and lead citrate and examined in an RCA 3A, Philips EM 200 or Philips EM 300 electron microscope.

Fixation quality

The quality of the fixation could be roughly determined by macroscopic examination of the spinal cord. After successful perfusions, the cord was an even yellow colour, firm, and somewhat elastic; the blood vessels on the surface were filled with a clear fluid. The gray substance was usually better fixed than the white, the latter often exhibiting small white spots. In the light microscope, lacunae around the capillaries, extracellular rims around the neuron perikarya and/or markedly split myelin were observed in some specimens. Such phenomena were taken as indications of an unsatisfactory fixation.

Ultrastructurally, the general appearance of the gray matter in well fixed material was similar to that reported earlier from the CNS (Karlsson and Schultz 1965), after aldehyde perfusion. Common criteria for a good ultrastructural preservation of central nervous tissue (Palay *et al.* 1962, Pease 1964, Karlsson and Schultz 1965) were applied in evaluating the different fixation methods. With all methods it was very difficult to

obtain a proper fixation of the heavily myelinated motoraxons (see Conradi 1969 c). They nearly always showed splitting of the myelin sheath.

Comparison of the fixation methods

The general ultrastructural appearance of the gray matter with regard to membrane relationships was rather constant, when buffers between 100 mOsm and 500 mOsm were used (cf. Karlsson and Schultz 1965, Johnston and Roots 1967, Westrum 1967). With stronger buffers, however, the outline of the neuron cell bodies and dendrites was often somewhat wrinkled, as compared to the smooth outline, obtained with hypotonic or isotonic buffers. The addition of Rheomacrodex to the fixative did not change the fixation quality markedly, but the fixation of the white matter seemed to be improved.

The quality of the fixations was related to the perfusion method. With the first method mentioned above, in which the aorta was clamped before perfusion, a few experiments resulted in excellent fixation, but usually the result was poor. Insertion of the perfusion catheter directly into the aorta, without previous clamping, produced the following results:

Perfusions performed at a constant pressure, regardless of whether a pressure of 150 or 70 mm Hg was used, resulted in a rapid flow of fixative through the animal and the fixation was very poor. The spinal cord was soft and white, while the spinal muscles were often brown and hard. When, however, the perfusion pressure was varied periodically between about 50 mm Hg and zero, the fixation of the cord was good. In these cases, the deep spinal muscles appeared hard, although the superficial ones seemed nearly unfixed.

Quantitative study

Two animals were used for the quantitative investigation. Equal halves of the material were taken from each of the animals, which were fixed through perfusion at a discontinuous pressure, with 5% purified glutaraldehyde in 300 mOsm Millonig buffer. 2.7% Rheomacrodex was added to the rinsing fluid and fixative. Consecutive semithin transverse sections were cut in cranio-caudal direction, through a specimen from the most cranial millimetre of L 7, in animals in which the size of the lumbosacral roots, on macroscopic examination, seemed to indicate a prefixed lumbosacral plexus (Sherrington 1892).

When a motoneuron was cut through the nucleus, 2—4 grids with ultrathin sections, the depth of some microns apart, were made. About half of the specimens were cut through in this way The ultrathin sections of each animal included, in total, about 20 *motoneuron cell bodies, which were cut roughly through the middle of the nucleus,* judging from inspection of the actual profile in the electron microscope. On the fluorescent screen there were, namely, some markings, through which it was possible to control that the profiles of all the motoneuron nuclei had about the same diameter as the profiles of those nuclei which were cut through the nucleolus. The nucleolus was cut through in about half the cases. Profiles of motoneurons, both those in which long profiles of proximal parts of the dendrites were included and those in which no dendrite was seen to project, were chosen from these sections. The profiles of 10 motoneurons were photographed in each animal. Three long profiles of proximal

parts of dendrites, projecting from motoneurons, in which the nucleus had not been ideally cut, plus 15 long profiles of thin, longitudinally-sectioned dendrites from the neuropile just outside the motoneurons, were also photographed in each of the animals. Thus, the majority of the countings on the dendrites refers to horizontally-directed processes. The origin of the thin dendrites could not be determined; nevertheless, an investigation of the membrane relationships of the thin dendrites was thought to be of interest since at least some of them ought to belong to motoneurons (see the discussion). The primary magnification of the photographs was about 3000X and the paper magnification 5X. This magnification was chosen since the surface contact of every bouton with the actual profiles could easily be recognized. The copies were taped together to montages. Usually 5—10 copies were required to cover the circumference of one motoneuron cell body. On the montages, the border between the motoneuron cell body and the dendrites, roughly defined as the inflexion point of the membrane in the plane, was demarcated.

The long profiles of proximal dendrites were divided into two parts. The most proximal part, (DA), was defined as the region covered at one side by the first 20 boutons, counting from the cell body. The part distal to this was denoted DB. The cell body was depicted SO and the thin dendrites d. Hereafter, the relationships of these regions of the motoneuron were treated separately. When proximal parts of dendrites had been cut obliquely, forming only a slight hump on the profile of the cell body, the membrane relationships were included in the DA group.

The dimensions of the profiles of the cell bodies and dendrites were measured on the montages. The least diameter was noted for the cell bodies, since occasional ovoid contours were thought possibly to have been due to the nearness of the bases of a thick dendrite, which was out of the plane of the section. The diameter of the nucleus and presence of nucleolus were noted. The diameter was measured on the dendritic profiles except in those cases, in which only very short stumps projected from the motor cell bodies. The length of the membrane of every profile was measured with a rolling map distance measurer.

The type of every bouton or other tissue component on the cell bodies and dendrites was determined through direct inspection of the actual section at high magnification in the electron microscope and the result of this typing was depicted on the montages. Finally, the length of apposition to the profiles of the motoneurons and dendrites, of the different boutons and other tissue components and the height of every bouton profile were measured on the montages. The values were set up in table form. Apart from the total number of bouton profiles on every motoneuron or dendritic profile, the relative proportion and mean length and height of the different bouton types was calculated. The membrane covering of the boutons on the profiles was expressed either as

$$\frac{\text{total length of apposition of the boutons}}{\text{membrane length}} \quad \text{or} \quad \frac{\text{membrane length}}{\text{no. of boutons}}.$$

The former was calculated both for all boutons, or for the different types and requires knowledge of the dimensions of the boutons. The latter, which can be translated as mean distance along the membrane between the centres of adjacent boutons, does not require knowledge of the size of the boutons. The tables in the present and the following papers (Conradi 1969 d, Conradi and Skoglund 1969 a) are

neuron cell membrane, but they are most often found at a greater distance, in the surrounding neuropile (Fig. 2). Proximal parts of the motoneuron dendrites are covered by astrocytic extensions to a lesser extent than the cell bodies. A greater proportion surface area of the proximal parts of the dendrites is covered by boutons. The dendrites in the neuropile are surrounded by many flattened astrocytic extensions.

Oligodendrocytes (see Magnaini and Walberg 1964, Kruger and Maxwell 1966, Wendell-Smith et al. 1966) are usually found in the neuropile (Fig. 2) or as satellite cells at the motoneuron cell bodies (Fig. 4), but seldom at proximal parts of the dendrites and thin dendritic profiles. In nearly all cases, a thin astrocytic lamella is interposed between the cell membrane of the oligodendrocyte and the motoneuron (Fig. 4). In fact, direct apposition between oligodendrocytic and neuronal cell membranes, except at the myelin, is seldom observed anywhere in the neuropile. Some glial cells, similar to microgliacytes, were also observed in the neuropile (Fig. 2) (for references and further information see Conradi 1969 c and d).

Myelinated fibres and capillaries were sometimes observed just outside the motoneuron cell membrane, but in the majority of the cases, thin astrocytic lamellae were interposed.

Dendrites

At some places, most often at the dendrites, the motoneuron membrane has immediate contact with adjacent dendritic profiles. Two types of contacts were observed.

The most common type consists of a mere apposition of the motoneuron cell membrane and an adjacent dendrite without any visible membrane specialization and little, if any, extracellular material interposed (Fig. 5). The second type consists of a desmosome-like arrangement, similar to the contact between adjacent neurons in the lateral geniculate nucleus as described by Peters and Palay (1966), which shows a symmetric apposition of contrasting material at the cytoplasmic side of the membranes and an intervening 100—200 Å wide cleft, containing a dense material (Fig. 6). In addition to this, two adjacent dendritic profiles, separated only by a single flattened astrocytic process, were often observed.

Boutons

In an extensive review of the ultrastructure of synapses, the term "synaptic complex" is defined as a region of specialized contact between two neuronal

extensions (Gray and Guillery 1966). The presynaptic extension is most often an axon enlargement, named bouton or synaptic knob, which is filled with synaptic vesicles. This specialization exhibits the following characteristics:

a) A presynaptic membrane, at the inner side of which the synaptic vesicles and usually a thin layer of contrast-rich material are apposed.
b) A synaptic cleft, which has a uniform thickness and seems usually to contain a contrast-rich material.
c) A postsynaptic membrane, which is covered by a layer of contrast-rich material.

The above-mentioned criteria for the recognition of synaptic complexes have been adopted in the present study and proved very useful for an analysis of the synaptic complexes on the motoneurons.

General features of the synaptic complex. The synaptic cleft usually occupies only a minor part of the apposition region between the boutons and the motoneurons cell membrane, and except at C boutons (see below), it very seldom reaches the periphery of the apposition region (Figs. 7 and 8). The contrast-rich material at the presynaptic membrane is usually less pronounced than at the postsynaptic membrane. Sometimes "dense projections" (Gray 1963) could be observed at the presynaptic membrane. In boutons with a large synaptic cleft, the synaptic vesicles are most often apposed only at part of the presynaptic membrane. The contrast-rich material filling the synaptic cleft is very dense and homogeneous in well-fixed specimens (Fig. 8).

As revealed by serial sectioning, practically all boutons seemed to establish a synaptic complex or a structure similar to this, many of them establishing more than one synaptic complex with the motoneuron cell membrane. It is rather seldom observed that boutons in synaptic contact with a motoneuron profile make synaptic contact with still another profile. When observed, such "double synapses" occur most frequently at thin dendritic profiles in the neuropile (Fig. 7).

Membrane relationships of the boutons

The convex side of the boutons is generally surrounded by thin astrocytic lamellae (cf. Wolff 1965) which can be observed in Fig. 13. Some of the boutons, especially bigger ones, are also contacted at the convex side by thicker astrocytic extensions. In many cases the glial encapsulation was incomplete and adjacent boutons were directly apposed (Fig. 8). In some rare instances, a desmosome-like junction was present at apposing boutons.

Near the synaptic complex "coated" vesicles and invaginations were sometimes observed (cf. Andres 1964). Lateral to the synaptic cleft, the cell membrane of the bouton and postsynaptic profile were mostly tightly apposed, and arrangement quite similar to that in earlier descriptions from various regions of the CNS. Small desmosome-like junctions (Hamlyn 1962, Karlsson 1966 b, Gray and Guillery 1966, Mugnaini *et al.* 1967) were frequently observed in this region (this is seen in Fig. 13) and seemed to be present at all bouton types. They extended for about 400—1000 A; the membranes were 100—200 A apart. These desmosomes were often isolated from the synaptic cleft, although in some cases they seemed to form the lateral border of the synaptic cleft. At low magnification, large desmosome-like figures are difficult to distinguish from synaptic complexes.

In many places, especially around motoneuron cell bodies, some of the boutons were not perfectly aligned to the postsynaptic membrane. Instead, a 200—700 A wide extracellular space (Fig. 9), commonly containing a fine, granular material, was interposed. Sometimes the space was observed to extend into the region between two adjacent boutons, where "coated" invaginations and vesicles could be found at the cell membranes. Such spaces were also observed, when a 100 mOsm buffer system was used. A small, flattened, membrane-bound sac was frequently situated below the cell membrane of the postsynaptic profile at these spaces (Fig. 9). Continuity between the sac and granular endoplasmic reticulum was noticed in some cases, and a dense material could often be observed between the sac and the motoneuron cell membrane (cf. Siegesmund 1968). Some boutons were apposed at spinous projections from the motoneurons (cf. Bodian 1964, 1966 b).

Preterminal axons. In single sections, connexions between preterminal axons and boutons are rather seldom observed. Many observations, both from single and serial sections, however, revealed that the majority of the preterminal axons are unmyelinated 2—5 μ, before the bouton (Fig. 10). This also holds true for the biggest boutons. Boutons *de passage* were rather infrequently found. At myelinated preterminal axons, a thin rim of extracellular material was observed around the axon just distal to the myelin sheath. A similar arrangement has previously been described at boutons in the rat brain (Karlsson 1966 b).

Different types of boutons

The boutons and the synaptic complexes adjoining them could be divided into several morphologic types, some of which have been described earlier

in the spinal cord of different species (Rosenbluth 1962, Gray 1963, Bodian 1964, 1966 a, b, Uchizono 1966, Ralston 1967). The description and abbreviations used by Bodian will be followed as far as possible in this study. Boutons containing spherical synaptic vesicles and in which the layer of postsynaptic material was of even thickness, were denoted S (spherical) (Fig. 11). In those cases where postsynaptic dense bodies were observed, the term T (Taxi) was used (Fig. 12). Boutons containing flattened synaptic vesicles were denoted F (flattened) (Fig. 13). Some of these contained a dense ground substance and often membrane-bound dense bodies; they were called FD (dense) (Fig. 14). Big boutons, containing spherical synaptic vesicles, and in which a subsynaptic cistern was situated below the boutons, were denoted C (cistern) (Fig. 16). Some big boutons containing synaptic vesicles showed a large synaptic complex of irregular shape, almost completely covered by the postsynaptic bodies of Taxi (1961). Since these boutons seemed to disappear after dorsal root section (Conradi 1969 d), they were denoted M (monosynaptic) (Fig. 18). At the convex side of these and apparently at some big S boutons, small boutons, containing small vesicles of irregular shape, were apposed; these boutons were designated P (presynaptic) (Fig. 18). Some boutons, often those with spherical synaptic vesicles also contain dense-cored vesicles, 700—100 A in diameter (Fig. 20). These dense-cored vesicles are usually not apposed at the presynaptic membrane. Since the relative number of such vesicles varies between the boutons, it is difficult to define a separate bouton type based on the presence of these vesicles. Recent work indicates that large, dense-cored vesicles form an unspecific characteristic, not believed to be linked to, for instance, any particular transmitter substance (Pellegrino de Iraldi and de Robertis 1968, Hökfeldt 1968).

The different types of boutons were investigated through serial sections. Generally, the shape of the synaptic vesicles in each bouton remained constant throughout the series. In a few cases, some of the vesicles inside the same bouton appeared spherical, others appeared to be flattened. These were classified as belonging to the F-type.

In nearly all instances, it is rather easy to distinguish S from F boutons on single sections when the tissue is well fixed. A curious difference between F boutons and the other types was noted in this study. When the specimens were rinsed and osmificated in veronal acetate buffer, a fine, granular precipitate was often present in the tissue, even in unstained sections. The precipitate was usually concentrated on membranes, mitochondria and synaptic vesicles. On the synaptic vesicles, however, it was much more intense in F

than S boutons (Fig. 21). When Millonig buffer was used instead of the veronal acetate, most of the precipitate disappeared.

In some big boutons, mostly those containing spherical synaptic vesicles, neurofilaments could be observed. These frequently formed a bundle, which seemed to be continuous with the neurofilaments inside the preterminal axon. Membrane-bound dense bodies were observed in some boutons, often those of the FD-type.

The S-type. (Fig. 11). Many 0.5—4 μ long profiles of boutons containing spherical vesicles are observed at all regions of the motoneuron cell membrane. The diameter of the vesicles is 350—500 A and these boutons generally exhibit a clear ground substance. The synaptic cleft is about 150 A thick, and the layer of postsynaptic material varies somewhat in thickness, between 50 and 200 A. Some contrast-rich material is usually attached to the presynaptic membrane.

The T-type. (Fig. 12). The boutons exhibiting postsynaptic dense bodies have the same general characteristics as the S-type. The synaptic cleft is often somewhat larger and about 150 A thick. Especially at thin dendritic profiles, boutons of this type show comparatively large synaptic complexes. There is a 200—300 A thick layer of postsynaptic dense material, below which the postsynaptic dense bodies are situated; 3—7 of these bodies can ordinarily be seen in one section. This type of synaptic complex has earlier been found in the spinal cord (Gray 1963, Bodian 1964, 1966 b) and in other regions of the CNS. In the present material, it was often observed that several boutons showing this type of synaptic complex were situated near each other.

In some cases, the same bouton made synaptic complexes of both the S- and T-type (see Conradi 1969 b). In the quantitative estimation, such boutons were classified as the T-type.

The F-type. (Fig. 13). Boutons containing flattened synaptic vesicles, 200—300×400—600 A in diameter (cf. Uchizono 1966, Bodian 1966 b), are intermingled with boutons of other types on all regions of the motoneuron surface. These boutons nearly always contain a clear ground substance, usually each bouton establishes several synaptic complexes. The synaptic cleft, 90—130 A thick, is narrower than at the S-type (cf. Ralston 1967). A thin layer of contrast-rich material, 50—150 A thick, is attached to the postsynaptic membrane (cf. Ralston 1967, Colonnier 1968). As a rule, no postsynaptic bodies of Taxi were observed below boutons with flattened

vesicles. The synaptic clefts of the F boutons are either small, roughly 0.1—0.5 μ, or large, roughly 0.5—2 μ (Figs. 13 and 15).

Some of the F boutons with the large synaptic cleft could be very big; usually showing a dense ground substance containing dense membrane-bound profiles and often small, circular, contrast-rich profiles (Figs. 14 and 15). Such boutons could be seen to be partially invaginated in the postsynaptic profile. The number and appearance of these boutons, which were denoted FD, varied between the specimens; they were therefore not included in the statistical evaluations as a separate entity.

The C-type. (Figs. 16 and 17). On the motoneuron cell bodies and proximal parts of the dendrites, 3—7 μ long profiles of boutons are often observed. These boutons form the biggest bouton type on the motoneurons and, as Bodian (1964) noted, two or more of these boutons are frequently grouped together. The type has also been described by Rosenbluth (1962), Gray (1963), Bodian (1964, 1966 b), Charlton and Gray (1966) and van Harreveld and Khattab (1967). The boutons are filled with tightly-packed spherical vesicles, 350—500 A in diameter, among which some dense-cored vesicles are often intermingled. A subsynaptic cistern is located just inside the postsynaptic membrane. The synaptic cleft, which is very large and very narrow, 30—80 A, extends under almost the entire bouton. Furthermore, no material is attached at the pre- or postsynaptic membranes, and the synaptic vesicles are not apposed along the whole of the presynaptic membrane. The very flat subsynaptic cistern extends inside the entire postsynaptic membrane and sometimes the cistern is seen to communicate with the sacs of granular endoplasmic reticulum. One single cistern may extend below 2 or 3 adjacent boutons. Below the cistern, the postsynaptic cytoplasm often contains granular endoplasmic reticulum. This is especially prominent on the proximal parts of the dendrites, where several sac-like profiles of the endoplasmic reticulum can often be seen. These profiles are oriented parallel to the cell membrane, which frequently bulges below the boutons (Fig. 16). No C boutons were observed on the smaller neurons in the neuropile. The presence of C boutons was, in fact, one of the criteria for distinguishing the neurons, assumed to be motoneurons, in this study.

The M-type. (Figs. 18 and 19). At proximal parts of the motoneuron dendrites, profiles of big boutons, 4—7 μ in length, and containing spherical synaptic vesicles, 350—500 A in diameter, are sometimes found. The vesicles are usually somewhat scattered and distributed throughout the bouton, which otherwise exhibits a very clear ground substance. These boutons form large

synaptic complexes of irregular shape, in which the whole postsynaptic membrane is covered by a 200—300 A thick layer of contrast-rich material and the postsynaptic dense bodies. Several profiles of synaptic complexes are commonly seen in one section, where, due to this, 15—20 postsynaptic dense bodies often can be visible below one bouton. In some cases, M boutons were situated at several dendritic spines. On the convex side of these boutons, small P boutons, containing small vesicles of irregular shape, 250—400 A in diameter, are regularly apposed. The large size of the extension of the synaptic complex and the presence of the P boutons differentiates the M from the T boutons.

When longer series of consecutive ultrathin sections are studied (Conradi 1969 b, d), P boutons are sometimes also found to be apposed at big boutons containing spherical vesicles. These boutons have then to be classified as belonging to the S-type, since they do not exhibit the large synaptic complex covered by a great number of postsynaptic dense bodies, typical for the M-type. In the quantitative estimation, all boutons on which P boutons were apposed were classified under the same heading. In single sections, it is not always possible to judge whether the actual bouton profile is an M bouton, sectioned outside the synaptic cleft, or a big S bouton, of the variety just mentioned.

Sometimes the P boutons were apposed both at one of these big boutons and at the motoneuron cell membrane. If these P boutons were cut through and no synaptic complex of the bouton could be seen, it was not possible to judge by inspection alone whether the profile was of the P- or F-type. No separate heading for the P boutons was used in the quantitative estimation, which accounts for some P boutons possibly having been included under the F heading in the quantitative study of single sections.

The M boutons and the big S boutons, having P boutons apposed at the convex side, will be further dealt with in connexion with the findings after dorsal root section (Conradi 1969 d).

Quantitative estimations

The size and distribution on the motoneurons of bouton profiles of the different types was investigated on single transverse sections through the lateral motoneuron nucleus, in the most cranial millimeter of L 7 (see Material and Methods). Four regions were investigated: the motoneuron cell bodies (SO), the proximal parts of the motoneuron dendrites (DA, DB) and small, longitudinally-sectioned dendritic profiles in the neuropile (d). The

bouton profiles have been typed according to the criteria given above. Data from the different motoneuron profiles are presented in Table 1. The ensuing description will concentrate on the mean values of the different parameters presented in Table 2.

Profiles of cell bodies and dendrites (Table 2)

The mean least diameter of the cell bodies was about 49 μ, a figure which agrees well with that in the earlier light microscopic studies from this region (Mellström and Skoglund 1969). There are some variations between the different cells. Since the sections cut the cell bodies at a defined level (see Material and Methods), the diameters obtained here are probably a closer estimate of the true diameter than is the case for the dendrites, which were sectioned at random. The mean diameter of the dendritic profiles decreases with increasing distance from the cell body, and the mean value for the diameter of the dendrites in the neuropile is less than half that from the proximal parts of the motoneuron dendrites.

Location of the different bouton types (Table 2)

S, T and F boutons are found on all regions of the motoneuron surface. There is an increase in the relative proportion in the number of apposing F boutons in the sections from the distal dendrites towards the cell body, where these boutons form more than half the number of apposing boutons. The situation for the proportion of apposing S boutons is the reverse. T boutons are most frequently encountered at thin dendritic profiles. C boutons are restricted to motoneuron cell bodies and proximal parts of the dendrites: about twice as many occur at the former location. The M boutons are almost exclusively found at the proximal parts of the motoneuron dendrites. Thus, each of the regions of the motoneurons seems to be surrounded by a specific spectrum of the various types of boutons. The occurrence in the sections of bouton profiles of these types is, of course, dependent upon the size of the boutons. There is a greater chance for big boutons to be included in the sections. This must be taken into account when estimating the true numerical proportion of boutons of different types on the regions of the motoneurons (see the Discussion). The most appropriate way to express the population of boutons seems to be as the percentage of bouton covering on the cell membrane of the motoneuron cell bodies and dendrites. This expression can be calculated both for all boutons as well as for each type separately, and is independant of the size of the boutons (see below).

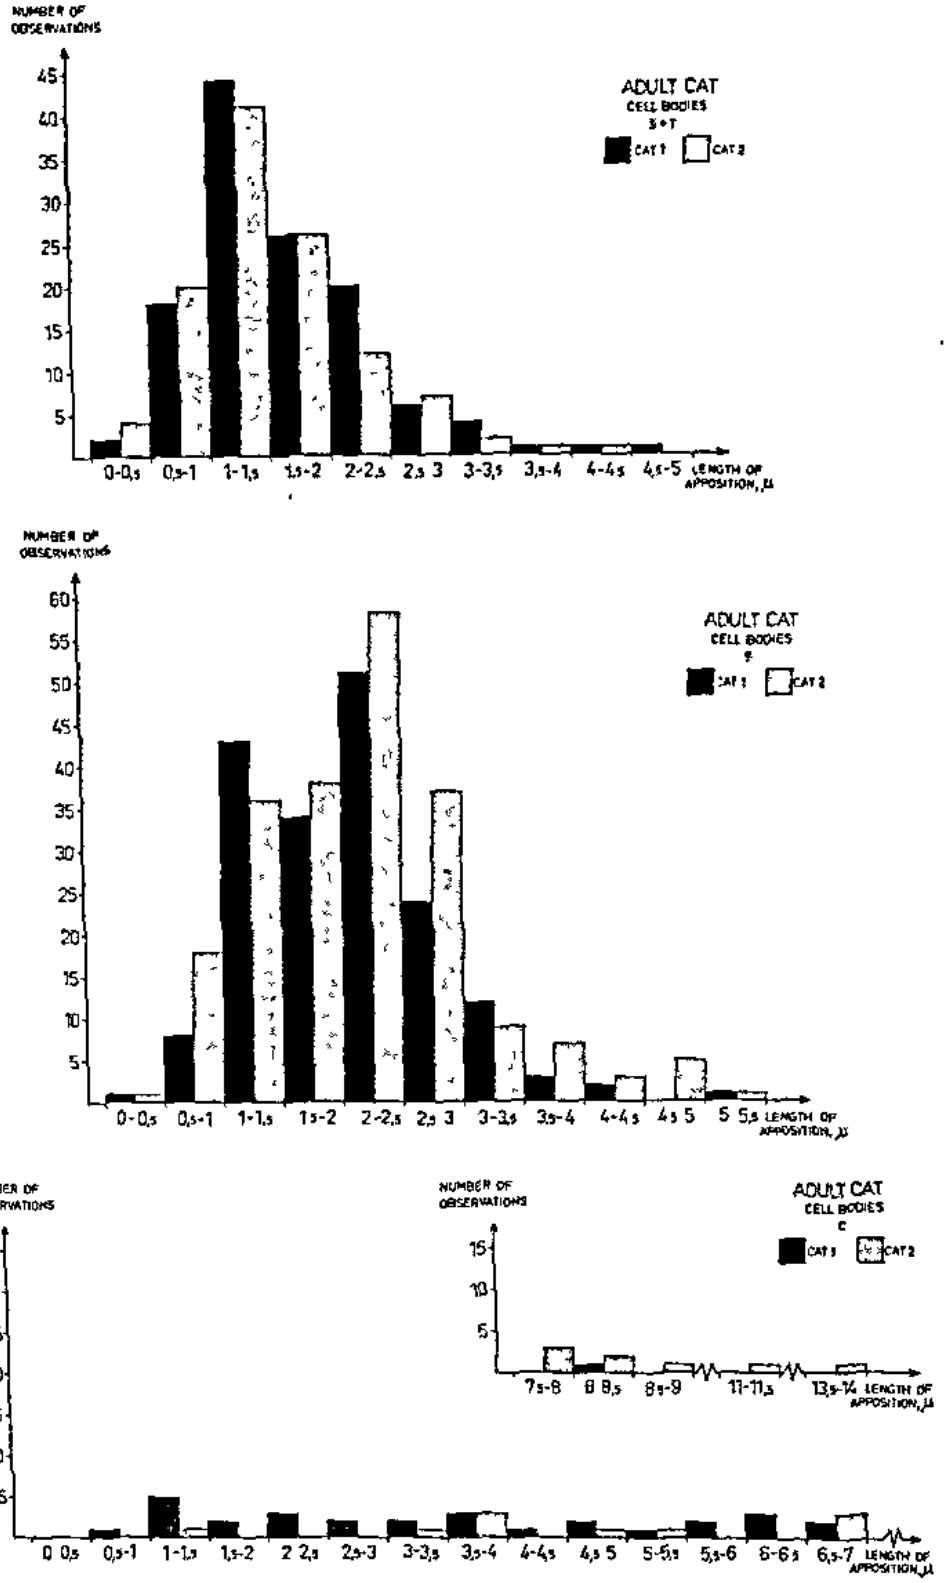
Mean size of the different bouton types (Table 2)



The mean length of apposition of the profiles of S, T and F boutons is around 2 μ. The F boutons are slightly bigger than the S boutons, especially on the cell bodies ($10\% > p > 5\%$) while the C- and M-types are 2—3 times bigger than the others. Boutons with higher values for length of membrane apposition usually are greater in height. For the S and T boutons, the mean length of apposition is rather similar in the different regions, but there is a tendency for the F boutons on the cell bodies to be bigger than those on the thin dendrites ($10\% > p > 5\%$).

The range in the length of apposition for the profiles of the boutons of different types on the cell bodies is depicted in Text-Fig. 1. Since one and the same bouton could be observed to establish synaptic complexes of both S- and T-types (see above), these two types are included under the same heading in the figure and in the ensuing text. The size-distribution of the bouton profiles for the S+T and F boutons, is roughly bell-shaped. In both cases, the diagrams are slightly asymmetric, with the size-range larger above than below the mean values (see Table 2), although the length of very few profiles is greater than twice the mean value. Furthermore, the size-distribution is similar between the two animals. For the F boutons, the total size-range is greater than for the S+T boutons, and it is clear that the profiles of F boutons are generally somewhat larger than the S+T boutons. The majority of the observations also cover a wider range. Possibly there are two peaks in the diagram for the F bouton profiles. The statistical analysis showed that the size-range of both S+T and F boutons was similar at both the cell bodies and the thin dendrites.

Bouton covering (Tables 1, 2 and 3)

The highest bouton covering, i.e. above 70%, is found on the proximal parts of the motoneuron dendrites. Only about half the surface of the cell bodies is covered by boutons, which seems also to be true of the thin dendrites. These regional differences are significant ($p < 5\%$). The bouton covering for the different types separately is presented in Table 3.

From the table it is seen that the covering of the S+T boutons on the cell bodies is only about 12%, which is significantly ($p < 5\%$) lower than on the proximal parts of the dendrites, where it is about 25%. There seems to be little if any difference in the covering of the S+T boutons between the proximal dendritic profiles and the thin dendrites in the neuropile. The covering of the F boutons on the cell bodies is about twice that of the

Text-Fig.: Diagram showing the length of apposition of all the bouton profiles on the motoneuron cell bodies in the quantitative study.

Table 3. Percentage bouton covering, for the different bouton types separately

Type	SOMA		DA		DB		d	
	Covering, %	% of covering	Covering, %	% of covering	Covering, %	% of covering	Covering, %	% of covering
S+T	12.6	26.8	24.5	34.0	26.0	35.3	23.8	48.9
F	27.2	57.8	39.7	55.0	41.9	56.9	24.2	49.6
C	7.0	14.9	6.1	8.5	4.7	6.4	0.5	1.0
M	0.2	0.4	1.9	2.6	1.1	1.5	0.2	0.4

S+T boutons, though the regional differences are not significant. The values for the proximal parts of the dendrites are higher than on the cell bodies and thin dendrites, but the total bouton covering is also the highest in this region. The quotient between the bouton covering of S+T- and F-types, however, seems to vary between the regions ($10\% > p > 5\%$). The covering of the C boutons decreases from the cell body towards the dendrites ($10\% > p > 5\%$), and the covering of the M and big S boutons is greatest on the proximal parts of the dendrites ($10\% > p > 5\%$).

Other profiles on the motoneuron surface (Table 2)

Only a very small part of the motoneuron cell membrane is seen to lie in apposition at adjacent dendrites, an arrangement which seems to be most common at proximal parts of the dendrites. Apposition between the motoneuron cell membrane and oligodendrocytes is restricted to the cell bodies (those cases were omitted in which a single astrocytic sheath was interposed). Rather few dendritic spines were encountered.

DISCUSSION

Fixation

Perfusion-fixation with buffered aldehydes is a generally accepted method for ultrastructural studies (Sabatini *et al.* 1963, for references see Maunsbach 1966). Earlier work has presented general information on the appearance of central nervous tissue after such a fixation procedure, and on changes in the appearance of the tissue according to the fixation method (Bodian and Taylor 1963, Westrum and Lund 1966, Karlsson and Schultz 1965, Johnston and Roots 1967). Considering these data plus current criteria for

a good ultrastructural preservation of central nervous tissue, it is obvious that perfusion-fixation of the spinal cord is more involved than that of the brain.

The fact that the cord often showed poor fixation when the circulation had been arrested before perfusion, confirms previous results from the CNS and other regions (Palay *et al.* 1962, Pease 1964, Karlsson and Schultz 1965, Maunsbach 1966, Osvaldo and Latta 1966). It is more difficult, however, to explain the reason for perfusions at a discontinuous pressure giving the best fixation of the spinal cord and roots (cf. Berthold 1968), when the circulation was not interrupted before perfusion. Perfusion with a discontinuous pressure from the infusion sets was introduced in this study since those at constant pressure resulted in a poor fixation, whereas some of the perfusions with syringes gave a very good preservation. The fluctuations in the pressure were thought to mimic the effect which must have occurred when the syringes were changed. In earlier studies on vascular perfusion of the renal medulla, the best perfusion resulted from free-hand injection from syringes (Moffat and Fourman 1963). The fact, however, that there are no earlier similar reports on the brain makes it tempting to suggest that at least one reason for the poor fixation of the spinal cord after perfusions at a continuous pressure might involve the complicated vascular supply, via small segmental vessels (see Jellinger 1966), to the spinal cord. Continuous pressure might either: 1) force the fixative too fast through the large arteries so that much of it bypasses rather than enters the very thin, long vessels which branch directly off from the arteries, or, 2) cause a rapid fixation with ensuing rigidity of the big spinal muscles which perhaps affects the flow of fixative to the smaller vessels.

Discontinuous pressure, on the other hand, through reducing the rate of flow of the fixative through the large vessels, might be sufficient to distribute it to the small vessels; moreover, discontinuous pressure more closely simulates the *in vivo* flow of blood.

Besides the fixation method, the dehydration and embedding procedures are also known to affect the appearance and dimensions of tissue components. Although there seems to be some swelling of retinal-rod membranes after aldehyde fixation alone (Robertson 1966), the interperiod distance of peripheral myelin shrinks about 30% following aldehyde fixation and Vestopal-embedding (Karlsson 1966 a). These data for tissue shrinkage must be born in mind when the diameters of various profiles, as obtained here, are compared with those in the earlier light microscopic works, or when the dimensions *in vivo* are sought.

Sampling

Earlier light microscopic studies (Schadé and van Harreveld 1961, Mellström and Skoglund 1969) show that the size of the motoneuron cell bodies varies considerably. There are, in fact, no clearcut criteria for separating the alfa-motoneurons from gamma-motoneurons, which are believed to be intermingled (Nyberg-Hansen 1965). The profiles of big neurons investigated in the present study, however, form a homogeneous population, in regards to size and cytologic characteristics, thereby justifying their being considered alfa-motoneurons. Furthermore, as mentioned above, the C boutons seemed to be present only at the bigger neurons.

The present investigation has been restricted to the lateral motoneuron nucleus in L 7. Due to the thin light microscopic sections used in the present work, the motoneuron pools described by Romanes (1951) are difficult to outline. This seems especially clear in light of the earlier observation (see for example Testa 1964), confirmed in the present study, that the horizontal extension of the motoneuron columns varies considerably between different levels of the cord. Some of the observations here might then refer to neighbouring motoneuron nuclei. In the quantitative estimation, however, the lateral motoneuron nucleus could be adequately distinguished by using a large number of consecutive transverse, semithin section.

Both transverse and longitudinal sections of the cord were used, but for the purpose of orientation, most observations were made on transverse sections. Since this is also true for the quantitative estimation, the values obtained refer thus only to horizontal dendrites. Although these are quite numerous, judging from Golgi studies (Sprague and Hongchien 1964), it has been shown that the system of vertical dendrites may be even more prominent (Lhermitte and Kraus 1925, Weil 1927, Scheibel and Scheibel 1966).

The description of the surface relationships of the motoneurons refers chiefly to cell bodies and proximal parts of the dendrites emanating from these. Although the contacts of the thin dendritic profiles in the neuropile were also studied, even in the quantitative estimation, the origin of these profiles was not known. Golgi studies (Sprague and Hongchien 1964, Scheibel and Scheibel 1966) show that the neuropile of the ventral horn contains dendritic ramifications, not only from adjacent and distant motoneurons, the dendrites of which can be 500—1000 μ long. There are also many dendrites belonging to adjacent small neurons (Balthasar 1952), possibly inter- and gamma-neurons. Since the distribution of boutons seemed to differ between small and big cell bodies, a similar difference might also be true for the thin dendritic branches. In the quantitative estimation, some

characteristics of the population of boutons on the thin dendrites were, however, common to most profiles, namely a low percentage bouton covering on the surface, few C and M boutons and a relatively high number of the S- and particularly T-types of boutons. At least some of the thin dendritic profiles might belong to alfa-motoneurons.

The synaptic complex

The morphologic criteria for the synaptic complex, as defined by Gray and Guillery (1966), were adopted and proved very useful in the present study. Synaptic complexes or structures similar to these seem to occur at practically all boutons investigated through serial sections (see also Conradi 1969 b).

The region of apposition of the C boutons at the motoneuron does not fulfill the criteria for a synaptic complex as described by Gray and Guillery, although in earlier descriptions of similar boutons, both in the spinal cord (Rosenbluth 1962, Gray 1963, Bodian 1964, Lewis and Shute 1966, Charlton and Gray 1966, Bodian 1966 b, van Harrevald and Khattab 1967) and in the cochlea (see for example Smith and Rasmussen 1965, Wersäll 1968), they have been classified as "synapses". This fact raises the question as to which criteria are crucial for the definition of a synaptic complex. At the C boutons, there is no contrast-rich material attached at the pre- and postsynaptic membranes and often the vesicles are not apposed along the whole presynaptic membrane. The synaptic cleft is extremely narrow, although a dense material is usually visible. However, the general membrane relationships in the CNS, as well as the occurrence of extracellular material, vary with the fixation method (see Discussion in Conradi 1969 c). Assuming that every bouton establishes at least one synaptic complex, nevertheless the results presented in this study indicate that the C boutons establish synaptic contact with the motoneurons. They were, namely, never observed to establish similar junctions with other neuronal structures.

Types of boutons

The boutons were classified into six types. All of these, apart from the M- and P-types, have been described by earlier authors, in studies on the cat or other species (Rosenbluth 1962, Gray 1963, Bodian 1964, 1966 a, b, Uchizono 1966, Charlton and Gray 1966, Ralston 1967). Some of the parameters underlying the typing will be briefly discussed.

The synaptic vesicles were described as being either spherical or flattened. This simple delimitation was used since it allows typing by mere inspection

of the boutons. When the boutons are thoroughly studied at high magnification, subgroups appear to be present in both the S- and F-types. Small variations in the size, shape and contrast of the vesicles in different boutons of the same type can than be observed. A further subtyping would, however, have complicated the statistical evaluation enormously, although in some other systems of the CNS, typing of boutons according to small variations in the size of the vesicles has been done (Mori 1966, Larramendi *et al.* 1967, Gobel 1968).

Boutons containing flattened synaptic vesicles, which seem to be present in specimens from the CNS fixed with aldehydes, were at first described by Uchizono (1965) in the cerebellum of the cat, where such boutons were exclusively distributed on the cell bodies. Other authors have later described such boutons in several regions in the CNS (see for example Walberg 1968) and the spinal cord (Uchizono 1966, Bodian 1966 a, b, Sedar and Moskowitz 1967, Ralston 1967).

Recently, it has been claimed that the proportion of boutons with flattened vesicles can vary with the fixation method (Holländer *et al.* 1969). In the present study, several differences other than shape of the vesicles were noted between boutons with spherical and flattened vesicles, namely:

a) The synaptic cleft of F bouton type is narrower and the layer of postsynaptic dense material is often thinner than at the S- and, particularly, T-type.
b) Very few F boutons exhibit granular synaptic vesicles or postsynaptic dense bodies.
c) Big boutons, with a subsynaptic cistern, covering the whole apposition region of the bouton, were never observed to contain flattened vesicles.
d) In some fixations, there was a granular precipitate, which was most intense in F boutons.
e) The location and percentage covering of F boutons on the motoneuron cell membrane differed from that of other bouton types.

The above observations indicate that boutons with spherical and flattened vesicles, respectively, form separate systems. Needless to say, no evidence has been presented to claim that the shape of the synaptic vesicles after aldehyde fixation represents the shape *in vivo*.

In a few cases, it was difficult to type some boutons, especially in single sections. This was the case, for example, when very few vesicles were present, when the synaptic complex was not observed or when some vesicles appeared flattened and some spherical. Although this is a source of error in the quantitative estimation, it might not contradict the suggestion that there are

boutons of different morphologic types on the motoneurons. If it is assumed that the vesicles of the F bouton are discoid, then some vesicles will always appear rounded in single sections.

The presence of a granular precipitate in some fixations, mainly in F boutons, could be indicative of chemical differences between F and other bouton types.

Quantitative estimation

The primary aim of the quantitative estimation was thus to get an idea about the population of boutons of different types on the various regions of the motoneurons. Earlier studies on other types of neurons have shown that the spectrum of apposing boutons varies with the location on the neuron (see, for example, Purkinje cells: Larramendi and Victor 1967, Hippocampus Pyramidal Cells: Hamlyn 1962 and the neurons in Clarkes column: Sedar and Moskowitz 1967); this might thus also hold true for the motoneurons. Furthermore, the present quantitative study should serve as a basis for evaluating the changes after dorsal root section and during the postnatal development. This study, together with a forthcoming report (Conradi 1969 b), is, however, also intended as a contribution to the methodology for quantitative studies on nervous connexions. Rather few quantitative ultrastructural studies on the size and distribution of the boutons on neurons have appeared (see, for example, Blackstad and Dahl 1962, Green and Pease 1966, Karlsson 1966 b, Larramendi *et al.* 1967, Holländer *et al.* 1969) even though the interest for such studies seems to increase (see for example Lemkey-Johnston and Larramendi 1968).

It has to be pointed out that the material underlying the present study is very small. Only a restricted part of the ventral horn was studied, and single sections, which might not be quite representative, were used. Despite this, some of the tendencies described were quite consistent. In some respects, the present results confirm those of earlier light microscopic studies.

In the present study, the mean length of apposition of the most commonly-occurring boutons was 1.5—2.0 μ. The bigger bouton types (C- and M-types) had a mean length of apposition of about 4—6 μ. In several of the earlier studies, which were performed on different species, the majority of the boutons were reported to have a length of apposition of 1—2 μ and the biggest boutons were about 5 μ long (Hoff 1932, Gibson 1937, Phalen and Davenport 1937, Barr 1939, Minckler 1940, Barnard 1940, Haggar and Barr 1950, Wyckoff and Young 1956, Gelfan and Rapisarda 1964, Illis 1964). Barr (1939) also reports that 38% of the motoneuron cell body is

covered by boutons, a value quite similar to the one obtained in the present study. Several of the earlier authors have also noted that the thinnest dendritic branches are covered by boutons. There are only some slight differences between the earlier and present results. In the region investigated in this study, it was shown that the bouton covering of the motoneurons was highest on proximal parts of the dendrites, decreasing outward and towards the cell body; this does not seem to have been pointed out earlier. From the present study, the location of boutons with a big zone of apposition (C- and M-types) seems to be restricted to cell bodies and the proximal parts of the dendrites, whereas for the others, the mean length of apposition of the boutons is rather similar on different parts of the motoneuron surface. The percentage covering of the boutons on the motoneurons has been investigated with the electron microscope (Green and Pease 1966). Although no details on the sampling procedure and the methodology are given, these authors conclude that 48% of the proximal parts of the motoneuron dendrites is covered by boutons. The decrease in value towards thinner dendritic profiles agrees with the present findings. However, the authors obtain a higher percentage bouton covering on the cell bodies (49%) than on proximal parts of the dendrites. This differs from the finding in the present study and might be due to regional or sampling differences.

As mentioned, the percentage of covering of the motoneuron cell membrane varied for some bouton types amongst the various regions of the motoneurons. Besides the bouton covering for the different types, it is also of interest to calculate the numerical proportion of the bouton types on the different regions of the motoneuron surface. Values can then be compared for example with three-dimensional reconstructions of parts of the motoneurons (see Conradi 1969 b, c). It is obvious that the relative number of the different bouton types, as obtained from single sections, cannot be representative for the true situation, since there is, as mentioned, a greater chance for big boutons to be included in the sections. Also, the size-range of the bouton profiles could be of importance. If there are relatively many big bouton profiles in one of the types, this type might be over-represented, since a big bouton cut through the periphery is easier to recognize than a smaller bouton cut in the same way. However, the diagram on the length of apposition of the bouton profiles on the cell bodies showed a peak near the mean values for both the S + T- and F-types. The statistical analysis showed that the variance of the values for these two bouton types was similar on the cell bodies and the thin dendrites

If it is assumed that the area of apposition on the motoneurons of all the bouton types shows the same size-range, the same shape, and the same

Table 4. Numerical proportion of boutons of the different types as seen in the sections ("present") and the corresponding values when the proportion has been corrected for mean length of apposition ("corrected")

		SOMA %	DA %	DB %	d %
S+T	Present	35.5	39.6	42.0	51.9
	Corrected	43.3	45.3	47.8	55.6
F	Present	57.5	55.3	54.9	47.5
	Corrected	53.9	52.3	50.7	44.2
C	Present	6.9	3.9	2.4	0.4
	Corrected	3.0	1.8	1.0	0.2
M	Present	0.1	1.2	0.7	0.2
	Corrected	0.04	0.6	0.4	0.1

orientation towards the plane of section, then an estimate of the true numerical proportion of boutons of different types can be obtained by dividing the proportion of one bouton type, as seen in the single sections, with the mean length of apposition of that type. The sum of the new percentages will be less than one hundred, but for clarity, these percentages can easily be adjusted upwards so that the sum reaches that value. This has been done in Table 4.

It can be seen in the table that the proportion of F boutons shows a slight decrease from the cell bodies towards the dendrites, whereas the reverse is true for the S+T boutons. On the cell bodies, the F boutons apparently outnumber the S+T boutons; the situation is reverse on the distal dendrites. The C boutons occur most commonly on the cell bodies, decreasing in number rather sharply towards the dendrites.

When this table is compared with Table 3, it is most noticeable that the covering of the bigger bouton types is much higher than the numerical proportion. The values in Table 3 for percentage of the total bouton covering by the different bouton types, however, show the same tendencies for location of the boutons as in Table 4.

Physiologic considerations

In the initial description of boutons containing flattened synaptic vesicles, these boutons were suggested to be inhibitory (Uchizono 1965), since they exclusively surround the cell bodies of Purkinje cells, where inhibitory influences should be localized according to the physiologic evidence cited. If a similar function is true for the F boutons on the motoneurons (cf. Bodian 1966 a, b), at least one inhibitory input is distributed both on the cell

bodies and dendrites, probably also on the distant branches. If it is further assumed, as in the original report, that boutons containing spherical vesicles are excitatory, then about 60% of the area of the motoneuron cell bodies covered by boutons could be subjected to inhibitory influences, compared to scarcely 50% at the distal dendrites.

The physiologic evidence for the localization of inhibitory synapses on the motoneurons is conflicting. Eccles (1964) argues that the localization of the inhibitory synapses is restricted to the cell bodies or neighbouring regions. Granit *et al.* (1966) and Terzuolo and Llinas (1966), have presented evidence to the contrary, showing that inhibitory synapses may also be localized at a distance far from the cell bodies. A recent report, based on a large number of measurements with the intracellular recording technique, combined with extensive theoretical calculations, concludes that the inhibitory synapses ought chiefly to be located on or near the cell bodies, whereas the excitatory synapses are distributed over the entire motoneuron surface (Smith *et al.* 1967).

Following post-asphyxial hind limb rigidity, which is thought to be caused by a mass destruction of perhaps mostly inhibitory interneurons in the spinal cord, there is a loss of boutons on the motoneurons and the loss is most pronounced at the cell bodies (Gelfan and Rapisarda 1964). The remaining boutons have also been studied ultrastructurally but no quantitative analysis has been performed (van Harreveld and Khattab 1967). The predominance of F boutons on the cell bodies found in the present study might confirm these results. The above assumption (Uchizono 1965), that the boutons containing flattened vesicles are inhibitory, does not, however, imply that all boutons containing spherical vesicles are excitatory. Following the assumption in the present material that the bouton covering and proportion of inhibitory boutons decrease from the cell body towards the dendrites, then the localization of the C boutons is compatible with an inhibitory function of these boutons. The C boutons occur most commonly on the cell bodies, and, to some extent, on the proximal parts of the dendrites, whereas they are scarcely seen at all on the thin dendrites. If both the F and C boutons are inhibitory, then more than 70% of the area of the motoneuron cell bodies covered by boutons is subjected to inhibitory influences.

Boutons similar to those of the C-type are formed by the presumably inhibitory endings of the olivocochlear bundle (see Smith and Rasmussen 1965, for references, see Wersäll 1968). The big size and characteristic appearance of these boutons must be of help in attempting to determine the site of origin. It might then be possible to study the significance of the

regularly-occurring apposition of subsurface granular endoplasmic reticulum, and of the fact that the synaptic cleft of these boutons seems to contain A Ch-E activity (Lewis and Shute 1966).

ACKNOWLEDGEMENTS

I am much indebted to Professor Sten Skoglund for his encouragement and helpful discussion, and to Miss Christina Trägårdh and Miss Maj Berghman for skilful technical assistance. The work has been supported by grants from Karolinska Institutet (Reservationsanslaget) and from the Swedish Medical Research Council, projects no. B69—14X—136—05C and B70—14X—136—06.

SUMMARY

The membrane relationships of the motoneurons in the lateral part of segment L 7 were studied in 33 adult cats, fixed through perfusion with buffered glutaraldehyde. The motoneurons are contacted by glial cells, adjacent dendrites and boutons. Flattened astrocytic extensions are found on all parts of the motoneuron surface and cover nearly half of the motoneuron cell bodies. Oligodendrocytes are found both as perineuronal satellites and in the surrounding neuropile. The boutons on the motoneurons and in the neuropile can be divided into six morphologic types. Of the boutons containing spherical synaptic vesicles, 350—500 A in diameter, the S-type shows synaptic complexes with a 50—200 A thick layer of postsynaptic material. The T bouton type exhibits postsynaptic dense bodies at the synaptic complex. The type of big boutons, mainly localized on the motoneuron cell bodies and proximal parts of the dendrites, where a subsynaptic cistern was found below the synaptic complex was denoted C. The big boutons of the M-type contain spherical synaptic vesicles and a large, irregularly-shaped synaptic complex, covered by many postsynaptic dense bodies. On the convex side of these and some big boutons of the S-type, there are apposed small boutons, P-type, which contain small synaptic vesicles of irregular shape. Boutons with flattened vesicles are also found, F-type.

As a background for studies on operated adult cats and kittens, the size and distribution of the boutons of different types on the motoneuron cell bodies and dendrites, and in the neuropile, were studied quantitatively on single sections. The sections were taken from a restricted region of the ventral horn in two cats. The F boutons were the more frequent on or near the motoneuron cell bodies, whereas the S- and T-types occurred most frequently in the neuropile. The mean length of apposition to the motoneurons varied between the bouton types. The percentage of motoneuron and dendrite membrane covered by boutons was higher on the proximal parts of the motoneuron dendrites than on the cell bodies and in the neuropile. The percentage of membrane covering was also expressed for each type of bouton separately. A further attempt was made to calculate the numerical proportion of boutons of different types at different regions of the motoneurons. The results are discussed briefly against the background of the earlier suggested relationship between vesicle shape and function of the boutons.

Ultrastructure and distribution of neuronal and glial elements on the surface of the proximal part of a motoneuron dendrite, as analyzed by serial sections

by

SEBASTIAN CONRADI

INTRODUCTION

In a preceding paper (Conradi 1969 a), the ultrastructure of the neuronal and glial elements contacting the motoneuron cell membrane was described. The boutons were classified into six different types, according to observations on single or short series of sections. The size and distribution of the bouton profiles on the motoneurons was investigated on single sections from a sharply defined region of the ventral horn.

It seemed desirable, however, to investigate further a part of the material in the quantitative study through longer series of consecutive sections. The aim was the following:

a) To study the shape of the apposition region, and the size and shape of the synaptic complex of the different types of boutons, in order to investigate further the criteria underlying the typing of the boutons. The latter seemed important also since there are few ultrastructural reports on the three-dimensional appearance of the synaptic complex.

b) To show the topographic relationships of the different types of boutons on the motoneuron surface. It even seemed possible to determine whether boutons of the same types could be connected to the same preterminal axon.

c) To get some information on the relevance of the observations from single sections. The values for the size of the area of apposition of the different bouton types could be controlled and the size-range estimated. Further-

more, the percentage of bouton covering, both total and for the different types separately, as well as the numerical proportion of boutons of the different types could be studied and compared with the values obtained in the earlier quantitative estimation.

Part of the motoneuron cell membrane was chosen to be depicted in one plane, because of the difficulty in adequately illustrating complex volumes, for example by wax-reconstruction. The surface of the proximal part of a motoneuron dendrite was analyzed, since all the types of boutons, according to the quantitative estimation, are found on this part of the motoneuron.

MATERIAL AND METHODS

The measurements on cell 20 in the quantitative study (see the preceding paper) were made on one of a longer series of consecutive sections. The series consisted of 750 consecutive ultrathin transverse sections through the lateral motoneuron nucleus in the most cranial mm of L 7. The series passed in cranio-caudal direction through a horizontal proximal part of a motoneuron dendrite, which was cut through in 220 sections and the observations in the quantitative study were made on one of these sections (see below). In one instance, 3 consecutive sections were lost; otherwise, only a few single ones were lost. Assuming a cylindrical shape of the dendrite, the mean section thickness was about 800 Å, as calculated from measurements on the diameter of the dendrite at several places.

The dendrite left the motoneuron cell body in a ventro-medial and horizontal direction (Fig. 3). The diameter of the first part of the dendrite was rather constantly at 11 μ. After a distance of about 30 μ, the dendrite curved medially and caudally, sending out a downward branch. Then the dendrite, now about 9 μ in diameter, again took a horizontal course. After a distance of about 40 μ, it curved slowly cranially and disappeared out of the sections. The horizontal parts of the dendrites were analyzed.

Every second section through the dendrite was photographed at a primary magnification of 3,700×. For each section, 5—6 photographs were required; they were enlarged 3 times and the copies taped together to montages. The type of each bouton on the dendrite was then determined on every 7—10th section through inspection in the electron microscope at high magnification, and the result was transferred to the montages.

The membrane relationships of the dendrite were visualized thus: the analyzed parts of the dendrite were cylindrical. The plane of sectioning was parallel to the longitudinal axis of the cylinder. From the diameter and length of the dendrite, the mantle surface at the magnification used was calculated and depicted on a transparent paper. Each section through the dendrite was represented on the paper as a pair of parallel, longitudinal, lines: the uppermost section, as two lines in the middle of the paper; the lowest section, as two lines on each side of the paper. (See Fig. 4). The transparent paper was then placed on the montages in consecutive order. Each time the outline of

the dendrite in the actual section was aligned with the corresponding line on the paper, and the length of apposition of every bouton and other types of extensions were depicted along this line.

Other parameters also transferred to the paper were: the presence, direction and myelination of the preterminal axons; the presence of small boutons (P-type) on the convex side of the boutons; the presence of a synaptic complex with an additional dendrite ("double synapse", in Figs. 7 and 8), and localization of dendritic spines and of granular endoplasmic reticulum just inside the surface of the dendrite.

The extension of synaptic complexes and desmosome-like junctions were depicted at some of the boutons, but were restricted to those parts of the dendrite, where the cell membrane was cut rather perpendicularly, i.e., some distance away from the upper and lower margin of the dendrite. In this part of the investigation, the boutons were studied at high magnification in the electron microscope at each section. The extension and position of the synaptic complexes and desmosome-like junctions were judged by inspection and transferred by free-hand to the transparent paper.

Some difficulties are encountered in the use of this method. The copying procedure often produces small differences in the magnification between the montages; thus when the large montages are analyzed, the distance between the proximal and distal border of the montages varies. In such cases, the transparent paper has to be moved slightly lengthwise along some of the montages, resulting in some inaccuracy, not so much as regards the size of the apposition areas of the boutons, as to the distance between the boutons.

There are also some difficulties involved in illustrating adequately the membrane relationships at the upper and lower margin of the dendrite. If the diameter of the dendrite varies slightly, some of the sections at the cranial and caudal edges will pass through the dendrite at those places where the diameter is greater. At the slightly narrower parts, the sections will pass just outside the dendrite (Fig. 2) In such instances, the site of the vertical plane through the centre of the dendrite had to be depicted as a straight line on the montages, and the apposition regions of the different boutons were drawn on the transparent paper according to the distance from this line, instead of on the line corresponding to the actual section. In region A of the dendrite, there was also a slight continuous decrease in the diameter of the dendrite away from the cell body. Due to this, the pair of lines representing each section was brought to converge slightly towards the distal part of the reconstruction (see Fig. 5).

The number and size of the parameters to be analyzed in the drawing determine the magnification of the montages. In the present study, the interest was primarily focused on the apposition areas of the boutons. With the final magnification, about 11,000×, it was not possible to analyze the astrocytic sheaths surrounding the boutons. The location and extension of the synaptic complexes had to be drawn merely from inspection, since if the magnification should have been big enough to permit recognition of these complexes on the montages, it would have been necessary to increase the number of photographs tenfold or more.

The outline of the apposition areas of the boutons at the regions A and B, respectively, on the transparent papers, was transferred to an ordinary paper in the same scale. Some measurements were made on the latter.

All the boutons on each drawing were counted and the numerical proportion of the different types calculated. The maximum length of apposition *in the direction of the*

longitudinal axis of the dendrite was measured for all the boutons, and from this, the mean value for each type of bouton was calculated. This definition of maximum length was used, since the measurements on the bouton profiles on dendrites in the single sections (Conradi 1969a) roughly represented the length of apposition along the longitudinal axis of the dendrites, which were cut lengthwise. Both the maximum longitudinal length and the length of the profiles were measured on those boutons which were included in section 114, used in the quantitative estimation in the preceding paper. To calculate the packing density of the boutons, the largest square on the surface of the dendrite was depicted on each of the two drawings and the number of boutons inside it was counted. In order to make possible comparisons with earlier light microscopical findings, the values were transferred to no. of boutons/100 μ^2.

Finally, the percentage covering of the boutons, both total and for each type separately, was calculated, and for this purpose, photographic copies of the two drawings, measuring about 25×15 cm, were used. At first, the whole drawings were each weighed with an accuracy of 0.001 g. Then the apposition areas of all the boutons were cut out and the profiles, representing the same type of bouton, were weighed together. During the cutting procedure, special care was taken in order not to contaminate the copies. The percentage covering of the boutons of different types was calculated as the ratio.

$$\frac{\text{weight of the bouton profiles}}{\text{weight of the whole drawing}}$$

RESULTS

General

All the six types of boutons, described in the preceding paper, were present on the dendritic segments (see Figs. 5—10). Thus, there were boutons with spherical synaptic vesicles, denoted S-type, except for those instances in which postsynaptic dense bodies (T-type) or a subsynaptic cistern (C-type) could be observed. It is clearly seen in the figures that some of the boutons with spherical synaptic vesicles establish synaptic complexes both with and without postsynaptic dense bodies. In the following description, therefore, the S and T bouton types are not dealt with separately. Some big boutons (M-type), containing spherical synaptic vesicles and showing a synaptic cleft of an obviously irregular shape and completely covered by postsynaptic dense bodies are also present. Small boutons (P-type), containing rather small synaptic vesicles of an irregular shape were found to be apposed at the convex side of the M boutons and some big S boutons. By mere inspection at high magnification in the electron microscope, profiles of P boutons cannot be distinguished with certainty from profiles of boutons with flattened vesicles (F-type). Due to this and to the fact that the type of the bouton

profiles was controlled in the microscope at about every 7th section, the P and F bouton types were demarcated in the same way in the figures 5—10. Some big boutons with flattened vesicles were found to have a rather dense ground substance (FD-variety).

In Figs. 5 and 6 it is seen that a large part of the dendritic mantle surface is covered by boutons, which are usually tightly packed. At a few places, the surface is covered by myelinated axons or adjacent dendrites, but in these cases, thin, intervening astrocytic sheaths are always present. The apposition areas of the boutons are mostly of similar shape, often slightly ovoid, with the longitudinal axis parallel to that of the dendrite. It is clearly seen, however, that there is a considerable size-range even among boutons of the same type. Most of the boutons are surrounded by thin astrocytic sheaths, but due to the thinness of the latter and the fact that they do not completely cover the boutons, they were, as mentioned, not included in the drawing.

Distribution of the different types of boutons

The F boutons seem to be clustered at some places on the reconstructed mantle surface. Some big boutons with spherical synaptic vesicles (S-, T- and M-types), in which each bouton is surrounded by several dendritic spines, form a row in proximo-distal direction at the left side in region A (Fig. 10). Apart from this, the distribution of the boutons of different types appears to be random.

Preterminal axons

The presence and direction of the identified preterminal axons are depicted in Figs. 7 and 8. The preterminal axons could be recognized at only some of the boutons. This could be due to the fact that the vast majority of these axons are unmyelinated some distance before the boutons. If such thin axons are cut transversely in the series, they are difficult to recognize. That few boutons *de passage* were observed might be due to the fact that rather few of the preterminal axons could be traced. None of the bigger boutons seemed to be formed *de passage*. Many of the identified preterminal axons were directed parallel to the longitudinal axis of the dendrite. In some cases, the preterminal axons were apposed to the dendritic surface immediately before the bouton. This can be seen by the shape of the apposition area, which shows slender lateral protrusions at some of the boutons. In two cases, an unmyelinated preterminal axon crossed the areas

of apposition of another bouton, an arrangement which thus formed a "tunnel" between the bouton and dendrite.

Tracing the course of the preterminal axons could have clarified whether several boutons belong to the same preterminal axon; however, such determinations require a higher magnification than that used in this study and would have increased the number of photographs markedly.

The synaptic complex

Practically all the boutons on the analyzed dendrite seemed to make synaptic contact with the dendrite, and out of all the boutons on the membrane region investigated, only 4 boutons established synaptic contact with an additional dendrite (Fig. 8). In these cases, the second synaptic complex was established to thin adjacent dendritic profiles.

The size and distribution of the synaptic complexes were analyzed on part of the dendritic membrane; the result is depicted in Fig. 9. Most boutons are seen to establish several circular or ovoid synaptic complexes, the size of which vary somewhat. The complexes of S, T, F and M boutons occupy only a part of the apposition area of the boutons and usually do not reach the periphery of it. Only boutons of the C-type give rise to one synaptic cleft of *the same size-order as the zone of apposition of the bouton. Since this bouton* type is the biggest, one single C bouton may have a synaptic cleft the size of 10—20 smaller boutons together.

The synaptic complexes of S and F boutons are of rather uniform size, apart from some big complexes belonging to F and, particularly, FD boutons. *The synaptic cleft of M boutons seems to be irregular in shape. It was in fact* rather difficult to judge whether there was one big, irregular synaptic cleft or several smaller ones, situated very close together at the M boutons. The entire postsynaptic membrane is covered by postsynaptic dense bodies and the size of the synaptic complex is bigger than at other boutons of the S- and T-type.

Small P boutons were apposed at the convex side of the M boutons. Some of these P boutons also made contact with *the surface of the dendrite.* P boutons were also apposed at the convex side of some big S boutons (Fig. 10). At one of these, part of the postsynaptic membrane was covered by postsynaptic dense bodies (Fig. 9). Apart from this, it can be clearly seen that the anatomy of the synaptic complex differs between the M boutons and these big S boutons.

*Besides the synaptic complexes, every bouton forms several desmosome-*like junctions with the dendrite. Due to the small size of these structures, it was not always possible to determine whether the profiles in the consecutive

sections belonged to the same or different junctions. Some "dense projections" (Gray 1963) from the presynaptic membrane may also have been misinterpreted as desmosomes.

Dendritic spines and postsynaptic granular endoplasmic reticulum

The dendritic spines are not distributed at random on the surface of the dendrite. Except in a few cases, most spines are arranged as palisades around some M boutons and some big S boutons, to which P boutons are apposed at the convex side (Fig. 10). Granular endoplasmic reticulum, localized just inside the cell membrane of the dendrite, was regularly present at C boutons. Many of the M boutons showed a similar relationship, but for the rest, the distribution of the endoplasmic reticulum appeared to be random.

Size of the boutons

The size of boutons of the same type shows rather large variations and there are several very small boutons of both the S- and F-types. The C and M boutons are, as a rule, bigger than boutons of the other types. The biggest S boutons are bigger than the biggest F boutons. It must be noted, however, that at some places several F boutons are observed to be interconnected by means of short bridges, (Figs. 5 and 6) making it difficult to define the delimitation of the single boutons.

In table 1, the dimensions of the boutons of different types, as obtained from the two reconstructions, are compared to those obtained on single sections in the preceding communication (Conradi 1969 a). Region A in this study has roughly the same extension as DA in the preceding paper.

In (a) and (b), the values for the mean maximum longitudinal length of apposition of all the boutons in the two reconstructions are compared with the mean length of apposition of all the bouton profiles, included in the quantitative estimation on single sections (Conradi 1969 a). In regard to the most commonly occurring bouton types, the values for the F-type are rather similar in (a) and (b), but the values for the S+T type are 10—25% higher in (a). In (c) is shown the sum of the figures for the maximum longitudinal length of apposition of the boutons, included in section 114, which was the section used in the quantitative estimation. The values exceed those for the sum of the length of apposition of the bouton profiles, which could be seen in section 114 (d). The difference is 25—35%.

Table 1. Comparison between dimensions of boutons of different types as obtained by serial or single sections

(a) Mean maximum longitudinal length of appositon of all the boutons		A, μ	B, μ
	S+T	2.1	1.9
	F	2.3	2.0
	C	6.2	3.4
	M	7.7	4.9
(b) Mean length of apposition of all the bouton profiles in the quantitative estimation (Conrad 1969 a)		DA, μ	DB, μ
	S+T	1.8	1.7
	F	2.1	2.1
	C	4.5	5.4
	M	4.4	4.2
(c) Sum of the values for maximum longitudinal length of apposition of the boutons, included in section 114		A, μ	B, μ
		68.5	85.5
(d) Sum of the length of apposition of the bouton profiles in section 114		A, μ	B, μ
		50.5	62.0

Percentage bouton covering

The values underlying this estimation are presented in Table 2. For comparison, the figures from the preceding paper are included.

The percentage bouton covering of A above, seems somewhat higher than at other proximal parts of the dendrites. Apart from this, the values agree rather well with the preceding estimation. In region A, the surface area covered by the S+T boutons is comparatively large. The findings are further dealt with in the discussion.

Table 2

	A weight g	Weight of total surface %	DA bouton covering %	B weight g	Weight of total surface %	DB bouton covering %
Total surface	5.388			5.983		
Boutons, total	4.293	79.5	72.1	4.285	71.7	73.7
S+T	1.586	29.4	24.5	1.490	24.9	26.0

M	1	0.5	0.6	3	1.2	0.4
SUM	200			239		

Numerical proportion of the boutons of different types

The relative numerical proportion of the boutons of different types is presented in Table 3. For comparison, the proportion, corrected for the mean length of apposition, as obtained in the quantitative estimation on single sections (Conradi 1969 a) is included.
The proportion of the boutons of different types is seen to be rather similar in the present and the preceding investigation. The findings are further dealt with in the discussion.

Packing density of the boutons

In region A, 161 boutons are situated within a square, measuring 30.5 × 30.5 μ^2. This corresponds to 17.5 boutons/100 μ^2. In region B, 202 boutons are found inside 26.5 × 35.0 μ^2, which means 22.0 boutons/100 μ^2.

DISCUSSION

It is obvious that serial sections have to be used, not only for the morphological definition of different bouton types, but also for the study of the size and distribution of the boutons. Present techniques, however, permit analyses of only restricted areas and a small number of sections. Therefore, the present study comprises only a limited region of one single motoneuron. This must be born in mind when comparisons with the results from the quantitative estimation in the preceding paper (Conradi 1969 a) or with earlier light microscopic findings (see below) are made. The interest in this study was focused on the methodology for investigations of the

membrane relationships of neurons through serial sections, and the topography of the location of boutons of different types.

For investigations, similar to the present one, it seems advantageous to depict the membrane of the nerve cell in one plane. Although some difficulties are involved—the same applies to three-dimensional reconstructions—the topography of the membrane relationships, at least in regard to the boutons, can be clearly seen and measurements on the drawings can easily be done. Longitudinally-sectioned cylindric profiles are the easiest to visualize in this way and require relatively few sections. It is, however, also possible to study obliquely- or transversely-sectioned cylindrical processes. In the former, the lines representing the sections on the transparent paper will be elliptical, while in the latter, the lines will be straight and parallel and directed at right angles to the longitudinal axis of the dendrite. It is also possible, with some limitations, to visualize the mantle surface of curved dendrites, in which the diameter is not constant (see Conradi and Skoglund 1969 a). For stereometrical reasons, however, it is very difficult to visualize the whole surface of a neuron cell body using the method in this study.

Distribution of the boutons

Apart from a possible clustering of the F boutons, the distribution of the boutons of different types on the dendritic mantle surface seemed to be rather random. Due to the typing used here a more exact pattern of localization of different bouton types might have been overlooked. Undoubtedly, it would have been advantageous if the preterminal axons could have been traced. In the present and preceding paper it was observed that one bouton can make synaptic contact with two dendrites of different dimensions and possibly also of different origin. Lorente de Nó (1941), when studying the synaptology of the motoneurons in the light microscope, also found that boutons from the same preterminal axon can make contact with several different neuronal processes. These observations might indicate that the spatial specificity for the establishment of synaptic contacts, at least with regard to the boutons, could be rather inexact.

Quantitative estimations

The aim of the quantitative studies on the reconstructions was, as mentioned, to get some idea on the relevance of the data from the quantitative estimation on single sections.

Bouton size. It could be seen that the C and M boutons formed a larger area of apposition than other bouton types. The area of apposition showed a relatively large size-range, even between boutons of the same type, but the shape of this area was rather similar between the boutons.

As expected, the mean maximum longitudinal diameter of the boutons in the reconstructions exceeded the mean length of all bouton profiles on the proximal parts of the motoneuron dendrites in the quantitative estimation on single sections (Table 1). The difference between the S+T and F boutons in the reconstructions, however, was smaller than in the quantitative study. This could mean that the boutons on the analyzed dendrite were not representative for the whole population (see below). Another possibility is that there are differences in the morphology of these two bouton types, introducing errors in investigations on single sections. The maximum longitudinal length of apposition of all the boutons in section 114, used in the quantitative study in the preceding paper, exceeded the length of apposition of the bouton profiles in that section by 25—35%. Nevertheless, the material is too small to allow any general conclusions on the ratio between the length of apposition of bouton profiles in single sections and the true values. For such studies, either a greater number of reconstructions must be used, or the measurements must be performed on several sections in each reconstruction.

In the earlier light microscopic studies on various species (Hoff 1932, Gibson 1937, Phalen and Davenport 1937, Barr 1939, Minckler 1940, Barnard 1941, Schadewald 1941, Haggar and Barr 1950, Illis 1964, Gelfan and Rapisarda 1964), most of the boutons on the motoneurons ranged in size between 1 and 2 μ, although bigger boutons were also observed. When these values are compared with those in Table 1, it is seen that the figures obtained in the present work are slightly higher. The discrepancies can be due to the different sampling and preparative procedures used. It should be pointed out, however, that the packing density of the boutons as obtained in this study (about 20 boutons/100μ^2) is of the size-order as the highest values (15—20 boutons/μ^2) from the light microscopic studies. (Barr 1939, Minckler 1940, Wyckoff and Young 1956, Gelfan and Rapisarda 1964). If the value obtained in the present study is representative, and the shrinkage factors are comparable, the impregnation of the boutons in the earlier works seems to have been effective.

Bouton covering. The total percentage bouton covering on the surface of the dendrite in region B, was rather similar to the one obtained for DB in the preceding study (Table 2). The value for region A was about 10% higher

membrane relationships of neurons through serial sections, and the topography of the location of boutons of different types.

For investigations, similar to the present one, it seems advantageous to depict the membrane of the nerve cell in one plane. Although some difficulties are involved—the same applies to three-dimensional reconstructions—the topography of the membrane relationships, at least in regard to the boutons, can be clearly seen and measurements on the drawings can easily be done. Longitudinally-sectioned cylindric profiles are the easiest to visualize in this way and require relatively few sections. It is, however, also possible to study obliquely- or transversely-sectioned cylindrical processes. In the former, the lines representing the sections on the transparent paper will be elliptical, while in the latter, the lines will be straight and parallel and directed at right angles to the longitudinal axis of the dendrite. It is also possible, with some limitations, to visualize the mantle surface of curved dendrites, in which the diameter is not constant (see Conradi and Skoglund 1969 a). For stereometrical reasons, however, it is very difficult to visualize the whole surface of a neuron cell body using the method in this study.

Distribution of the boutons

Apart from a possible clustering of the F boutons, the distribution of the boutons of different types on the dendritic mantle surface seemed to be rather random. Due to the typing used here a more exact pattern of localization of different bouton types might have been overlooked. Undoubtedly, it would have been advantageous if the preterminal axons could have been traced. In the present and preceding paper it was observed that one bouton can make synaptic contact with two dendrites of different dimensions and possibly also of different origin. Lorente de Nó (1941), when studying the synaptology of the motoneurons in the light microscope, also found that boutons from the same preterminal axon can make contact with several different neuronal processes. These observations might indicate that the spatial specificity for the establishment of synaptic contacts, at least with regard to the boutons, could be rather inexact.

Quantitative estimations

The aim of the quantitative studies on the reconstructions was, as mentioned, to get some idea on the relevance of the data from the quantitative estimation on single sections.

ACKNOWLEDGEMENTS

I am much indebted to Professor Sten Skoglund for his encouragement and helpful discussion, and to Miss Christina Trägårdh and Miss Maj Berghman for skilful technical assistance. The work has been supported by grants from Karolinska Institutet (Reservationsanslaget) and from the Swedish Medical Research Council, projects no. B69—14X—136—05C and B70—14X—136—06.

SUMMARY

In order to study the three-dimensional morphology and distribution of neuronal and glial elements on the motoneuron surface, the membrane relationships of the proximal part of a motoneuron dendrite were analyzed through ultrathin serial sections. One of the sections through the dendrite was included in the quantitative estimation on single sections in the preceding paper (Conradi 1969 a). The membrane relationships were illustrated in drawings, showing the mantle surface of the dendrite unfolded. The morphology of the area of apposition of the boutons was investigated, as well as the distribution of boutons of different types on the surface of the dendrite. The arrangement of the preterminal axons of the boutons and the size and shape of the synaptic complexes and desmosome-like junctions were also investigated.

The boutons were tightly packed over nearly the entire analyzed surface. All the types of boutons described in the preceding communication were present, and two types of big boutons containing spherical synaptic vesicles were found to have smaller boutons apposed at the convex side. The distribution of boutons of different types seemed almost random. Most of the boutons established more than one synaptic complex and several desmosome-like junctions with the dendrite. Nearly all the preterminal axons were unmyelinated for the last distance before the boutons and a few boutons *de passage* were found.

Some quantitative parameters were also studied and the results were compared with the findings from single sections in the preceding communication. The mean maximum length of apposition of the boutons in the direction of the longitudinal axis of the dendrite exceeded the mean length of apposition of the bouton profiles in the single sections. The percentage bouton covering, both totally and for the different types of boutons separately, was similar to that found for proximal parts of the dendrites in the quantitative study on single sections.

It is concluded that a good estimate on the size and distribution of boutons can be obtained from observations on single sections.

Observations on the ultrastructure of the axon hillock and initial axon segment of lumbosacral motoneurons in the cat

by

SEBASTIAN CONRADI

INTRODUCTION

From physiologic experiments with the intracellular recording technique there is evidence that activation of a motoneuron, synaptically or antidromically, is initiated in the first, unmyelinated part of the motoraxon, or sometimes in the first node of Ranvier (Fuortes *et al.* 1957, Coombs *et al.* 1957). At these two places, the threshold for impulse-initiation is considered to be lower than at the cell body and dendrites of the motoneuron (Eccles 1957). From the site of origin, the active impulse is propagated downward, along the myelinated motoraxon and upward, invading the cell body and dendrites.

The ultrastructure of the initial axon segment of various types of central neurons other than the spinal motoneurons has been described earlier (Green 1961, Herndon 1963, Kohno 1964, Johnston and Roots 1966, Westrum 1966, Ehrenbrand 1967), but the ultrastructure of the relationships of the neuron cell membrane at the initial segment had not been dealt with when the present results were presented in preliminary form (Conradi 1966). Recently, however, an ultrastructural specialization of the cell membrane at the initial axon segment has been observed in several types of neurons (Campos-Ortega *et al.* 1968, Westman 1968, Palay *et al.* 1968, Peters *et al.* 1968). The results presented therein are similar to the ones found in the spinal motoneurons.

The ultrastructure of the central nodes of Ranvier has been described earlier, mostly on rather thin fibres (Pease 1955, Uzman and Villegas 1960,

Peters 1960, Maturana 1960, Bunge *et al.* 1961, Bunge *et al.* 1965, Meturals 1965; see also Bunge 1968) on which the ultrastructure of the axon membrane after aldehyde fixation has also been described (Andres 1965, Peters 1966, Karlsson 1967) or on large axons in the fish brain (Robertson *et al.* 1963). There are, however, no previous reports on nodes belonging to large mammalian central myelinated fibres.

The present work describes the ultrastructure of the motoneuron at the initial axon segment and at the transition zone between this and the cell body; this zone is usually called the axon hillock. Attention is focused on the ultrastructure of the motoneuron cell membrane and the immediate environment at these two places. Some observations on the relationships of the motoraxon cell membrane at the central motoraxon nodes are included.

Earlier light-microscopic studies on the motoneurons show that boutons seem to be located at the axon hillock (Lorente de No 1938, Barr 1939, Haggar and Barr 1950) but the relationship to the initial axon segment has not been ascertained. In the present study, special care was taken to determine whether boutons are situated on these two parts of the motoneuron. It is concluded that boutons are found only on the axon hillock, and the distribution of the boutons of different types in this zone is compared with that on the motoneuron cell bodies and dendrites, an analysis of which was the subject of the two preceding studies (Conradi 1969 a, b).

MATERIAL AND METHODS

The same material as used in the preceding papers on the relationships of the motoneuron cell membrane (Conradi 1969 a, b) was used here. Some of the observations were also made on animals which had been subjected to unilateral dorsal root section, 1—14 days before fixation (see Conradi 1969 d). The material thus comprises a total of about 60 cats. The description refers to observations on about 30 initial segments and roughly the same number of nodes from a total of about 20 animals.

Semithin transverse sections of the spinal cord in the segments, L 6, L 7 and S 1 were stained with toluidine blue and examined in the light microscope. Some observations on the initial segment and nodes of the motoraxons were made on these sections. The lateral part of the ventral horn was trimmed out and cut into ultrathin sections. For the studies on the motoraxon nodes, the ventral part of the gray substance, just dorsal to the region where the motoraxons enter the white substance, was trimmed out in transversely-cut specimens. Some profiles of big axons, quite similar to those studied in the ventral part of the gray substance, were also found at random around the motoneurons.

Ultrathin sections were collected on one-hole grids, usually 5—15 sections per grid, according to the method of Galey and Nilsson (1966). One longer series of ultrathin transverse sections through the lateral part of the ventral horn was also used for the

study of the initial axon segment. In order to include complete initial segments, the series had to start at random at a region where several neighbouring motoneurons were found in the lateral motoneuron nucleus. Through consecutive light-microscopic sections before the start of the ultrathin sectioning, it was possible to determine that the majority of the actual motoneurons had thus far only been cut through the periphery. In order to include as many motoneurons as possible, the ultrathin sections had the same width as the hole in the grid and were so high that only 7—9 sections could be collected on each grid. Series made in this way, if continued long enough, will sooner or later include whole initial segments. In the present case, actually 2 initial segments were included in the same series at nearly the same level. The series consisted of 200 consecutive ultrathin sections, of which 10 single sections were lost. The mean section thickness, 960 A, was determined from the number of sections required to pass longitudinally-cut dendrites, which were assumed to be cylindrical and the maximal diameter of which was measured on the photographs. At every secon section, the two initial segments were photographed at a primary magnification of 3,300×. The initial segments were reconstructed from paper copies with wax-plates, 1 mm thick. The final magnification, 5,200×, was adjusted to the thickness of the plates, and calculated from the expression: final magnification $= \frac{1 \text{ mm}}{\text{mean section thickness} \times 2}$.

The types of the boutons on the axon hillock were controlled through inspection of the sections at high magnification in the electron microscope and the result was transferred to the copies. The transparent wax-plates were placed on the copies, and the contours of the initial segment, myelin sheath and axon hillock with related boutons and glial extensions were traced with a small knife through the wax. The wax-contours were then glued together and various parts of the reconstruction were painted.

RESULTS

Light microscopy

In toluidine-stained, semithin transverse sections of the spinal cord, longitudinally-sectioned initial axon segments which leave the motoneurons are rather commonly observed (Fig. 1). This gives the impression that many of the initial motoraxon segments run horizontally. Most axons originate at the motoneuron cell body (cf. Strong 1906, Ramon y Cajal 1909, Chu 1954), but axons leaving from the proximal parts of a dendrite were also observed. Most of the initial segments observed were directed ventrally, although some motoneurons, especially in the dorsal part of the ventral horn, send axons medially or dorsally, as has earlier been pointed out (Balthasar 1952).

The myelinated motoraxons in the ventral part of the gray matter usually form a rather dense plexus just proximal to the entrance into the white substance. Only a minority of these fibres run exactly in horizontal direction. In such instances, however, nodes of Ranvier can sometimes be observed. In

a few cases, thin myelinated collaterals were observed to leave the motoraxons at a node (cf. Ramon y Cajal 1909, Scheibel and Scheibel 1966). Outside the myelin sheaths of the motoraxons, rounded compact profiles are often found. They resemble myelin both in staining and outlook (Figs. 1 and 2).

The heavily myelinated large fibres seem difficult to preserve properly with the fixation method used here. Nearly always there was a marked splitting of the myelin (cf. Webster 1964).

Electron microscopy

The axon hillock

The transition between the motoneuron and the initial axon segment, called axon hillock, is cone-shaped. The motoneuron cytoplasm in this region differs from that inside the cell body by lacking granular endoplasmic reticulum (see Palay *et al.* 1968, Peters *et al.* 1968). Instead, there are many neurofilaments and 200 Å neurotubuli, which are mainly longitudinally-oriented (cf. Palay *et al.* 1968, Campos and Ortega *et al.* 1968). Mitochondria and ribosomes are also present (Fig. 2, see also Fig. 8). The motoneuron cell membrane at this region is quite similar to that found at the cell bodies as described earlier (Conradi 1969 a), and it is covered in the same manner by boutons and glial extensions.

The initial segment

At the distal part of the axon hillock, there is a gradual transition into the initial segment (Fig. 2). This is straight and the diameter is nearly constant along its course. In none of the cases was the initial segment observed to branch. The cytoplasm contains many longitudinally-arranged 200 Å neurotubuli, which in longitudinal sections often appear paired (cf. Palay *et al.* 1968, Fig. 3), a phenomenon also observed in the distal part of the axon hillock. In addition, there are some longitudinally-arranged neurofilaments as well as mitochondria, some of which are situated just below the cell membrane. Dense bodies, vesicular profiles and ribosomes are also present, but no granular endoplasmic reticulum is seen.

Dimensions

The dimensions of the axon hillock and initial segment were measured on single longitudinal sections and on the two reconstructions. The findings are presented in Table 1.

Table 1. Dimensions of axon hillock and initial segment

	Axon Hillock		Initial Segment		AH+IS length, μ
	length, μ	diam. base, μ	length, μ	diam., μ	
Model 1	14	8	23	3.3	37
Model 2	13	10	35	3.6	48
Single sections,					
Profile 1	8	9	26	3.3	34
2	8	7	24	3.4	32
3	6	7	23	3.3	29
4	21	15	25	4.2	46
5	13	6	29	2.9	42
6	8	10	28	3.5	36
7	11	11	38	3.7	49
8	12	8	26	3.5	38

It is seen that the initial segment is usually longer than the axon hillock. The diameter of the base of the axon hillock is 2—4 times as large as the diameter of the initial segment. Although the figures for the diameters as obtained from single sections probably do not represent the true values, the diameter of the initial segment seems small, compared to the total diameter of the myelinated motoraxons (about 20μ) in the ventral horn.

The cell membrane of the initial axon segment

The cell membrane of the initial motoraxon segments is specialized in a characteristic way. At the inner side of the membrane, a 200—400 A thick layer of contrast-rich material is attached and extends from the distal end of the axon hillock to the beginning of the myelin sheath (Figs. 4, 5 and 6). It covers the entire circumference of the axon (Figs. 7 and 9) with only a few exceptions (see below). At high magnification the material shows maximum density at a distance of about 100 A from the inner limit of the cell membrane (see Figs. 3 and 4). In this respect, the layer is very similar to the one reported to be present at the axon membrane at the central nodes of Ranvier (see Peters 1966). In longitudinal sections, the thickness of the contrast-rich layer is seen to vary. At regular intervals, there are, namely, dense projections of the material, about 400 A thick, situated about 800 A apart and directed towards the cytoplasm. (Fig. 4). When the axon membrane was cut nearly tangentially, these projections were especially prominent (Fig. 5).

The outside of the axon membrane is covered by a narrow extracellular space, where a finely granular material regularly is observed. The space has a constant thickness of 150—200 A along the initial segment (Fig. 4), but just proximal to the myelin sheath, the layer of granular material sometimes thickens and the material interdigitates with surrounding astrocytic processes (Fig. 6). The granular material is very dense in the best fixations. At many places, the axon membrane shows "coated" invaginations (Fig. 3) (Roth and Porter 1964, Anderson 1964, Andres 1964) which contain the same granular material. A similar finding was made by Campos-Ortega *et al.* (1968). "Coated" vesicles are also sometimes seen in the cytoplasm of the initial segment, and have previously been reported to occur in the axoplasm of central nodes of Ranvier (Andres 1965, Karlsson 1967). Although "coated" invaginations sometimes are observed at the cell membrane of the motoneuron cell body or dendrites, they seem to occur more often at the initial axon segment. At a few places, the axon membrane can show some single, short microvilli-like projections or small flattened-off bulges in which mitochondria are often found. The membrane specialization and extracellular material are usually lacking at these bulges.

As a rule no boutons were observed on the cell membrane of the initial axon segment. Instead, there are many tightly packed glial extensions just outside the extracellular material. Most of the processes were astrocytic-like (Mugnaini and Walberg 1964, Maxwell and Kruger 1965) containing a clear cytoplasm. These processes were usually flattened and oriented parallel to the axon membrane (Figs. 2 and 4). Glial cells with a relatively dark cytoplasm were also found just outside the axon. The nuclei of most of these cells were often chromatin-rich and the cells were frequently flattened and oriented parallel to the surface of the axon (Figs. 2, 5 and 8). In some cases, the initial axon segment seemed encircled by such flattened glial processes (Fig. 7). Most of the dark glial cells around the initial axon segment then looked rather like microgliacytes (Stensaas and Stensaas 1968, Holländer *et al.* 1968, Blinzinger and Kreutzberg 1968, third glial cell type: Vaughn and Peters 1968) than oligodendrocytes (Mugnaini and Walberg 1964, Kruger and Maxwell 1966). Capillaries were often found quite near the initial motoraxon segment.

The boutons on the axon hillock

Boutons are situated on the axon hillock, although not on the initial segment. A few boutons can be observed at the transition between these two regions. The boutons on the axon hillock have much the same characteristics as those

found on other parts of the motoneuron cell membrane (Conradi 1969 a, b). Boutons of the S-, C- and F-types (Conradi 1969 a, b) were regularly present on the axon hillock; M boutons were never observed, and T boutons appeared only rarely. The spectrum of boutons of different types is thus similar to the one found on the motoneuron cell bodies, but different from that found on the dendrites (see Conradi 1969 a, b). Although measurements on the dimensions of the boutons on the axon hillock were not made, the percentage covering of boutons on the cell membrane of the axon hillock seemed rather similar to that found on the motoneuron cell bodies.

The distribution of the boutons on the axon hillock in the two reconstructions is shown in Figs. 9 and 10. No C boutons were present on either one. Some F boutons seem to be clustered together but apart from that, no distinct pattern of localization of the boutons of different types could be distinguished. In the second reconstruction, one adjacent dendrite made contact with the axon hillock. The extension of a dark glial cell, probably a microgliacyte, adjacent to the initial segment, is also shown in the reconstruction.

The first reconstruction shows 32 boutons situated on the axon hillock; two of these were found at the transition between the axon hillock and initial segment. 21 of the boutons were of the F-type, or 66% of the total population; the rest were S-type. In the second reconstruction, 46 boutons were situated on the axon hillock. Of these, 27 boutons, or 59% of the population, were of the F-type, and 19 were S-type.

The myelinated part of the motoraxon

At the beginning of the myelin sheath, the axon is usually somewhat constricted (Fig. 11). The axon is covered by the terminal cytoplasmic pockets (cf. Berthold 1968) of the myelin for 3—4 μ and there is immediate contact between the cell membrane of these structures and the axon membrane, which is not specialized as it is at the initial segment. Usually, not all of the cytoplasmic pockets reach the axon membrane, instead an arrangement similar to the one found at the peripheral motoraxon nodes is observed (cf. Berthold 1968) (Fig. 11). In a few instances the cytoplasmic pockets derived from the most superficial myelin lamellae terminated freely, without making contact with the axon membrane.

Just distal to the beginning of the myelin sheath, the axon diameter increases. The axoplasm contains many neurofilaments and neurotubuli, like other central axons (see Metuzals 1963, Peters 1966, Hirano *et al.* 1967, Bunge 1968). In this region, small figures resembling the granular endoplasmic reticulum in the motoneuron cell bodies were observed in the axo-

plasm in several cases (Fig. 11). Otherwise, the absence of granular endoplasmic reticulum is one of the main criteria for diagnosing profiles of axons in ultrathin sections (Palay 1956).

The myelin sheath of the motoraxons shows some peculiarities as compared to smaller central myelinated axons (Metuzals 1963, Hirano *et al.* 1967, Bunge 1968).

1) Incisures of Schmidt-Lantermann are regularly observed (Figs. 12 and 13). These are relatively abundant and run through the myelin in a zig-zag fashion. The possible existence of the incisures in central myelin has been much debated previously (see Bielschowsky 1928, Lehmann 1959), but they have been demonstrated ultrastructurally in the white substance of the spinal cord of the cat (Bunge et al. 1960).

2) The myelin sheath sometimes shows protrusions, or more frequently compact circular profiles of myelin, 3—6 μ in diameter, are found just outside the myelin sheath, often near incisures and nodes (Fig. 12). Analysis of serial sections revealed that these bodies mostly are spheroid. Usually, they were not continuous with the myelin around the motoraxon, thus, not quite similar to the "redundant" myelin sheaths described by Rosenbluth (1966). In survey articles on the morphology of central myelin, nothing is mentioned about these bodies (Bielschowsky 1928, Lehmann 1959, Sulzmann 1962, Bunge 1968).

Ultrastructure of the axon membrane and surrounding structures at the motoraxon nodes

At the nodes, the motoraxon is usually constricted. The nodal axon membrane faces the node-gap, which is formed between the two adjacent internodal myelin segments (Fig. 14). The length of the node-gap is 0.7—1.1 μ at the axon membrane, as measured on longitudinal sections of 20 profiles. The terminal cytoplasmic pockets of the myelin lamellae are often smaller and filled with a more contrast-rich cytoplasm than the corresponding structures distal to the initial segment (Fig. 15). As in this region and at the peripheral motoraxon nodes (Berthold 1968), not all of the terminal pockets do reach the axon membrane. Instead, in longitudinal sections, several rows of consecutive terminal pockets are seen to project from the axon membrane into the myelin (Fig. 15). Similar structures have not been observed at central nodes of smaller myelinated fibres (Andres 1965, Peters 1966, Karlsson 1967, Hirano *et al.* 1967, Bunge 1968). Here, the terminal cytoplasmic pockets cover 3—4 μ of the axon.

The axoplasm at the node sometimes contains profiles of mitochondria which may be localized just inside the nodal axon membrane. Many mitochondria are also often present in the axoplasm adjacent to the nodes, and in some cases, actual clusters could be observed here (Fig. 16). No aggregation of mitochondria is found just outside the myelin near the nodes, as is the case in peripheral nodes (Williams and Landon 1963, Berthold 1968).

The nodal axon membrane is covered on the inside by a layer of contrast-rich material, quite similar to that found around the initial segment. The node-gap is filled with granular extracellular material (Figs. 17, 18 and 19). This material, which is of the same ultrastructural appearance as that around the initial segment, extends from the axon to the outer margin of the myelin sheath, or even farther. Outside the material, there are many astrocytic extensions, which are also found in the node-gap (Figs. 17, 18 and 19). Few, if any, oligodendrocytic processes are found near the node-gap. Sometimes neuronal profiles were found just outside the extracellular material, but they were usually surrounded by thin astrocytic capsules.

It has to be mentioned that all nodes belonging to small myelinated axons in the ventral horn exhibit only a thin rim of extracellular material, as has previously been found at other places in the CNS (Andres 1965, Peters 1966, Karlsson 1967), after a similar fixation.

In a few instances, the motoraxon was observed to give off a thin, myelinated collateral from the central nodes, near the entrance to the white substance (Fig. 20) (cf. Ramon y Cajal 1909, Scheibel and Scheibel 1966). At these places, the general morphology of the node was similar to that just described. The specialization of the nodal axon membrane and extracellular material extended along the collateral to the myelin sheath.

DISCUSSION

The initial motoraxon segment thus shows a characteristic "undercoating" and is surrounded by dense extracellular material. Since either both or none of the components of the membrane specialization is observed at the same time, they are considered as one entity. Since a similar specialization of the nerve cell membrane seems to be present at the initial segments of other types of neurons (Campos-Ortega *et al.* 1968, Palay *et al.* 1968, Peters *et al.* 1968, Westman 1968) and at central nodes (Andres 1965, Peters 1966, Karlsson 1967) after a similar fixation, the specialization could be a commonly-occurring feature, linked to specific functional properties of the neuron cell membrane.

It might seem controversial to characterize one of the components of the membrane specialization at the initial axon segment as an extracellular material. The presence and appearance of an extracellular compartment in central nervous tissue prepared for electron microscopic studies has, namely, been claimed to be dependant on the preparative procedure. Following permanganate or osmic acid fixation of central nervous tissue, an extracellular space of about 200 A or less is found at most places between the neuronal and glial extension (see for instance Palay *et al.* 1962, Peters 1962, for historic notes, see Robertson *et al.* 1963, Bondareff 1966). It has been claimed that macromolecules can be transported through narrow intercellular channels in the CNS (Brightman 1965, Pappas *et al.* 1966, Torack 1966). Furthermore, there is histochemical evidence that small amounts of an extracellular material are regularly present between the extensions in the CNS (Bondareff 1965, 1967, Pease 1966, Rambourg and Leblond 1967). The material has been suggested to be a mucopolysaccharide, and it has been claimed that such material could serve as a cation exchanger (Bennet 1963). ATPase activity has also been demonstrated at the interfaces between neuronal and glial membranes in the CNS (Torack and Barnett 1963), and physiologic experiments on unmyelinated central axons of amphibia have shown that ionic shifts accompaning impulse-activity, primarily engage small intercellular clefts (Kuffler *et al.* 1966).

After aldehyde fixation, however, central nervous tissue usually exhibits tight apposition of adjacent cell membranes at most places (Karlsson and Schultz 1965, Peters 1966, see also Conradi 1969 a). Some authors claim that this is an effect of the dehydration procedure (Westrum and Lund 1966, Bondareff 1966, Johnston and Roots 1967). From the studies on small central nodes of Ranvier (Andres 1965, Peters 1966, Karlsson 1967) on aldehyde-fixed material and from the present results, it seems, however, clear that aldehyde-fixation, even followed by Vestopal-embedding, is capable of preserving extracellular material. The localization of the material, as described in the present work, could fit well with the above mentioned suggested physiological significance of an extracellular compartment in the CNS.

There is a greater amount of extracellular material around central motoraxon nodes than around nodes belonging to small central fibres. Aggregates of extracellular material, similar to those found around the motoraxon nodes, have only been reported to occur around nodes and boutons belonging to thick myelinated fibres in the fish brain (Robertson *et al.* 1963). Although the significance of this is unclear, it could indicate that the dimension of the axon might in some way be related to the amount of the material.

In this study many "coated" invaginations containing the material were found at the neuron cell membrane at the initial segment, though infrequently at the surrounding glial cell membranes.

Using mostly the same animals as in the present study, Berthold (1968) analyzed the ultrastructure of peripheral motoraxon nodes in the ventral root. Some comparisons can be made: The peripheral nodal axon membrane is like the central one covered at the inside by a layer of contrast-rich material. The dimensions of the node-gap are comparable and just outside the nodal axon membrane, in both the central and peripheral node, there is an extracellular material. At the peripheral part of the motoraxon, there are large accumulations of mitochondria in the Schwann cell cytoplasm in paranodal furrows of the myelin sheath on both sides of the node. At the central nodes, there is no crenation of the myelin sheath paranodally. Compact myelin bodies were, however, often found here. Neither could any accumulations of mitochondria be observed just outside the node. Mitochondria were observed in the axon at the nodes, and in some cases, accumulations of them were found in the axon near the nodes. The latter findings could substantiate Friede's observations (1961) that central white matter histochemically appears to contain little oxidative enzymes; the enzymatic activity was found mainly inside axons, particularly bigger ones, and in some glial cells.

Distribution of boutons on the axon hillock

Due to the nearness to the presumed site of impulse-origin, the boutons on the axon hillock might exert a powerful influence upon the impulse-activity of the motoneurons. Before comparisons with the distribution of boutons on other parts of the motoneurons (see Conradi 1969 a, b) are made, it must be pointed out that the observations in the present work refer to laterally-situated motoneurons in L 6, L 7 and S 1. The quantitative estimations in the preceding papers were performed in a strictly defined small region of L 7; therefore the results may not be comparable. Moreover, the numerical proportion of the different bouton types was investigated on only two reconstructions, which naturally does not permit generalisations. For the most part, however, the general features were the same in both cases.

As already pointed out, the same types of boutons were present on the axon hillock as on the motoneuron cell bodies. The numerical proportion of F boutons, 66% and 59%, respectively, was of the same size-order as, or even higher than the value, corrected for mean length of apposition, obtained for the cell bodies (54%). If the latter is valid, there seems thus to be a continuous decrease in the proportion of F boutons from the axon hillock

towards the distal parts of the dendrites (see Conradi 1969 a). The tendency for the S+T boutons (see Conradi 1969 a) would be the reverse.

If it is assumed that the F boutons are inhibitory (Uchizono 1965, Bodian 1966) and the S+T boutons excitatory, then the inhibitory boutons on the axon hillock seem to outnumber the excitatory ones by about 50%. If the F boutons are slightly bigger than the S+T boutons, as seemed to be the case on the cell bodies, approximately 3/4 of the surface of the axon hillock covered by boutons could be subjected to inhibitory influences. The dorsal root boutons (see Conradi 1969 d) did not seem to be localized at the axon hillock.

ACKNOWLEDGEMENTS

I am much indebted to Professor Sten Skoglund for his encouragement and helpful discussion, and to Miss Christina Trägårdh for skilful technical assistance. The work has been supported by grants from Karolinska Institutet and the Swedish Medical Research Council, projects nr. B69—14X—136—05C and B70—14X—136—06.

SUMMARY

The axon hillock and initial axon segment of the lumbosacral motoneurons in the cat were studied with the electron microscope. The cell membrane of the initial motoraxon segment is covered from the inside by a thin layer of contrast-rich material and it is surrounded by a narrow rim of extracellular material. Adjacent to the initial segment, glial cells containing a dark cytoplasm are often found. Boutons are found on the axon hillock but not on the initial segment. Two wax-models of the axon hillock and initial segment were prepared from ultrathin serial sections. The distribution of boutons of different types on the axon hillock was investigated on these models and it is concluded that the population of boutons is rather similar to that on the motoneuron cell bodies which has previously been described.

Some observations on the motoraxons in the gray substance are included. At the myelinated part of the motoraxon, the myelin sheath exhibits incisures of Schmidt-Lantermann and just outside the myelin sheath there are spheroid, compact bodies of myelin. At the central nodes of Ranvier, the motoraxon is surrounded by a thick layer of extracellular material.

LEGENDS TO THE FIGURES

Fig. 1. Light microscopic photograph of a motoneuron and the first part of the axon. ×410

Fig. 2. Survey electron micrograph of the axon hillock (AH) and initial segment (IS) of a motoneuron. The beginning of the myelin sheath is also seen. Note the compact myelin bodies (C) outside the myelin. Three glial cells with dark cytoplasm are seen near the initial segment, two are oligodendrocytes (OL); the third, probably a microgliacyte (MG). ×1,900

Fig. 3. Part of an initial segment at higher magnification. The axon is surrounded by flattened astrocytic extensions. The contrast-rich material inside the axon membrane is seen. Note the longitudinal neurotubuli (NT), some of which are grouped together. ×22,400

The inset shows a "coated" invagination of the axon membrane. The contrast-rich material at the inside of the latter is seen to the left (arrow). ×116,500

Fig. 4. Detail of the axon membrane at the initial segment. Just outside the axon membrane a thin rim of extracellular material is seen (×). Outside this, there are astrocytic extensions (AS). Note that the contrast-rich material inside the axon membrane shows maximum density some distance away from the membrane (arrow). The contrast-rich material shows projections, directed inward (DP). ×137,000

Fig. 5. Detail of an initial segment cut obliquely. The dense projections (DP) shown in the preceding figures are prominent. Outside the initial segment, there is a glial cell, probably a microgliacyte (MG). ×13,500

Fig. 6. Detail of an initial segment (IS) just proximal to the myelin sheath (MY). There are large accumulations of extracellular material (×). ×49,400

Fig. 7. Cross section of an initial axon segment (IS). Note the contrast-rich material at the axon membrane. The axon is surrounded by many dark, flattened glial extensions (G). ×17,200

Fig. 8. Survey of the axon hillock (AH) of a motoneuron. A dark glial cell, probably a microgliacyte (MG), is situated at top left. Several boutons are seen to cover the axon hillock; one of these is of the C type (C). ×6,200

Fig. 9. Wax-model of an axon hillock (not painted) and initial segment (stippled with black), reconstructed from serial sections and seen from the front and from behind. Cell body at the bottom of the figure. Note the compact myelin body just outside the beginning of the myelin (arrow). The boutons on the axon hillock are also included. Black=F-type; white stippled=S-type.

Fig. 10. Wax-model of another axon hillock and initial segment (black stippled). Cell body at the bottom of the figure. The boutons are indicated as in the preceding figure. The extension of a flattened glial cell, probably a microgliacyte, is included. Such a cell in similar position was also present at the initial segment in the preceding reconstruction, but was not included. There is apposition between the axon hillock and an adjacent dendrite, part of which is included in the model (arrow).

Fig. 11. The beginning of the myelin sheath distal to the initial segment (IS) is shown. The terminal cytoplasmic pockets of the myelin (TP), not all of which reach the axon membrane, are seen. In the axoplasm inside the myelin, some profiles of granular endoplasmic reticulum (arrow) are observed. ×9,700

Fig. 12. Myelinated part of the motoraxon. Two incisures of Schmidt-Lantermann (SL) are observed. Outside one of these, there is a compact myelin body (arrow). ×4,800

Fig. 13. Detail of an incisure of Schmidt-Lantermann. ×22,600

Fig. 14. A central node of a motoraxon in the gray substance. The axon is seen to be constricted at the node. Some profiles of mitochondria (arrow) are seen in the axon near the node. ×9,600

Ultrastructure of dorsal root boutons on lumbosacral motoneurons of the adult cat, as revealed by dorsal root section

by

SEBASTIAN CONRADI

INTRODUCTION

The aim of the present study was to obtain information on the ultrastructure and location of the dorsal root boutons on the motoneurons in the adult cat, which is a prerequisite for studies on the postnatal development of these boutons (see Conradi and Skoglund 1969 b). As pointed out earlier (Conradi and Skoglund 1968), the evaluation of changes in boutons during the first days after dorsal root section requires information on the ultrastructure of the boutons on the motoneurons in the normal state. This has been presented in two earlier communications (Conradi 1969 a, b). For calculations on the loss of boutons several weeks after dorsal root section, knowledge of the frequency and distribution on the motoneurons of these boutons in the normal state (Conradi 1969 a, b) is also needed.

It is of great interest to study in detail the morphology of the dorsal root boutons on the motoneurons.

1) Due to the favourable anatomical conditions, the dorsal root fibres are more readily available for transection than any other of the fibre systems contacting the motoneurons. For the same reason, the conditions for stimulating and recording are also favourable, which explains why the physiologic properties of the monosynaptic pathway are more fully understood than those of other fibre systems projecting on the motoneurons.

2) Presynaptic inhibition was first described in the monosynaptic pathway (Frank and Fuortes 1957). It has been suggested that the phenomenon is

caused by the activity of small boutons, making synaptic contact with the dorsal root boutons on the motoneurons (Eccles 1964, see also Gray 1962). It has not hitherto been possible to prove this, and the present morphological knowledge of the connexions between the dorsal root collaterals and the motoneurons emanates from light microscopic studies (see for example Sprague 1958, Szentágothai 1958, Mikeladze 1966, Illis 1967, Sterling and Kuypers 1967, Carpenter *et al.* 1968, Scheibel and Scheibel 1969). Axo-axonic synapses, however, have been described ultrastructurally in several regions of the brain and spinal cord (see Kidd 1962, Colonnier and Guillery 1964, Walberg 1965, Ralston 1965, 1968 a, Peters and Palay 1966, Szentágothai *et al.* 1966, Karlsson 1967, Pecci Saavedra *et al.* 1968).

The method of mapping fibre connexions by means of degeneration after axon section has been frequently used in neuroanatomic work. At the ultrastructural scale, three main types of degenerative bouton changes following axon section have hitherto been described to occur in the CNS:

a) The boutons are filled with a dense material (see Colonnier and Gray 1962, Walberg 1963, 1964, Mugnaini *et al.* 1967, McMahan 1967, for references, see Aiksne *et al.* 1966).
b) The boutons are filled with neurofilaments (Gray and Hamlyn 1962, Colonnier and Guillery 1964, Dowling and Cowan 1966, Pecci Saavedra *et al.* 1969, for references, see Mugnaini and Walberg 1967).
c) The boutons are engulfed by glial cells (see for example Colonnier 1964, Smith *et al.* 1966).

Boutons showing any of these changes were searched for, when trying to identify the degenerating dorsal root boutons during the first postoperative week. There is light microscopic evidence (Szentágothai 1958) that rather few of the boutons on the motoneurons are of dorsal root origin. Due to this and to the fact the acute ultrastructural changes in boutons were slight, it was decided first to investigate the loss of boutons a comparatively long time after the operation.

Two boutons types, the M type and a variety of the S-type (see Conradi 1969 a, b), both of which have small boutons (P-type) apposed at the convex side, were found to have disappeared already during the first postoperative week. The acute changes in these boutons during the first postoperative days were then studied. The normal anatomy of the two bouton types was studied in detail through serial sections. Although the zone of apposition between the P boutons and these big bouton types does not clearly fulfil conventional criteria for a synaptic complex (see Gray and Guillery 1966), as stated earlier (Conradi and Skoglund 1968), this is the only neuroneuronal contact of the

P boutons which is similar to a synaptic complex and accordingly, it is concluded that dorsal root boutons on homolateral motoneurons are postsynaptic in axo-axonic synaptic complexes.

Some of the results have been published earlier in preliminary form (Conradi and Skoglund 1968, Conradi 1968). In the ensuing description, the normal ultrastructure of the M and big S boutons will be dealt with first, then the changes after dorsal root section will follow.

MATERIAL AND METHODS

24 adult cats of both sexes were subjected to unilateral dorsal root section proximal to the spinal ganglion, under aseptic conditions. The animals were anaesthetized intraperitoneally with Nembutal® (Abbott) 20—40 mg/kg of body weight. A wide laminectomy, comprising the three lowest lumbar vertebrae was performed in most cases. The dura was incised longitudinally for 3—5 cm, and the left dorsal roots L 6, L 7 and S 1 were cut. The degeneration was studied in the segment L 7, but the adjacent roots were also cut in order to obtain maximal degeneration, since it has been shown (Sprague 1958) that every dorsal root sends collaterals to 1—3 segments above and below the site of entrance. In a few cases, only the left 7th lumbar dorsal root was cut just proximal to the spinal ganglion, thus allowing the opening in the dural sac to be restricted. The only disadvantage with the wide incision was that at sacrifice, a herniation of the spinal cord was sometimes found.

An attempt was made to cut all the dorsal root fibres at an equal distance from the spinal cord, and in order to avoid damage to the cord, the roots were cut as distally as possible. Often, the dorsal root arteries could be saved, but the arrangement of these vessels varied greatly. After the operation, the dorsal muscles, fascia and skin were sutured separately, and in most cases, Polymyxin B® (Pfizer) unguent was left in the wound. The operations usually lasted for one-half to one hour. The postoperative care included penicillin, Suspenin® (Kabi) 300,000 IE/day i.m. and cleaning of trophic ulcers in a few cases. The mortality was about one out of ten animals, death occurring during the operation. After a survival time of 1—42 days (Table 1), the animals were subjected to the same fixation procedure as already described (see Conradi 1969 a). Nearly the whole material was perfused at a discontinuous perfusion pressure and 2.7% Rheomacrodex® was added to the perfusates.

For comparison, 12 adult rats were also operated upon and subjected to perfusion fixation in the same way as the cats at survival times of 1—7 days. This material was not analyzed in detail, but some of the main findings were the same in both animals. Fig. 19 is taken from the rat material.

After the fixation, the lumbosacral spinal cord was removed and the 7th lumbar segment was cut into 0.5—1 mm thick transverse sections. The operated and unoperated sides of the cord were postfixed and embedded in the same way as the normal material.

Semithin transverse sections of half the spinal cord were cut, stained with toluidine blue and examined in the light microscope. On these large sections, it was possible to judge the axonal degeneration on the operated side fairly well. The lateral part of the

Table 1. Survival times of the operated animals

ventral horn was then trimmed out and cut into ultrathin transverse sections, which were collected on one-hole grids. Single sections, as well as consecutive series comprising 20—100 sections, in which only a few single sections were lost, were investigated. Sections from the normal material and the unoperated side served as control.

In those cases, in which the cord was herniated after the operation, the profiles of the motoneurons were sometimes elongated in the anteroposterior direction. In a few of the animals with a short survival time, there seemed to be accidental degeneration, probably an affect of the operation. A few obviously degenerated axons could then be seen in the white substance. This did not, however, interfere with the findings in general.

The number and proportion of the remaining boutons of different types on the motoneurons 42 days after homolateral dorsal root section was estimated on two cats with the same fixation and sampling methods as were used for the normal material (see Conradi 1969 a). Briefly, the boutons on profiles of 20 motoneuron cell bodies (SO) cut through the mid-nucleus plane and adjoining proximal parts of the motoneuron dendrites (DA, DB), as well as on 30 thin, longitudinally-sectioned dendritic profiles in the neuropile (d), were counted on single transverse sections through the lateral motoneuron nucleus in the most cranial millimetre of L 7 in prefixed (Sherrington 1892) animals. The only difference from the procedure used in the normal material was that the dimensions of the bouton profiles were not measured. Due to this, a low final magnification of the montages (× 1,860) could be used, thus markedly reducing the number of photographs that were used.

Two M boutons, including the apposing P boutons from the normal material, were reconstructed with 1 mm wax-plates from consecutive ultrathin sections, according to a technique, presented earlier (Conradi 1969 c). In both cases, none of the serial sections was lost. One of the boutons was taken from the series through the proximal part of a motoneuron dendrite belonging to a lateral motoneuron in the uppermost mm of L 7, the surface relationships of which were analyzed in a preceding communication (Conradi 1969 b). (The M bouton in reconstruction A). The second bouton was taken from segment L 7 of another animal, fixed in the same way. In both cases every section was used. The mean section-thickness was calculated from the number of sections required to pass longitudinally cut dendrites in the tissue. The dendrites were assumed to be cylindrical and the diameter of the dendrite was measured from the photographs. In the first reconstruction, the mean section-thickness was 880 Å, and the final magnification of the reconstruction was × 11,200. The bouton was passed in about 60 sections. A schematic drawing of the reconstruction of this bouton was also

made (Figs. 1 and 2). The second reconstruction (Figs. 3 and 4) shows an M bouton, located at the border between the motoneuron cell body and the proximal part of a dendrite. Here the mean section-thickness was about 560 Å, and the magnification of the wax-reconstruction ×17,800. The bouton was passed within 100 sections.

RESULTS

Evidence showed (see below) that the big bouton types, the M-type and a variety of the S-type, which have P boutons apposed at the convex side, disappear from the motoneuron surface during the first week after homolateral dorsal root section. Due to this, the normal ultrastructure of these boutons was studied in more detail. Serial ultrathin sections were used for this purpose. Special emphasis was placed on determining whether or not the contact between the P boutons and the bigger boutons fulfil the criteria for a synaptic complex. It was thought to be of further interest to investigate the number and distribution of P boutons on the convex side of the bigger boutons.

Normal material

The M boutons

Several M boutons were wholly or partially investigated through serial sections. In two cases, wax-models of such a bouton and the apposing P boutons were prepared (Figs. 1—4). A constant feature seemed to be that several P boutons could be apposed at one M bouton. Also, the P boutons were often situated along the lateral border of the M boutons, thus being apposed both at this and at the postsynaptic extension, which was usually the proximal part of a motoneuron dendrite.

In Figs. 1 and 2, one of the reconstructed M boutons is shown. In the adjoining schematic drawing, eleven P boutons are found to be apposed at this M bouton and nine of them are also apposed to the motoneuron cell membrane. Two big P boutons are apposed only at the convexity of the M bouton. From the schematic drawing, seven dendritic spines are seen to be situated along the lateral border of the M bouton. This and the extension of the synaptic complex of the M bouton are also shown in the reconstruction of the entire adjacent dendritic surface (Conradi 1969 b, Fig. 9).

The second reconstruction is shown in Figs. 3 and 4. This M bouton, which is somewhat bigger than the first one described, was situated at the soma-dendritic junction of a motoneuron. The preterminal axon, which is unmyelinated the last distance before the bouton, shows an ovoid expansion

filled with synaptic vesicles. The expansion is not, however, presynaptic to any other neuronal extension. Seven P boutons are apposed at the lateral margin of the M bouton and at the motoneuron cell membrane, and an additional four P boutons, somewhat bigger than the foregoing, are situated around the expansion. The extension of the synaptic cleft of the M bouton is depicted in Fig. 4 d. A few dendritic spines were situated adjacent to this bouton.

Thus, in both the reconstructions, some of the P boutons were apposed both at the motoneuron cell membrane and at the M boutons, others only at the M boutons. It was not, however, possible to distinguish different types of P boutons. Although the thin, unmyelinated preterminal axons of the P boutons could not be traced for longer distances through the series, it seemed, nevertheless, as if at least some of these axons were running on or very near to the motoneuron cell membrane.

The contact area between P and M boutons. In single sections, the contact area between P and M boutons was often difficult to resolve. When the plane of the section was ideal, the following features could be observed. At most places of the contact region, the cell membranes of the boutons showed immediate apposition, quite like the situation found at the interface between other neuronal cell membranes in the neuropile (see Conradi 1969 a) (Figs. 1 b and 3 c). Not infrequently, desmosome-like junctions were found at the cell membranes of the two boutons (Fig. 6). At low magnification, these were easily mistaken for synaptic complexes. At some places, a narrow zone of granular extracellular material about 100 A thick and only about 0.1 μ wide, was found between the cell membranes of the boutons (Fig. 5). The synaptic vesicles of the P boutons were apposed at the cell membrane here, but no corresponding arrangement was found inside the M boutons. There was a slight rim of contrast-rich material attached at the cell membranes of the boutons on both sides of the extracellular material (Fig. 5). Since these regions did not clearly fulfil the criteria for a synaptic cleft (cf. Conradi and Skoglund 1966) because of the small extracellular space, serial sections were required to judge whether the P boutons establish additional structures similar to synaptic complexes with any other neuronal extensions. From investigation of serial sections on about 25 P boutons it seemed clear that this was not the case. In those instancies, in which the P boutons were apposed also at the motoneuron cell membrane, no structure similar to a synaptic complex was found at the region of apposition. Assuming that every bouton makes at least one synaptic complex—and this seemed to hold true for nearly all the boutons on the proximal part of the motoneuron dendrite, analyzed in a preceding

paper (Conradi 1969 b)—the contact regions between the P and M boutons must then be interpreted as a synaptic complex.

The big S boutons with apposed P boutons

As pointed out earlier (Conradi 1969 a, b) it was sometimes observed on single sections from the normal material, that P boutons in a few cases are apposed at the convex side of big boutons on proximal parts of the motoneuron dendrites (Fig. 7). Since these profiles in some cases might have been derived from M boutons, sectioned in a plane outside the synaptic cleft, these profiles were included together with the M boutons in the quantitative studies on single sections. As mentioned earlier (Conradi 1969 b), the big S and M boutons differed most markedly in size and shape of the synaptic complex, the big S-type mostly establishing synaptic complexes indistinguishable from those of other S boutons. The contact region between P and the big S boutons seemed to be of a character similar to that between P and M boutons. Usually only one P bouton was observed on the analyzed big S boutons.

Distribution and dimensions of M and big S boutons on the motoneurons

As stated in connexion with the quantitative estimation on normal material (Conradi 1969 a, see also Table 2), the M and big S boutons seem to be located mainly on the proximal parts of the motoneuron dendrites.

Most of the boutons were situated in region DA (within that region of the dendrite covered at one side by the first 20 boutons in one section, counting from the cell body). In this region, about 1% of the bouton profiles were of these two types, as seen in the single sections, although the proportion varied between the different dendrites. From observations on single sections, several adjacent M boutons were often found on one and the same dendrite. This could be in keeping with the recent observations on the terminal axonal ramifications of the dorsal root fibres by Scheibel and Scheibel (1969). A few M boutons were also observed on the motoneuron cell bodies or on dendritic profiles in the neuropile. The preterminal axons of the boutons of these types were always noted to be unmyelinated for the last distance before the bouton. No bouton *de passage* was found. In only a few cases were M boutons found to make synaptic contact with more than one extension. No boutons of these types were observed to contain neurofilaments to a marked degree in the normal material. The mean length of the above-mentioned types seemed to be 3.5—5 μ, judging from single sections. The mean height was about 1.5 μ.

Operated material

Axon degeneration

In the light microscope, profiles of obviously degenerating axons were observed on the operated side of the spinal cord in segment L 7, from the second postoperative day on. In most cases, the axoplasm was dark and appeared shrunken. Collapsed myelin sheath or distended profiles of myelin, in which no axoplasm was visible, were also encountered. The degeneration was most apparent at the entrance zone of the dorsal root and in the dorsal funiculi. Degenerated axons were observed in large numbers in the ipsilateral dorsal horn and to a lesser extent in the ventral horn. On the contralateral side, there were few, if any, such profiles. The axon degeneration seemed to be maximal after about one week, but many degenerated axons could still be seen 6 weeks postoperatively.

In the electron microscope, profiles of degenerated axons were observed in the neuropile of the ventral horn from the third postoperative day. The number of those profiles seemed to increase until the 5—7th postoperative day. Then, several such profiles were always present on every ultrathin section, containing two to five motoneurons. At many places, profiles of dark degenerated axons were situated quite near the motoneurons, and in some instancies, the outline made them look very similar to big dark boutons at low magnification. At this stage a few degenerated axon profiles could also be seen in the contralateral ventral horn.

The degenerated axons nearly always had a dark axoplasm, which at high magnification appeared granular. Profiles of distended mitochondria and dense bodies could often be distinguished in the axoplasm (Fig. 8). This type of axon degeneration has been described earlier in several reports on Wallerian degeneration in the CNS (see for example Ralston 1965, McMahan 1967, Lampert 1967). Often, the myelin formed big loops outside the dark axoplasm.

At a few places, distended myelin sheaths lacking axoplasm were observed. The region inside the myelin appeared clear and in it, profiles of highly distended mitochondria and some floccular material could sometimes be observed (Fig. 9). In a few cases, highly distended profiles, often surrounded by myelin were observed on the operated side. At times, the interior of such profiles contained many neurofilaments (Fig. 11): at other times, many small mitochondria and membrane bound dense bodies could be seen to be distributed in a somewhat fibrillar ground substance (Fig. 12). Similar findings have been reported in earlier studies on the distal stump following axon transection in the central and peripheral nervous system (Webster 1962,

Blümcke *et al.* 1966, Schlote 1966, Lampert 1967, Pellegrino de Iraldi and de Robertis 1968, Zeléna *et al.* 1968).

Often the profiles of degenerated axons were surrounded by astrocytic extensions. The process of removal of the axons was not studied in detail. No degenerating unmyelinated axons were observed with certainty. The morphology of degenerating unmyelinated axons has been difficult to settle, even in regions where they ought to be abundant (see for example Hamori *et al.* 1968).

Bouton degeneration

When the neuropile in the ventral horn on the operated side is studied during the first postoperative week, the most apparent feature is the paucity of degenerating boutons, as judged by conventional criteria. No boutons were observed to show the dense type of degenerative change seen in other regions of the CNS (see Alksne *et al.* 1966, McMahan 1967), although such boutons have been described to be abundant in the dorsal horn after dorsal root section (Ralston 1965, 1968 b). It was also very difficult to distinguish any boutons, showing the neurofilamentous type of degeneration (see Mugnaini and Walberg 1967), partly because some boutons in the normal material contained neurofilaments (cf. Gray 1963). At only a few places, often near degenerated axons, membrane-bound profiles were observed inside glial cells. These structures were similar in size and appearance to degenerating boutons phagocyted by glial processes, as described earlier (Colonnier 1964). One such a profile is seen in Fig. 15.

Since no information regarding the type or types of degenerating boutons could be gained from these observations, it was decided to investigate whether the number of any of the bouton types seemed to decrease by one week postoperatively. It was then thought possible to evaluate the acute postoperative changes in the actual boutons prior to disappearance.

The number of the M boutons was found to be markedly reduced from about the third postoperative day. By about one week postoperatively, they had disappeared completely. The same seemed true for the profiles, looking like be big S boutons with apposed P boutons. These findings were based on observations on more than one hundred sections from the about twenty animals with a survival time of three days or more. In the normal material or on the unoperated side, usually one to three M boutons could be observed in a section comprising two to four profiles of motoneuron cell bodies.

Quantitative estimation

In order to ascertain the findings and to try to evaluate whether boutons of other types also disappear, a quantitative study of the boutons at a long time after the operation was performed in the same way as in the normal material (Conradi 1969 a). A survival time of six weeks was chosen, since according to quantitative studies on axon degeneration in the pyramidal tract, the degeneration of the biggest axons was not complete until about this time (v. Crevel and Verhaart 1963). The result is presented in Table 2 and the values from the normal material (Conradi 1969 a) are included. As was the case in the normal material, the M boutons and the big S boutons with P boutons apposed at the convex side are included under the same heading.

It can be seen that the mean minor diameter of the motoneuron cell bodies and dendrites is somewhat less in the operated than in the normal material. In regard to the boutons, both the number and relative porportion of the different types on different regions of the motoneurons are quite similar in the operated and normal animals. The boutons under the M heading were not present at all in the operated animals, but the number of T boutons was rather similar in the two materials. It was concluded that if boutons of any types other than the M- and big S-types disappear, the number of them is too small to be revealed by this type of investigation.

Bouton changes during the first postoperative days

As pointed out earlier, profiles similar to phagocyted boutons which were previously described (see for example Colonnier 1964, Smith *et al.* 1966), and boutons containing neurofilaments (Gray and Hamlyn 1962, Colonnier and Guillery 1964, Dowling and Cowan 1966, Mugnaini and Walberg 1967, Pecci Saavedra *et al.* 1969) were observed during the first postoperative week. These profiles were investigated in further detail, with special attention paid to, whether any profiles could be shown to arise from M boutons.

Phagocytosis. Circular, membrane-bound inclusion bodies, 1—2 μ in diameter, were observed inside glial processes, both just outside proximal parts of the motoneuron dendrites and in the neuropile between the 3rd and 7th postoperative day. The glial extensions were principally of two different types.

The inclusion bodies were most often found inside extensions of the astrocytic type (see Mugnaini and Walberg 1964, Maxwell and Kruger 1966). The

bodies were rather constant in appearance, with a dark or somewhat vacuolized ground subsubstance. This can be seen in Fig. 16 h.

At high magnification, profiles of distended mitochondria could sometimes be observed inside the inclusion bodies. Neither a synaptic complex nor part of a postsynaptic extension could be observed inside the glial cytoplasm, which structures were observed by Colonnier (1964).

At many places, inclusion bodies similar to phagocyted boutons were observed inside rather small glial cells containing a chromatin-rich nucleus. The cytoplasm of these cells was amorphous and somewhat more contrast-rich than the astrocytic cytoplasm, and can be seen in Fig. 12. This type of glial extension could be observed both just outside the proximal parts of the motoneuron dendrites and in the neuropile. Some cells of this type were also seen in the normal material and similar glial cells have been observed in other parts of the CNS, especially during degeneration (third neuroglial type: Vaughn and Peters 1969, microglia: Blinzinger and Kreutzberg 1968, Holländer *et al.* 1969). The inclusion bodies inside these cells were either similar to those found inside astrocytic extensions, or, most frequently, were very vacuolized. Often the glial cell membrane was intricately invaginated around these inclusions. (Fig. 12).

Postsynaptic material could sometimes be observed at the inside of the motoneuron cell membrane just adjacent to the glial extensions containing these inclusion bodies. Postsynaptic dense bodies were found immediately inside the postsynaptic material and quite long rows of the postsynaptic dense bodies could be seen (Figs. 12 and 13). This was observed frequently at proximal parts of the motoneuron dendrites. Intact postsynaptic dense bodies have been reported to occur below phagocyted degenerating boutons in sympathetic ganglia after section of the preganglionic axons (Taxi 1962, Sotelo 1968). In the present material, long rows of postsynaptic dense bodies, attached at a membrane fragment were also sometimes encountered in the cytoplasm of proximal parts of the dendrite, just inside the cell membrane (Figs. 12 and 13). The distance between the remaining boutons at both sides of the region of the motoneuron cell membrane occupied by the glial cell, was usually 5—7 μ. The boutons just adjacent to the glia often exhibited postsynaptic dense bodies.

Due to the presence of the long rows of remaining postsynaptic dense bodies and to the localization of these complexes on the proximal parts of the motoneuron dendrites, it was thought that these phenomena represented a disintegrating M bouton. In one instance, seven days postoperatively, a big bouton showing a synaptic complex with a long row of postsynaptic dense

bodies, thus probably of the M-type, was observed on the proximal part of a motoneuron dendrite. The bouton covered, however, only half the synaptic cleft. On the rest of the cleft, there was apposed a big extension, which contained tubular and vesicular profiles—most likely of glial origin (Fig. 14). This configuration might represent an intermediate stage between the normal state and the phenomena described above.

One of the dense membrane-bound inclusion bodies just outside the proximal part of motoneuron dendrite was analyzed through consecutive sections (Figs. 15 and 16). The body was found to be completely surrounded by glial extensions. Adjacent to the inclusion body, there were two small, apparently normal boutons, containing irregularly-shaped synaptic vesicles and embedded in glial extensions. These boutons were very similar to normal P boutons and did not establish synaptic contact with any neuronal extension in the series. The area occupied by the remaining postsynaptic dense material was large and completely covered by postsynaptic dense bodies; it was slightly invaginated at one place and a membrane-fragment with attached postsynaptic dense bodies was found inside the cytoplasm of the dendrite at the site of invagination.

The further studies included the cytoplasm of the motoneuron dendrites, since long rows of postsynaptic dense bodies attached to membrane-fragments had been observed inside the motoneuron cell membrane. At proximal parts of the motoneuron dendrites, a characteristic complex was found in several instances in different animals, from the 3rd to 5th postoperative day. In these cases, circular, membrane-bound bodies, about 0.5 μ in diameter, were situated in the motoneuron cytoplasm immediately inside the cell membrane (Figs. 17 and 18). Usually 1—3 profiles of similar appearance were grouped together. The interior of these bodies was mostly dark and somewhat granular or vacuolized. Profiles similar to distended mitochondria could also be observed. Immediately outside the limiting membrane of these bodies, there was a thin rim, about 150 A in width, filled with a granular material. Bordering this was another membrane parallel to the first, at the outside of which were attached a layer of contrast-rich material, about 300 A thick and long rows of circular bodies. The dense bodies were exactly alike the postsynaptic bodies of Taxi even to forming rows in the same way.

The inclusion bodies appeared as if part of the boutons, including the synaptic complex, had been invaginated into the motoneuron cytoplasm. Walberg (1963) has suggested that normal dendrites may play a role in the removal of degenerating boutons. The localization of the above-mentioned configurations at the proximal parts of the motoneuron dendrites and the

presence of the long rows of postsynaptic dense bodies were interpreted to indicate that the structures emanated from M boutons. In order to study the relationships of these profiles, analysis of serial sections was performed in one case (Fig. 17). It was found that at least one of the membrane-bound bodies—the only one completely covered by the series—seemed to be completely surrounded by motoneurons cytoplasm; and nearly the entire surface was covered by circular dense bodies apposed exactly as the postsynaptic bodies of Taxi (1961).

An attempt was also made to find an example, in which a bouton of the M-type was only partly invaginated into the motoneuron. Despite extensive searching, this could not be found in the material on the cat, but was present at one instance in the material on the rat (Fig. 19).

Neurofilaments. From the third postoperative day, some big boutons, containing spherical synaptic vesicles and to which P boutons were apposed at the convex side, were observed to be filled with neurofilaments. These boutons were observed both on proximal parts of the motoneuron dendrites and in the neuropile (Fig. 20). Postsynaptic dense bodies were usually not observed below these boutons, which is a reason why some of these boutons may have originally been big S boutons with axo-axonic synapses. Smaller boutons containing neurofilaments were also observed both on motoneuron cell bodies and dendrites and in the neuropile. The relative number of these boutons compared to those in the normal material was, however, difficult to evaluate. Generally, it seemed as if the proportion of boutons containing neurofilaments varied among the different animals. After the first postoperative week big, seemingly distended profiles, packed with neurofilaments, were observed in the neuropile (see Fig. 9).

Ultrastructural bouton changes inside intact M boutons during the first postoperative days

In order to study whether changes in the boutons occur prior to disintegration, the morphology of M boutons remaining during the first postoperative week was studied. During the third to seventh postoperative days, some M boutons were observed only a short distance away from obviously disintegrating boutons. These M boutons could exhibit rather numerous granular vesicles (Fig. 21), an increase in the number of which has been reported to occur inside degenerating boutons in sympathetic ganglia (Taxi 1962, Hunt and Nelson 1965, Hamori *et al.* 1968) and in the cerebellum (Smith *et al.* 1966). In some cases, the remaining M boutons were also observed to contain

distended mitochondria or membrane-bound dense bodies. The bouton depicted in Fig. 21 was also slightly invaginated into the postsynaptic dendrite. As a whole, however, the early postoperative changes inside M boutons seemed too slight and too varying to permit any general conclusions.

Other bouton changes during the first postoperative week

During the first postoperative week, some boutons containing membrane-bound, dense lysosome-like bodies were observed in the ventral horn (Fig. 22). Such bodies have earlier been observed in boutons and myelinated axons after axon transection (Webster 1962, Schlote 1966, Blümke *et al.* 1966, Lampert 1967, Hamori *et al.* 1968, Pellegrino de Iraldi and de Robertis 1968). In the present material the dense bodies were observed inside both small and bigger boutons, but whether any particular bouton type was affected could not be ascertained. Membrane-bound dense bodies were even present inside boutons in the normal material, particularly in the FD-type (Conradi 1969 a).

During the first postoperative week, some boutons were observed, which contained spherical synaptic vesicles, and in which the ground substance showed a slightly increased density. Below these or other boutons, containing spherical vesicles, postsynaptic dense bodies seemed to be clumped (Fig. 22). In a few cases, profiles, probably of neuronal origin, were observed to contain highly distended mitochondria and granular vesicles dispersed in a ground substance of a somewhat increased density (Fig. 23). These extensions seemed to show one of the degenerative bouton changes, described in the cochlea after transection of the olivocochlear bundle (Smith and Rasmussen 1965). Thus, there was some evidence that changes other than phagocytosis and an increase in the number of neurofilaments might occur in the boutons during the first postoperative week. However, it could not be definitely shown whether boutons other than those of the M- or the big S-types with axo-axonic contacts were regularly affected.

Structures in the operated material, considered to be indepentent of degeneration of the dorsal root terminals

Some dark, membrane-bound profiles, of about the same size as boutons and surrounded by astrocytic extensions, were observed outside the motoneuron cell membrane. Boutons were often apposed at these structures (Fig. 24). At high magnification no vesicles could be observed in these dense profiles. These profiles are obviously dendrites, which either shrank during

the preparative procedure or are in the process of degeneration (see Grant and Westman 1969). They can also be found in the normal material.

Sometimes, lamellae of granular endoplasmic reticulum, arranged as below the C boutons (see Conradi 1969 a), were observed just inside the motoneuron cell membrane, at a region covered on the outside by astrocytic extensions (Fig. 25). It has been argued that such figures represent degeneration of C boutons following dorsal root section (Uchizono 1968), although this arrangement was also observed in the normal material.

DISCUSSION

Ultrastructure and distribution of dorsal root boutons in the normal material

The findings in the operated material were interpreted as evidence for the M and big S bouton types being of dorsal root origin. The normal ultrastructure of the M boutons, which is the easier to recognize and possibly the one occurring more frequently of these two, has been described in two previous communications (Conradi and Skoglund 1968, Conradi 1968). In the present report, the ultrastructural characteristics of M boutons as described above, were defined from investigations of serial ultrathin sections. For practical reasons, as for example, in statistical evaluation or studies after experimental procedures, it is also useful to define the different bouton types so that they can be recognized in single sections (see Conradi 1969 a). In these the M-type is usually recognized by the big size of the boutons, the shape of the synaptic vesicles and the large number of postsynaptic dense bodies. There are almost no S boutons of the same size as M boutons on the motoneuron cell membrane. Some boutons, containing spherical synaptic vesicles and often localized at small dendritic profiles in the neuropile, can sometimes exhibit one or two large profiles of synaptic complexes, in which 6—9 postsynaptic dense bodies can be seen in one section (Conradi 1969 a). These boutons are smaller than those of the M-type; moreover, they are never observed to be postsynaptic to other boutons.

On the dendritic portion from the normal material, analyzed through serial sections (Conradi 1969 b), the M and big S boutons with axo-axonic contacts were surrounded by dendritic spines. It has recently been suggested (Szentágothai 1968) that the presence of spines adjacent to boutons is linked to the functional activity of these boutons; that is, the spines might be part of an arrangement, with which the size of the contact area between the bouton and postsynaptic membrane can be increased.

The axo-axonic synaptic complex. Axo-axonic synapses have been demonstrated ultrastructurally in several regions of the brain and spinal cord (see for example Kidd 1962, Gray 1962, Colonnier and Guillery 1964, Walberg 1965, Ralston 1965, 1968, Szentágothai *et al.* 1966, Peters and Palay 1966, Karlsson 1967, Pecci Saavedra *et al.* 1968). Axo-axonic synapses have been claimed to occur on cat spinal motoneurons (Khattab 1968), although the picture presented in that report shows no similarity to the structures described in the present paper. At most places, the above observations seem to fulfil conventional criteria for a synaptic complex (Gray and Guillery 1966). In the axo-axonic contact described in the present paper to be a synaptic complex, the thickness and extension of the synaptic cleft were less than those usually occurring at synaptic complexes. An apposition of the synaptic vesicles towards the presynaptic membrane, as found here, might be a more useful criterion for a synaptic complex than the existence of a synaptic cleft of certain dimensions.

Distribution of dorsal root boutons on the motoneurons. The majority of the M and big S boutons were situated on the proximal parts of the motoneuron dendrites, often very close to the cell body. In this region they seemed to form about 0.5% of the population (the values corrected for size of the boutons, see Conradi 1969 a). This comparatively low proportion seems to confirm the light microscopic findings of Szentágothai (1958), that there are relatively few but big dorsal root boutons on every motoneuron, the boutons being predominantly situated at proximal parts of the dendrites. The present findings do not, however, support some others from light microscopic studies (Illis 1967) in which the dorsal root boutons were found all over the motoneuron dendrites, where they were claimed to form about half the total population of boutons.

Several M boutons seemed often to be grouped on the same, horizontal dendrite. The investigation was not concerned with whether the M boutons might be predominantly localized at dendrites, projecting in a certain direction from the motoneurons. From light microscopic studies, it has been argued (Sterling and Kuypers 1967) that the dorsal root axons run in a vertical direction for the last distance before the motoneurons, consequently focusing the interest on the occurrence of dorsal root boutons on the vertical motoneuron dendrites.

Some M boutons were found in the neuropile surrounding the motoneuron cell bodies. The distance from the cell body at such instancies could, naturally not, be estimated. Since a few M boutons were observed to establish more than one synaptic contact, those apposed at small dendritic profiles in single

sections could thus make contact with the proximal part of a motoneuron dendrite, which was out of the plane of section.

As mentioned, it was difficult to judge whether there are dorsal root boutons of types other than those described here and localized for instance, at distal portions of the dendrites. If at all present, they ought, according to the quantitative estimation, to be relatively few. However, it has to be pointed out that the number of the M and the big S boutons is also so small, that if these types had not been recognized as separate entities, the disappearance of them a long time after the operation would not have been recognized in a quantitative estimation.

Physiologic considerations on the normal anatomy and distribution of the dorsal root boutons

Physiologically, the dorsal root synapses on ipsilateral motoneurons are excitatory (Lloyd 1943). The fact that these boutons contains spherical synaptic vesicles supports the hypothesis that there is a correlation between the shape of the synaptic vesicles and the effects on the postsynaptic membrane (Uchizono 1965, Bodian 1966). The finding that all M boutons seem to be of dorsal origin also indicates, that the morphologic typing of boutons can be of physiologic significance, which encourages further investigation along these lines. Based on investigations with the intracellular recording technique (Rall *et al.* 1967) it has been suggested, that the dorsal root synapses are predominantly situated at the motoneuron dendrites, but that the distance to the cell body varies. Results in the present study might confirm this suggestion although it was as mentioned difficult to judge the distance to the cell body of the relatively few M boutons located at small dendrites in the neuropile. Another suggestion has been that "tonic" and "phasic" motoneurons, respectively, receive dorsal root boutons varying in number and possibly also in localization (Burke 1968). If this is true, then such an arrangement could be important for the sampling procedure underlying quantitative estimations like those performed in this study.

Presynaptic inhibition. The physiological theory on presynaptic inhibition postulated the existence of excitatory synapses on the dorsal root terminals (Frank and Fuortes 1967, see Eccles 1964). The presynaptic boutons were thought to depolarize the dorsal root synapses. Most of the physiological evidence for this arrangement was obtained from experiments on extensor motoneurons. In the present study, however, the most lateral motoneurons in L 7 were investigated, and these neurons probably innervate physiologic

flexors (Romanes 1951). The correlations between the present findings and the physiological results, are thus somewhat restricted.

The synaptic vesicles of the P boutons are small and irregular in shape. Such a shape of excitatory synaptic vesicles contrasts to the general theory regarding the significance of the shape of synaptic vesicles (Uchizono 1965, Bodian 1966). However, the theory was based on observations of boutons on the cell bodies and dendrites of motoneurons and Purkinje cells, and might thus not be valid for the P boutons in this material.

In both of the reconstructions several P boutons, some of which belonged to the same preterminal axon, were apposed at the M bouton. Although the significance of this is unclear at present, it cannot be excluded that there are separate systems, with possibly different sites of origin, of presynaptic boutons on the same dorsal root terminal. No P boutons seemed to be located on the preterminal axons of the M boutons.

Some workers (Green and Kellerth 1966, Terzuolo and Llinas 1966) have suggested that much of the inhibition of the motoneurons, which has hitherto been denoted as presynaptic with regard to the dorsal root terminals, in reality is accomplished by boutons localized on the motoneuron dendrites, possibly those remote from the cell body. The present findings favour the hypothesis of Eccles (1964), but the above-mentioned suggestions might still be valid.

Operated material

The observation that the boutons, which in this study are claimed to be of dorsal root origin, disappear from the third postoperative day on, agrees well with findings from physiologic experiments. It has been reported that following stimulation of the central stump of the dorsal roots after dorsal root section, transmission through the monosynaptic pathway has nearly disappeared from the third postoperative day (Savoskina 1966). There are hitherto no ultrastructural quantitative reports on the loss of boutons after long-time degeneration. Therefore, neither the optimal survival time for such investigations nor the risk for errors due to functional inactivity or volume changes in the tissue (cf. Westman 1969), was known. The mean minor diameter of the motoneuron profiles seemed to be somewhat smaller in the operated material. At least as regards the cell bodies, this could have been caused by an elongation following herniation of the cord. Despite this, the number of boutons per motoneuron or dendrite profile seemed to be roughly similar in the normal and long-time degenerated materials.

It has, however, again to be pointed out, that the material in the quantitative study was very small, due to the rather complicated handling procedure, and therefore the conclusions must be drawn with considerable caution.

Ultrastructural bouton changes. Boutons, showing the dense appearance, described as a criterion for degeneration (Colonnier and Gray 1962, Walberg 1963, 1964, Aiksne *et al.* 1966, McMahan 1967, Mugnaini *et al.* 1967), were not observed in the present material, although such boutons are present in the dorsal horn during the first week after dorsal root section (Ralston 1965, 1968 b). The difference might be due to the use of different fixation methods or to local factors, for example the nearness of phagocyting cells. Furthermore, the boutons investigated here seem much bigger than those found by Ralston, which may be of importance. Profiles, similar to bouton fragments, as shown in earlier studies on degeneration in other regions of the CNS (Colonnier 1964, Smith *et al.* 1966), were, however, observed inside glial cells and the motoneurons during the first postoperative week in this material. Neurofilaments and other bouton changes, earlier reported to be signs of degeneration, were also observed inside boutons during the first postoperative week. Thus, many different types of early bouton changes after axon section could exist in this system. In the present material, some M boutons, lying only a short distance from disintegrating boutons exhibited an almost normal morphology during the first postoperative week. In view of these data and the fact that all possible types of early degenerative bouton changes in the CNS have probably not yet been recognized, it seems clear that almost no rigid statement on the normal structure, number or localization of boutons belonging to a certain fibre system, can be made from observations only a short time after axon section.

ACKNOWLEDGEMENTS

I am much indebted to Professor Sten Skoglund for valuable discussions and constructive criticism and to Miss Christina Trägårdh and Miss Maj Berghman for skilful technical assistance. The work has been supported by grants from Karolinska Institutet (Reservationsanslaget) and from the Swedish Medical Research Council, projects no. B69—14X—136—05C and B70—14X—136—06.

SUMMARY

In order to study the ultrastructure of the dorsal root boutons on the motoneurons, the ventral horn was studied in the material of normal adult cats, presented earlier (Conradi 1969 a) and on 24 adult cats, which had been subjected to unilateral dorsal root section 1—42 days before fixation. The loss of boutons on the motoneurons after the operation was estimated against the background of the ultrastructure and distribution of boutons of different types on the motoneurons in the normal state, as described in two preceding communications (Conradi 1969 a, b). Big boutons, M-type, containing spherical synaptic vesicles and predominantly located on the proximal parts of the motoneuron dendrites were found to disappear during the first week after homolateral dorsal root section. Some evidence is also presented that a few big boutons of the S-type disappear. On the convex side of the boutons of these two types, there are regularly apposed small boutons (P-type) containing synaptic vesicles of irregular shape. From analysis of serial sections the P boutons were found to establish a synaptic complex with these big boutons.

Changes in boutons during the first week after homolateral dorsal root section were also studied. Evidence is presented to verify that M boutons are engulfed by glial cells or by the motoneurons from the third postoperative day on.

FIGURES

Figs. 1 and 2. Reconstruction from serial sections of an M bouton on the proximal part of a motoneuron dendrite (the bouton is the M bouton in region A of the dendrite analyzed a preceding paper, Conradi 1969 b). In Fig. 2 the model is seen from the convex side of the bouton and below the photograph a schematic drawing is included. On the latter it is seen that the M bouton is surrounded by nine P boutons (black), some of which are covered by the M bouton when seen from above (stippled). Two P boutons are also localized on the convexity of the M boutons (striped). There are seven dendritic spines (concentric circles) along the lateral border of the M bouton, four of these (notched) are covered by the latter when seen from above. The extension of the synaptic complex of the M bouton is illustrated in Conradi 1969 b, Fig. 9.

In Fig. 1 a—e, five of the sections through the bouton are shown. The location of the sections is illustrated in the schematic drawing. The sections are directed along the longitudinal axis of the bouton as seen from the wax-plates composing the model.

In *Fig. 1 a* one of the sections along the upper edge of the schematic drawing is shown. Three P boutons are attached at the lower end of the M bouton. In b, one of the dendritic spines is seen to the left. One P bouton is situated below the spine, and one just above the spine. In c, there are still two P boutons cut through at the left side of the photograph. In d, the big black boutons at the lower side in the drawing is visible on the M bouton, the axon of which also is cut through. In e, all four P boutons at the lower end of the M bouton in the schematic drawing are cut through. (The two black boutons at the lower right are not quite correctly drawn, in comparison to the model).

Figs. 3 and 4 show the reconstruction of another M bouton at the soma-dendritic junction of a motoneuron. As seen from Fig. 4 b, this M bouton showed an expansion filled with synaptic vesicles, just proximal to the M bouton. The expansion is covered by four P boutons (black and stippled in Figs. 4 a and c), whereas the M bouton proper is surrounded by seven P boutons (black in Figs. 4 b and c). The extension of the synaptic cleft of the M bouton is shown in Fig. 4 d (black clefts in the M bouton, the black P boutons surround the lateral border of the M bouton).

The sections in Fig. 3 pass in order from the rear towards the reader in Fig. 4 a and the plane of section is seen from the contours of the wax-plates.

In Fig. 3 a, the M bouton is cut before the expansion was visible. Two P boutons are present at both sides of the M bouton.

In Fig. 3 b, the expansion (E) is seen and is covered by the four P boutons. At the right of the M bouton, another P bouton is seen.

Fig. 3 c shows the M bouton, cut through the connexion (arrow) with the expansion (E). Two of the P boutons on the latter are still visible and an additional P bouton is seen at the left side of the M bouton.

In Fig. 3 d, the expansion is passed. One P bouton is still visible at the convex side of the M bouton. At the right side of the M bouton, a dendritic spine is seen. ×17,400

Fig. 5. Part of the region of apposition between a P and an M bouton. It is seen that the synaptic vesicles of the P bouton are smaller than those of the M bouton and are of a somewhat irregular shape. A small extracellular space is present between the boutons and the synaptic vesicles of the P bouton are apposed at the membrane at this place. ×126,500

Fig. 6. Part of the region of apposition between a P and an M bouton. A desmosome-like junction (arrow) is present between the boutons. ×119,500

Fig. 7. Profile of a big bouton (S) containing spherical vesicles and to which two P boutons are apposed at the convex side. The big bouton was followed for about one micron through serial sections, but no postsynaptic dense bodies were observed. The bouton might have been of the big S variety described in the text. ×26,100

Fig. 8. Axon profile, containing a dark ground substance. The myelin sheath is somewhat wrinkled. Seven days postoperatively. ×16,100

Fig. 9. Profile of a distended myelin sheath, surrounding a clear area, containing some flocculer material and distended mitochondria. Four days postoperatively. ×10,500

Fig. 11. Profile containing numerous mitochondria, dense bodies and neurofilaments. Seven days postoperatively. ×11,000

Fig. 12. On the proximal part of a motoneuron dendrite (M) there is a dark glial cell, probably a microgliacyte (MG) which contains inclusions, some of which are vacuolized. Postsynaptic dense bodies are situated at the inside of the motoneuron cell membrane and there are two membrane fragments (double arrows) with postsynaptic dense bodies inside the motoneuron cytoplasm. These are shown in higher magnification in Fig. 13. Three days postoperatively. ×24,300

Fig. 13. Detail of the square in Fig. 12. The postsynaptic dense bodies are indicated by arrows. ×71,500

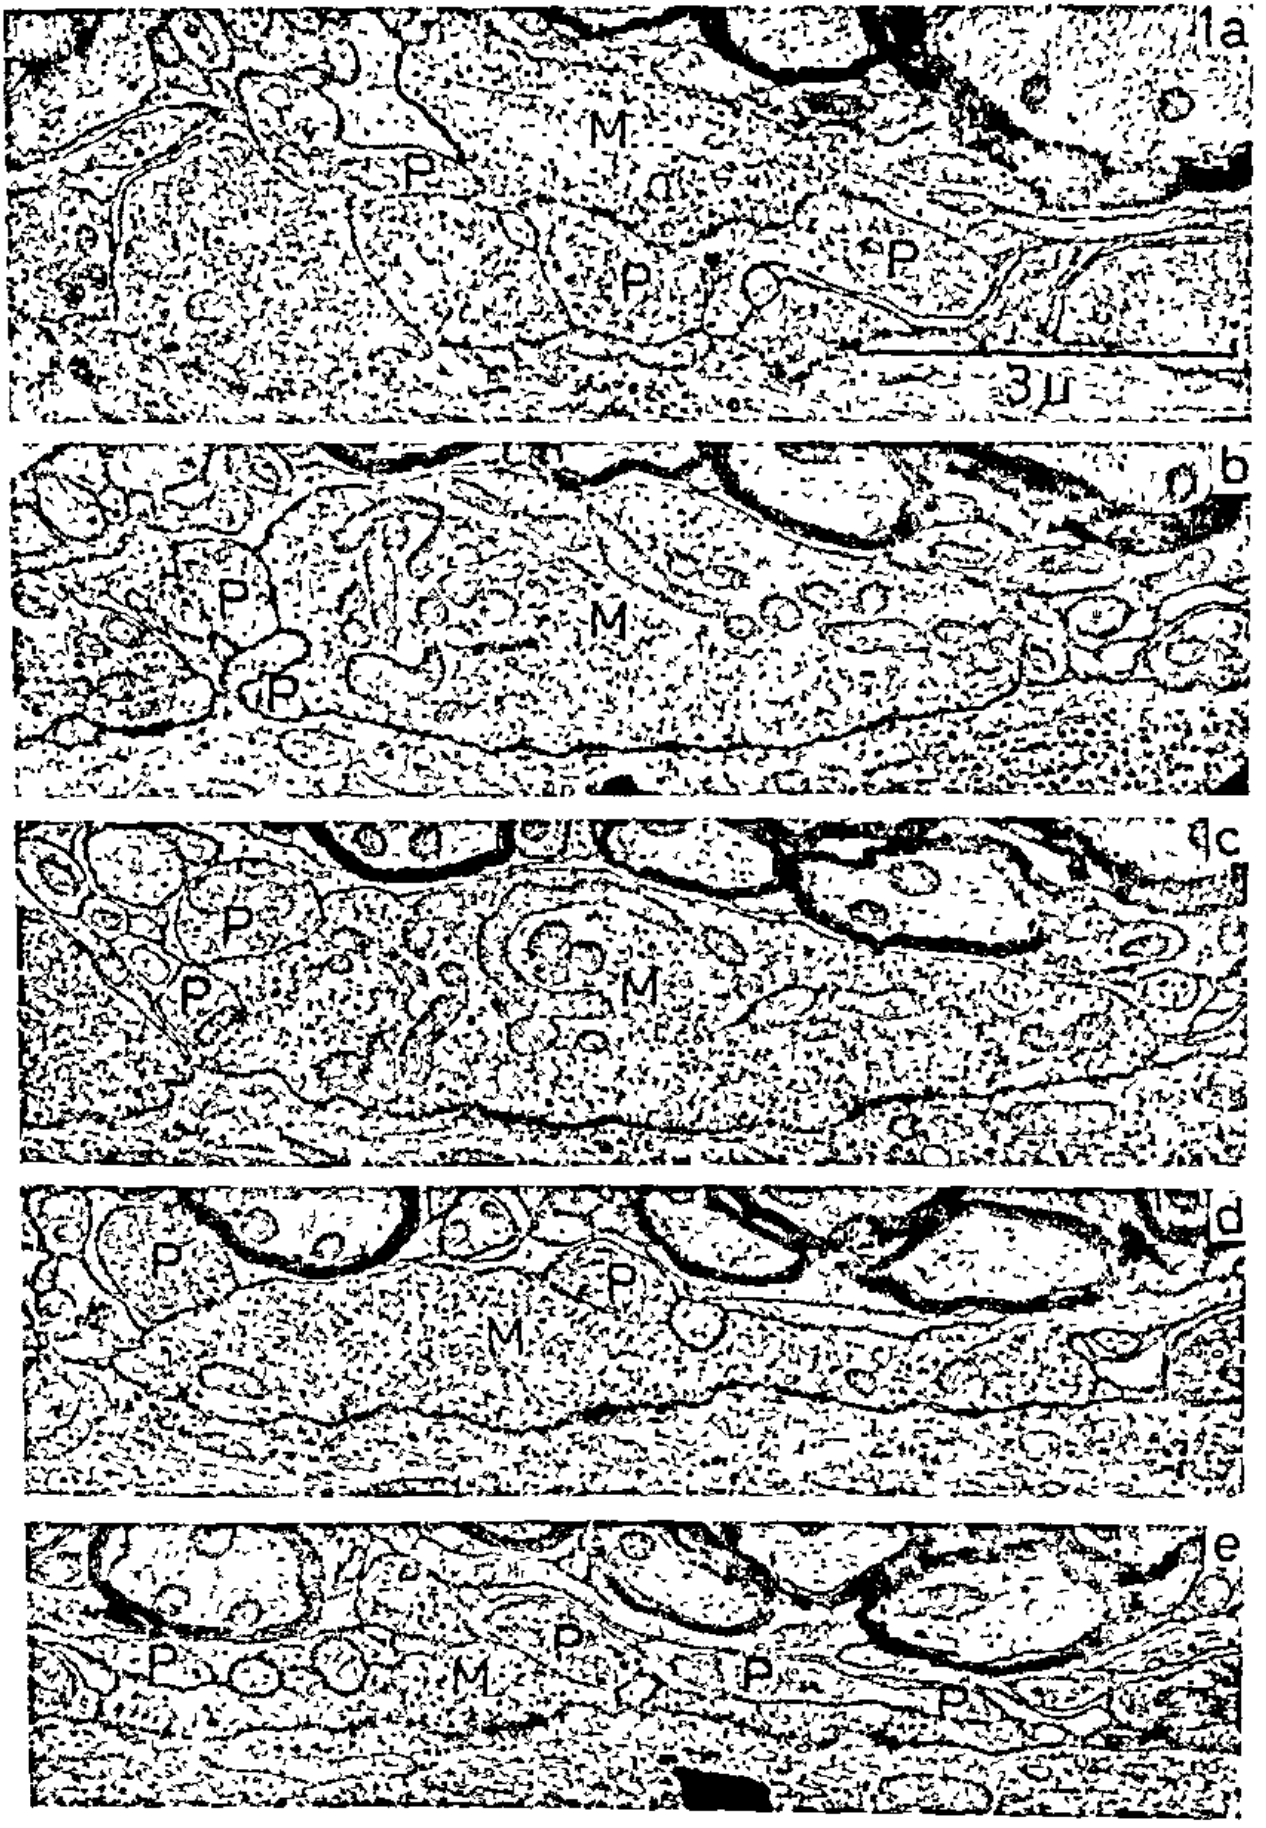

Fig. 14. On the proximal part of a motoneuron dendrite (M), a profile of a bouton (B) with spherical vesicles is surrounded by a large process (G), probably of glial origin. There is a long extent of apposition of postsynaptic dense bodies (arrows) at the inside of the motoneuron cell membrane, which is partly covered by the bouton, partly by the big glial process. Seven days postoperatively. ×31,400

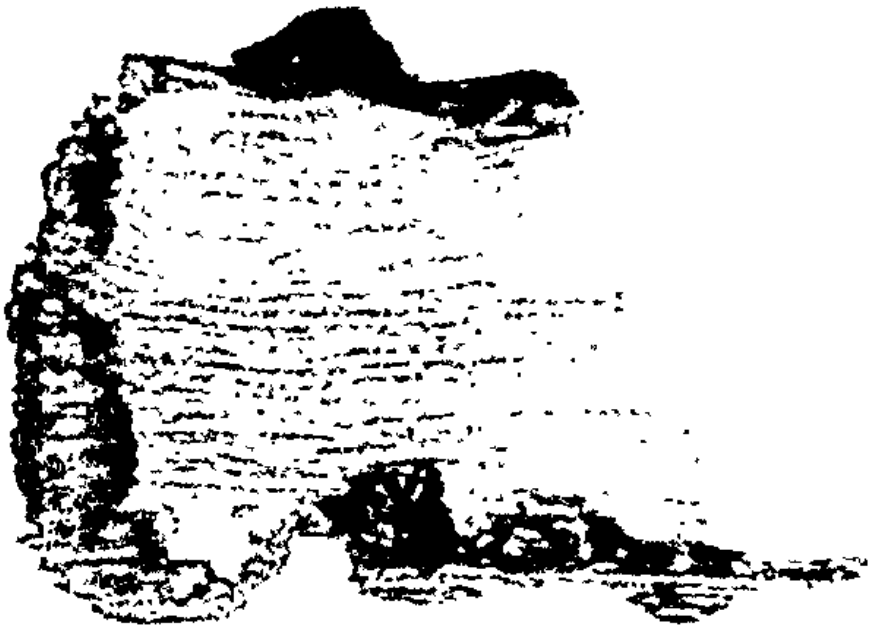

Fig. 15. Survey photograph at the proximal part of a motoneuron dendrite (M). A dark inclusion body is situated inside a glial process with dark cytoplasm, probably microgliacytic (MG). The region inside the square is followed through serial sections in the next figure. Three days postoperatively. ×13,100

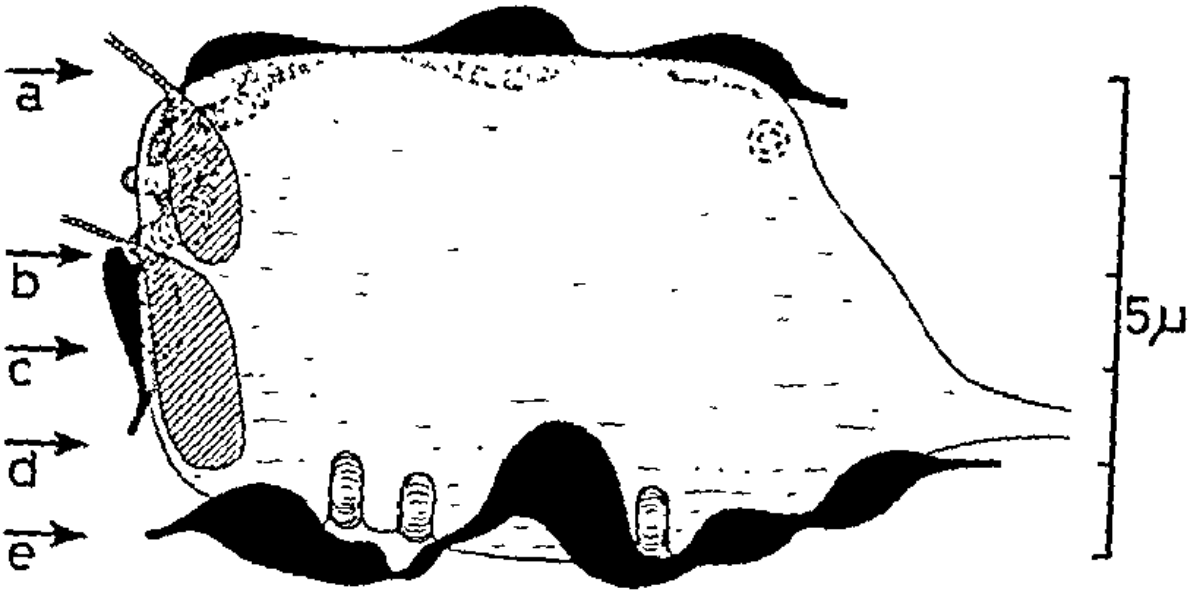

Fig. 16 a—h. Series through the inclusion body, seen in Fig. 15 and the surroundings.
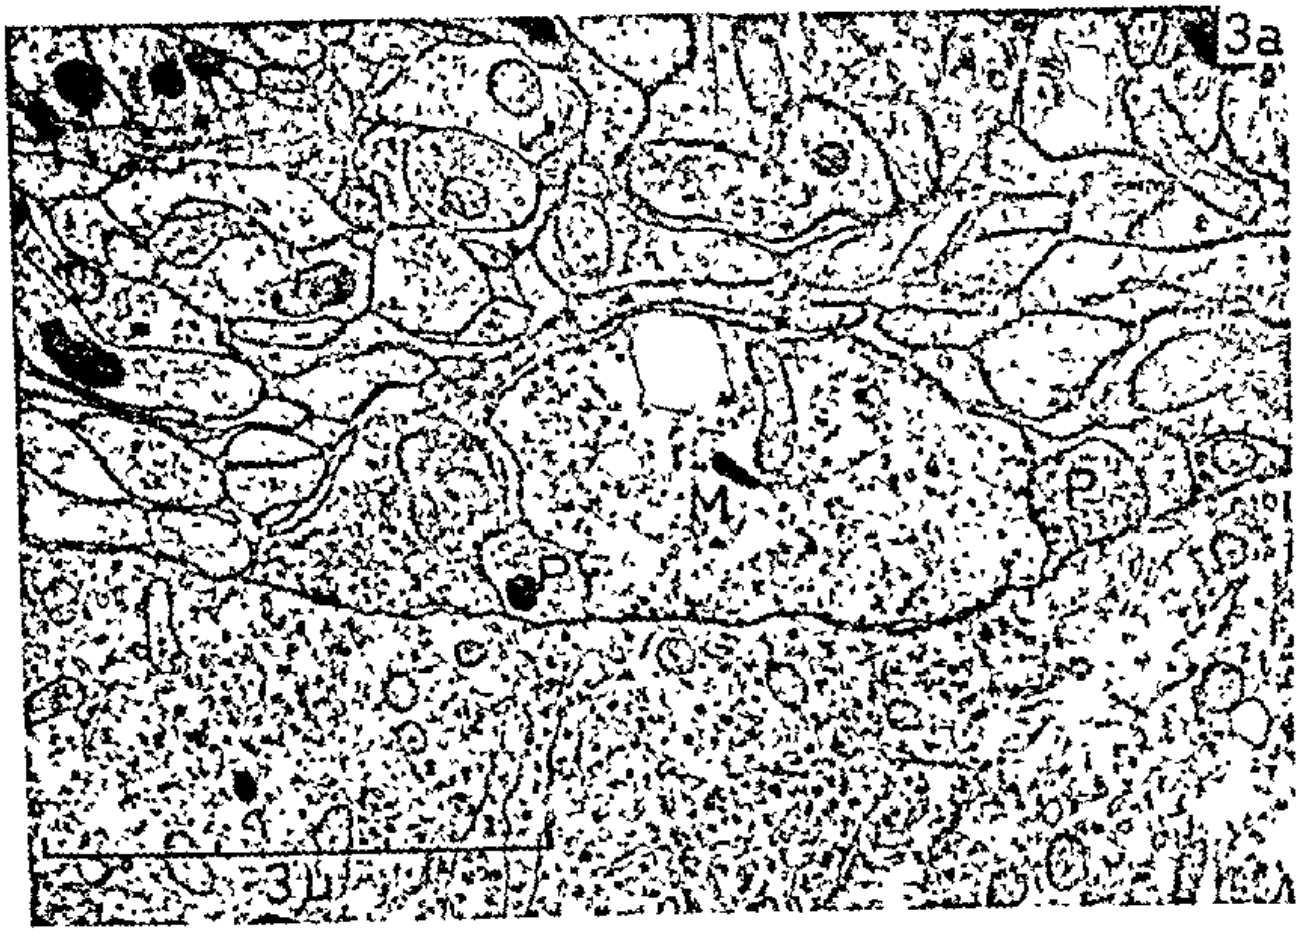
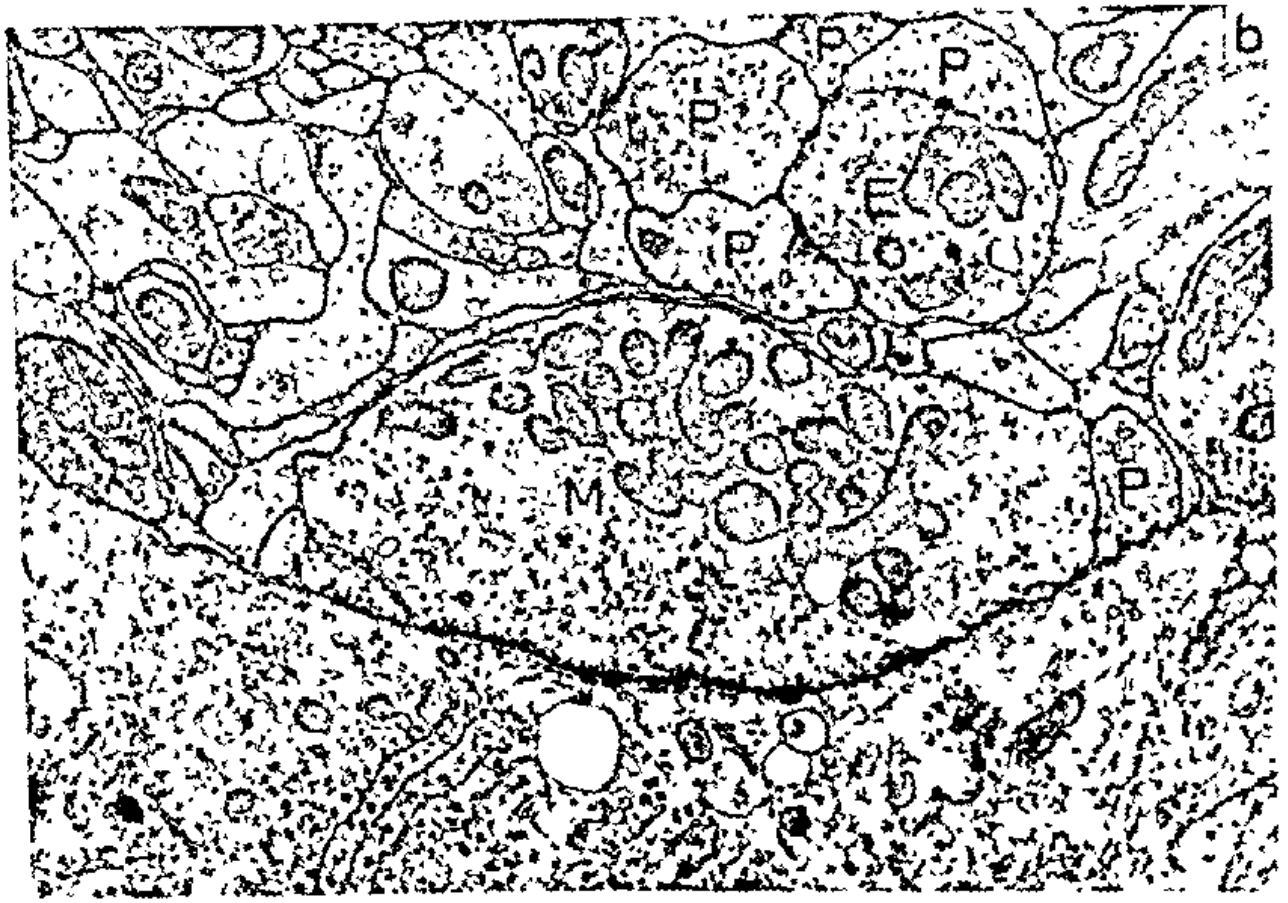
a, section 1. The same as in Fig. 15. ×28,000



b, section 6. Contrast-rich material is found at part of the apposition region between the glial cell and the dendrite.



c, section 12. The inclusion body has disappeared. Postsynaptic dense bodies (arrow) are apposed at part of the motoneuron cell membrane facing the glial process. The glial process to the left has a clear cytoplasm of the astrocytic type (AS). Inside this, a bouton profile (B) is seen in both this and the next figure. The bouton does not establish any synaptic complex in the series, and it is probably of the P type.

STOCKHOLM 1969

Observations on the ultrastruture and distribution of neuronal and glial elements on the motoneuron surface in the lumbosacral spinal cord of the cat during postnatal development

by

SEBASTIAN CONRADI and STEN SKOGLUND

INTRODUCTION

Against the background of the knowledge of the ultrastructure of the adult spinal motoneurons and their surface relationships, (Conradi 1969 a, b, c, d) an investigation has been performed on the postnatal development of these structures. So far, the developmental material is rather limited, but since it contains a number of new data, some even rather unexpected, the observations hitherto made are presented in two papers. The first one deals with the relationships of the motoneuron cell membrane during normal development, the second one describes the development of the initial motoraxon segment and degenerative changes after dorsal root section.

Studies of the developmental spinal physiology has revealed that great changes take place postnatally, especially during the first three weeks (for review, see Skoglund 1966). Some of these changes can be attributed to changes in the peripheral afferent pathway of spinal reflexes. Studies of the monosynaptic pathway, however, have shown that important changes with regard to excitation and inhibition take place centrally (see Skoglund 1966). Part of these changes might be due to postnatal modifications in the number and location of the boutons on the motoneurons.

The problem of the location on the motoneurons of boutons having different functions has long attracted considerable attention from Eccles and collaborators (Eccles 1964). Recently, a series of paper dealing with this very same subject appeared from Frank's laboratory (see Rall 1967). In this series,

the assumption was made that changes of the motoneuron membrane impedance during synaptically-induced activity point to a specific localization of the involved boutons. The actual localization of such boutons, however, is unknown.

A thorough knowledge of the distribution of boutons on the motoneurons at early developmental stages, compared to the situation in the adult, might thus make possible correlations with physiologic differences between these stages. The simultaneous changes in morphology and function during development offers a unique situation for correlative studies.

There is no earlier ultrastructural report on the central connexions of the motoneurons in the kitten. From light microscopic studies, quantitative information on the postnatal growth of the motoneurons and other parameters in the spinal cord of the kitten has, however, recently been obtained (Mellström and Skoglund 1969). Studies on the mouse have provided evidence of a postnatal growth and branching of the motoneuron dendrites (Sakla 1959). A postnatal increase in the number of glial cells in the gray substance has also been reported (Sakla 1965). In the earlier light microscopic studies, it was reported that the motoraxons are myelinated already at birth (Langworthy 1929, Windle 1930), whereas myelination of the fine fibres in the gray substance is not developed until the 4—5th postnatal week in the kitten (Windle 1930).

Although the ultrastructure and distribution of neuronal and glial extensions on the motoneurons during the postnatal development are not known, several aspects of the development of neurons, glial cells, boutons and axons have been described in ultrastructural studies on other parts of the CNS (for references, see the Discussion).

In regard to the function of the developing nervous connexions, the formation of the first synaptic complexes has been shown to be accompanied by changes in the electrical activity of the tissue. The statement results from studies of growing tissue cultures (see Bunge *et al.* 1967) and experiments with developing neocortex and hippocampus in the cat (Voeller *et al.* 1963, Purpura *et al. 1965*, Schwartz *et al.* 1968). In the latter investigations, the first synaptic complexes were situated at the proximal parts of the dendrites. Both excitatory and inhibitory influences were present in the earliest stages. Furthermore, in an ultrastructural and functional study of the spinal cord of monkey fetuses (Bodian 1966 b, Bodian *et al.* 1968) it has been shown that the appearance of segmental reflexes is coincidental with the appearanace of the first synaptic complexes, likewise situated on proximal parts of the motoneuron dendrites. Axo-somatic synaptic complexes appear at the time

of onset of more complex reflex patterns, when there is also a rapid increase in the number of boutons with flattened vesicles.

The aim in the present paper was to obtain knowledge of the ultrastructure of the individual glial and neuronal elements, particularly boutons, on the motoneuron surface, as well as of the distribution of these structures from birth. The quantitative estimation deals with chiefly the same parameters as were investigated in the adult (Conradi 1969 a, b), namely:

a) A rough estimation of the dimensions of the motoneuron cell bodies and dendrites.
b) The localization of the different types of boutons on the motoneuron surface.
c) Size of the profiles of boutons of different types.
d) Percentage bouton covering on the motoneuron cell membrane, both total and for each of the different types of boutons.
e) The numerical proportion of the boutons of different types on various parts of the motoneuron.
f) The packing density of the boutons.

At first, the situation in the newborn is described, in addition to observations from random sections, a quantitative study on single sections, performed in the same manner as in the adult (Conradi 1969 a), is undertaken. The proximal part of a motoneuron dendrite is also investigated in serial sections, as was done in the adult (Conradi 1969 b). Then some features of the postnatal changes of the membrane relationships are described. Some quantitative estimations at the 3-weeks stage are also included.

It is found that the motoneurons are covered by a large number of boutons already in the newborn stage. The boutons are much smaller than in the adult, but the general appearance of them and the morphology of the synaptic complex are nearly the same. All the bouton types found in the adult are present at birth, except for the M-type (Conradi 1969 a, d) which cannot be recognized with certainty until from the third postnatal week. The percentage bouton covering of the motoneuron surface in the newborn is generally somewhat lower than in the adult except on the cell bodies, where the values are about the same or somewhat higher than in the adult. In the newborn, the percentage covering of boutons with spherical synaptic vesicles on the motoneurons, particularly the cell bodies, is larger than in the adult. The findings are discussed against the background of the functional changes described earlier (Skoglund 1966).

MATERIAL AND METHODS

In all, 49 normal kittens, 0—100 days old, were used. Some of the observations were also made on the unoperated side in an additional 28 kittens, which had been subjected to unilateral dorsal root section, 1—7 days before the fixation (Conradi and Skoglund 1969 b, Table 1).

The kittens were fixed in the same way as has previously been described from the adult cats (Conradi 1969 a). For details of the fixation methods, the reader is referred to the aforementioned investigation and the study of Berthold and Skoglund (1968). Some brief remarks will be given.

Fixation method

In the earlier part of the investigation, a total of 30 kittens was perfused with prerinse and fixative from 10—50 ml glass syringes. The rinsing fluid was Ringer's solution. The fixative consisted of 5% glutar aldehyde, usually purified with active charcoal (Fahimi and Drochmans 1965) and dissolved in a phosphate buffer, giving a buffer tonicity of 360 mOsm in the fixative. Following tracheotomy and artificial respiration, a wide thoracotomy was made and the left lung was removed. The aortic arch was clamped, a cannula or teflon catheter was inserted downward into the descending aorta and the right auricula was opened. 10—30 ml prerinse at 37°C, immediately followed by 10—25 ml fixative at 37° and 50—200 ml icecold fixative were perfused for 10—15 min.

In the later stages of the investigation, and including all the operated animals, this method was modified and used in 19 normal animals. Five percent purified glutar aldehyde was then dissolved in Millonig buffer (Karlsson and Schultz 1965), which had been diluted with distilled water to give a tonicity of 250—300 mOsm in the fixative, which is isotonic to the serum of the cat (Handbook of Biological Data 1956). Usually 8.1% or 2.7% Rheomacrodex was added to the rinsing fluid and fixative. After removal of the left lung, as in the foregoing method, a cannula or sharpened teflon catheter was inserted downward directly into the descending aorta, without previous clamping. Then 10—30 ml rinse at 37°, 25—50 ml fixative at 37° and 50—500 ml icecold fixative were perfused from three infusion sets, connected to the perfusion cannula with a 3-way stopcock. Each infusion set was provided with a blood-pressure balloon and a manometer. Through this arrangement, the perfusion pressure could be changed and continuously controlled. When the perfusion catheter had been inserted downward into the aorta, the inferior v. cava was cut. Rinsing

Table 1. Age of the animals

Age, days	No. of animals	Age, days	No. of animals
0—3	10	22—28	4
4—7	8	29—42	4
8—14	8	43—56	3
15—21	9	56—100	3

fluid was perfused at 60—100 mm Hg for 10—20 sec., warm fixative for 20—30 sec. and cold fixative 10—15 min. The fixative was perfused either at a continuous pressure of 60—100 mm Hg in a few animals, or at a discontinuous pressure, varying periodically between about 50 mm Hg and zero, 2—3 times per minutes, in the majority of the animals.

After the perfusion, the spinal canal was opened and the lumbosacral cord removed. Thin transverse sections of segment L 7 were cut and divided into symmetrical halves. These were rinsed in either veronal acetate buffer (Cedergren 1959) or in 300 mOsm Millonig buffer, postfixed with 2% OsO_4, dissolved in either of these buffers, for 4 hours. After another rinse, the specimens were dehydrated in acetone and embedded in Vestopal W. Semithin transverse sections of half the spinal cord were cut with an LKB 4801 ultrotome and stained with toluidine blue. The most lateral part of the ventral horn was trimmed out and cut into ultrathin sections. The sections were collected on one-hole grids, according to the method of Galey and Nilsson (1966). Shorter series of 20—50 consecutive sections and longer series, comprising 250—400 sections, in which only a few single sections were lost, were also investigated. The sections were stained with uranyl acetate and lead citrate. A Philips EM 300 was used.

Fixation quality

The quality of fixation could be controlled by mere macroscopical examination. After successful perfusions the spinal cord was hard and yellow. At inspection in the electron microscope, especially the preservation of the mitochondria seemed sensitive to the quality of the fixation. The mitochondria were often vacuolized, particularly after poor perfusions. The best fixation was obtained after perfusions at a discontinuous pressure from the infusion sets. With kittens less than 14 days old, however, the fixation was rather good, regardless of whether a continuous or a discontinuous perfusion pressure was used. Moreover in these animals the cervical cord and brain were well perfused, despite the location of the perfusion catheter in the descending aorta. When the kittens were older than 14 days, the best results were obtained with a discontinuous perfusion pressure (cf. Berthold 1968).

Quantitative studies

A quantitative estimation on the membrane relationships of the motoneuron cell membrane from single sections was performed in the newborn stage (2 days old) and at 3 weeks. The method was again the same as used in the adult material (Conradi 1969 a). Briefly, the procedure was the following: Two kittens from two different litters were used at each age and equal halves of the material were taken from each animal. The animals, which according to macroscopical examination of the spinal roots seemed to have a prefixed lumbosacral plexus (Sherrington 1892), were perfused with 5% glutar aldehyde in 200 mOsm Millonig buffer from the infusion sets. Rheomacrodex was added to the rinse and to the fixative to give a concentration of 2.7%. The lateral motoneuron nucleus in the most cranial millimetre of L 7 was cut into semithin transverse sections in a cranio-caudal direction. When motoneurons were cut through the nucleus, 2—3 grids of ultrathin sections, 1—3 μ apart, were prepared. From these sections, the profiles of 20 motoneuron cell bodies, cut through the mid-nucleus level, and the profiles of proximal parts of horizontal dendrites projecting

from these motoneurons, were photographed. Six additional long profiles of horizontal proximal dendritic segments, belonging to motoneurons which were not ideally sectioned, as well as profiles of 30 thin, horizontal dendrites from the neuropile, were also analyzed. As pointed out earlier (Conradi 1969 a) nothing is known about the origin of these thin dendritic branches. As will be shown, several features of the membrane relationships of these profiles are, however, common in most of the animals. At least some of the dendrites might belong to motoneurons.

In the newborn animals, photographs were taken at a magnification of 3,250×. Four to six photographs were required for every motoneuron cell body. Paper copies with a final magnification of about 16 000 × were prepared and taped together to montages, on which the membrane length of the motoneuron cell bodies (SO) and dendritic profiles were measured. The minor diameter of the cell bodies and average diameter of the dendritic profiles were also measured. The dendritic profiles were divided into three categories: The proximal parts of motoneuron dendrites, covered at one side in the section by the first 20 boutons, counted from the cell body, were treated separately (DA), as were the parts of the profiles distal to this, (DB). The thin dendritic profiles in the neuropile were denoted d. The type of every profile of boutons or glial extensions on the motoneuron cell bodies and dendrites was judged from inspection of the actual section, at high magnification in the electron microscope, and the result was transferred to the paper. The length of apposition and height of every bouton profile was measured on the montages. These values and the number of boutons of the different types were set up in table form with separate headings for the four categories of motoneuron and dendritic profiles. The mean length of the profiles of the different bouton types was calculated in every column. In addition, the percentage bouton covering of the membrane, both total and for each bouton type was calculated. The numerical proportion of bouton profiles of the different types, as well as the mean distance along the cell membrane between the centres of adjacent boutons, were also calculated. Some of the results from the quantitative estimation in the newborn were studied statistically.

The membrane relationships of the motoneurons on the 3-week old kittens was investigated quantitatively in a somewhat simplified way. The length of apposition of the bouton profiles was not measured, allowing use of a lower final magnification (×1,800) and thus reducing markedly the number of photographs. The number and types of the boutons apposed to the profiles were likewise estimated on single sections in the above manner.

Statistical control

The bouton covering, both total and for each bouton type separately, on each of the four regions (SO, DA, DB, d), were compared, both to each other, using an F-test, and to the corresponding values from the adult (Conradi 1969 a) using a t-test.

The mean length of the profiles of the S+T and F bouton types (see Conradi 1969 a) was studied on the cell bodies and the thin dendrites. The values for the two types on the same region were compared using a t-test, as were the values for the same bouton type on the two regions. In each case, comparisons with the adult were made, likewise with a t-test. The variance of the values for length of apposition of these two bouton types on the cell bodies and thin dendrites was also calculated and compared to the corresponding values from the adult.

Reconstructions from serial sections

The membrane relationships of the proximal part of a motoneuron dendrite in the newborn stage were analyzed through serial transverse ultrathin sections, cut in a cranio-caudal order. The dendrite belonged to a motoneuron from one of the specimens on which the quantitative estimation in the newborn was performed. The reconstructed part of the dendrite was completely cut through within about 80 sections; one single section was lost. Assuming a cylindrical shape of the dendrite, the mean section-thickness was 600 A, as calculated from measurements of the diameter of the dendrite at several places. The dendrite, which was directed ventromedially from the motoneuron cell body, left the latter in a nearly horizontal direction after a short initial curve upward. The diameter of the dendrite in the most proximal part was about 3 μ, which seemed somewhat less than average for similar processes. About 20 μ from the cell body, the dendrite curved slightly medially and upward and became somewhat thicker, 4 μ. Again growing thinner, it bent slowly downward, then upward and finally disappeared out of the sections (see Fig. 13 a). In each section the dendrite was photographed with a primary magnification of 6,400×. Usually 3—4 photographs were required for each section and the copies were taped together to montages of the dendrite, where the final magnification was 18,000×.

The types of the different boutons on the montages were judged from mere inspection at high magnification in the electron microscope. Every 5—7th section was examined and the result transferred to the copies. The membrane relationships of the dendrite were illustrated in a drawing, where the cell membrane was depicted unfolded (see Fig. 13). The detailed technique has been presented earlier (Conradi 1969 b). Briefly, it was the following: the mantle surface of the dendrite at the magnification used is calculated and depicted on a transparent paper, on which the consecutive sections are represented as lines. The transparent paper is placed on the montages in successive order and the outline of the dendrite is aligned with the line representing the actual section. The type and length of apposition of the structure making contact with the cell membrane of the dendrite are then transferred to the corresponding line on the paper. If the analyzed dendrite has a cylindrical shape and is cut longitudinally, the mantle surface is a rectangular area, where the sections form straight parallel lines. The distance between these lines is thus greatest at those parts of the paper representing the upper and lower margins of the mantle surface.

In the present study, an attempt was made to apply the method to a curved dendrite, in which the diameter was not constant. Here, the mantle surface was imagined as consisting of the mantle surfaces of several, consecutive flat cylindres of different diameters, not placed concentrically For the sake of simplicity, the uppermost margin of the dendrite was represented on the paper as a straight line in the middle of the mantle surface area, and the sections as symmetrical curved lines on both sides (See Fig. 13 b). This representation of the sections gives rise to a considerable distortion of the membrane relationships at some places, particularly along the lower part of the mantle surface However, the major aim of this study was to judge the topography of the membrane relationships and some general features of the boutons at birth, and to give an appreciation of the packing density of the boutons. No calculations of the size and shape of the apposition areas of the boutons were made. The following parameters of the membrane relationships of the dendrite were analyzed: location,

from these motoneurons, were photographed. Six additional long profiles of horizontal proximal dendritic segments, belonging to motoneurons which were not ideally sectioned, as well as profiles of 30 thin, horizontal dendrites from the neuropile, were also analyzed. As pointed out earlier (Conradi 1969 a) nothing is known about the origin of these thin dendritic branches. As will be shown, several features of the membrane relationships of these profiles are, however, common in most of the animals. At least some of the dendrites might belong to motoneurons.

In the newborn animals, photographs were taken at a magnification of 3,250×. Four to six photographs were required for every motoneuron cell body. Paper copies with a final magnification of about 16 000 × were prepared and taped together to montages, on which the membrane length of the motoneuron cell bodies (SO) and dendritic profiles were measured. The minor diameter of the cell bodies and average diameter of the dendritic profiles were also measured. The dendritic profiles were divided into three categories: The proximal parts of motoneuron dendrites, covered at one side in the section by the first 20 boutons, counted from the cell body, were treated separately (DA), as were the parts of the profiles distal to this, (DB). The thin dendritic profiles in the neuropile were denoted d. The type of every profile of boutons or glial extensions on the motoneuron cell bodies and dendrites was judged from inspection of the actual section, at high magnification in the electron microscope, and the result was transferred to the paper. The length of apposition and height of every bouton profile was measured on the montages. These values and the number of boutons of the different types were set up in table form with separate headings for the four categories of motoneuron and dendritic profiles. The mean length of the profiles of the different bouton types was calculated in every column. In addition, the percentage bouton covering of the membrane, both total and for each bouton type was calculated. The numerical proportion of bouton profiles of the different types, as well as the mean distance along the cell membrane between the centres of adjacent boutons, were also calculated. Some of the results from the quantitative estimation in the newborn were studied statistically.

The membrane relationships of the motoneurons on the 3-week old kittens was investigated quantitatively in a somewhat simplified way. The length of apposition of the bouton profiles was not measured, allowing use of a lower final magnification (×1,800) and thus reducing markedly the number of photographs. The number and types of the boutons apposed to the profiles were likewise estimated on single sections in the above manner.

Statistical control

The bouton covering, both total and for each bouton type separately, on each of the four regions (SO, DA, DB, d), were compared, both to each other, using an F-test, and to the corresponding values from the adult (Conradi 1969 a) using a t-test.

The mean length of the profiles of the S+T and F bouton types (see Conradi 1969 a) was studied on the cell bodies and the thin dendrites. The values for the two types on the same region were compared using a t-test, as were the values for the same bouton type on the two regions. In each case, comparisons with the adult were made, likewise with a t-test. The variance of the values for length of apposition of these two bouton types on the cell bodies and thin dendrites was also calculated and compared to the corresponding values from the adult.

sometimes found. Rather thick astrocytic processes with a clear cytoplasm were often situated just outside the motoneuron cell membrane at the cell body/ and proximal parts of the dendrites, as well as at small dendritic profiles. It was often difficult to distinguish these from other profiles of possible neuronal origin.

b) *Boutons.* Boutons were found to make contact with the motoneuron cell bodies, proximal parts of the dendrites and small profiles of dendrites in the neuropile. The boutons seemed rather evenly distributed throughout these regions and were as a rule tightly packed (Fig. 5) and much smaller than in the adult. Synaptic complexes and desmosome-like junctions, quite alike corresponding structures in the adult, were regularly observed (see below). Usually, the synaptic complex, as in the adult, did not reach the lateral margin of the zone of apposition of the boutons. In contrast to the situation in the adult, the boutons on the motoneuron cell bodies and proximal parts of the dendrites often established synaptic contact with yet another neuronal profile ("double synapse"). For the most part, this second synaptic complex was made with very thin dendritic profiles, which were found in a large number just outside the motoneurons (Fig. 5).

In addition to the synaptic vesicles, the boutons contained a few small mitochondria, but in single sections mitochondrion profiles were not seen in all boutons, in contrast to the situation in the adult (Fig. 5). A few boutons were observed to contain granular vesicles. Often, glycogen-like particles were present in the boutons (cf. Konishi 1966) (Fig. 6), but neurofilaments and membrane-bound dense bodies were seldom encountered. At some places, boutons containing tubular profiles were observed during the neonatal period (Fig. 7). These boutons are very similar to those previously reported in various developmental disturbances in human neocortex (Gonatas *et al.* 1967). Similar boutons have been observed during normal ontogeny in the chick cerebellum (Mugnaini and Forströnen 1967).

Boutons were rather frequently apposed at the spinous projections from the motoneurons. Sometimes a contrast-rich material, 100—300 A thick, was attached at the inner side of the cell membranes of the spines, which at low magnification gave the impression of a dark interior of the spines (Fig. 8). When recognized, the preterminal axons of the boutons were always unmyelinated. Flattened astrocytic capsules were found around some of the boutons (Figs. 7 and 8) but not to the same extent as in the adult. Instead, the boutons were often covered by thicker astrocytic processes, adjacent boutons or unmyelinated axons.

c) *Formation of new synaptic complexes.* From some developmental ultrastructural studies (Glees and Sheppard 1964, Bodian 1966, Wechsler 1966, see discussion by Bunge *et al.* 1967), there is evidence that the first step in the formation of synaptic contacts is the establishment of a desmosome-like structure between an axon or bouton and a postsynaptic extension. Secondary to this, synaptic vesicles are observed on the presynaptic side. Some findings (Bodian 1966 b, del Cerro and Snider 1968) also indicate that the growth cones of neuronal extensions contain several profiles of large vesicles.

In the present material, it was rather difficult to distinguish between profiles of unmyelinated axons or axonal swellings on one hand and astrocytic extensions on the other; some boutons were, namely, very small and contained only few synaptic vesicles. Vesicle-like profiles could also be seen inside processes obviously of astrocytic origin. Desmosome-like junctions of a size comparable to that of a synaptic cleft, were seldom observed between the motoneuron cell membrane and small extensions containing only a few synaptic vesicles. Profiles, similar to the growth cones, mentioned above, were not encountered.

Different types of boutons

The boutons on the motoneuron cell membrane can be divided into morphologic types, similar to those found in the adult (see Conradi 1969 a).

S-type. Small boutons containing spherical synaptic vesicles (S-type) were regularly observed in the tissue. The diameter of the vesicles was 350—500 A. The synaptic cleft of these boutons was about 150 A thick, and the lateral extension of the cleft was 0.2—0.5 μ. A thin, contrast-rich material was attached at the presynaptic membrane and the layer of postsynaptic material was about 50—200 A thick (Fig. 9 a).

T-type. Boutons, containing spherical synaptic vesicles, in which the postsynaptic dense bodies of Taxi (T-type) could be observed below the postsynaptic membrane, were present to a lesser extent than in the adult. At many places, the postsynaptic dense bodies were very small and could not clearly be seen in the newborn, but this type of synaptic complex could often be recognized through the thick and somewhat irregular layer of contrast-rich material, 200—300 A thick (Fig. 9 b). When clearcut postsynaptic dense bodies were at hand, a band of contrast-rich material, described earlier by Gray (1963) in the adult spinal cord, was sometimes present just inside these bodies. (This is seen in Fig. 11.)

F-type. Boutons containing flattened synaptic vesicles (F-type) were also observed on the motoneurons in the newborn. (Fig. 9 c. These boutons are also seen in Fig. 6). The diameter of the vesicles is 200—300×400—600 A. As in the adult, the synaptic cleft is rather narrow, 90—130 A and the layer of postsynaptic dense material is thin, 50—150 A. Again as in the adult, there seemed to be F boutons with either large or small synaptic clefts, but this difference was not accounted for in the quantitative estimation. No F boutons with a dense ground substance (FD-type in the adult) were found in the newborn. There was sometimes a granular precipitate, especially prominent on flattened synaptic vesicles, in some of the specimens, in which veronal acetate buffer had been used in the postosmification procedure; this too resembled the situation in the adult animals.

C-type. Comparatively big bouton profiles containing spherical synaptic vesicles 350—500 A in diameter, where a large subsynaptic cistern is situated just below the whole postsynaptic membrane (C-type), were rather frequently observed on the motoneuron cell bodies and proximal parts of the dendrites in the newborn (Fig. 10). The synaptic cleft was very narrow, 30—80 A, and as in the adult, extended below nearly the entire bouton. No contrast-rich material was present at the pre- and postsynaptic membranes and the synaptic vesicles were usually not apposed at the whole extent of the presynaptic membrane. The C boutons were often seen to be partly invaginated into the motoneuron cell bodies (Fig. 10). As in the adult, these boutons were not observed on the smaller neurons in the ventral horn.

M-type. In the adult material (Conradi 1969 d), big boutons, obviously of two types and both containing spherical synaptic vesicles, were found to have small boutons, (P-type) containing small synaptic vesicles of an irregular shape, apposed at the convex side. One of these bouton types (M-type) showed a big, irregularly shaped synaptic complex, covered with postsynaptic dense bodies. The other type of bouton was quite similar to the boutons of the S-type. Clearcut M boutons were not observed in the newborn animals.

In some rare instances, profiles of rather big boutons containing spherical synaptic vesicles and having another bouton apposed at the convex side were observed (Fig. 12). One or more profiles of a synaptic complex between these big boutons and the motoneurons could be seen in the sections. Postsynaptic dense bodies were present in some cases. The synaptic vesicles of the small apposing boutons seemed to be of the same size and shape as at P boutons in the adult. These boutons are further dealt with in a forthcoming paper (Conradi and Skoglund 1969 b). In the quantitative study on single sections

in the newborn stage (see below), two types of bouton profiles were included below the heading "M- and big S-type", they are:

a) Boutons with spherical vesicles having another bouton profile apposed at the convex side.
b) Big boutons with spherical synaptic vesicles, showing one large or several smaller profiles of a synaptic complex, covered by a thick layer of postsynaptic material or several postsynaptic dense bodies.

It must be pointed out that these profiles *do not* completely fulfil the criteria for the M and big S boutons with axo-axonic contacts, established in the adult (Conradi 1969 a, d).

Quantitative estimation in the newborn stage

The size and distribution of bouton profiles of the different types on the motoneuron cell bodies and dendrites in the newborn were studied on single transverse sections through the lateral motor column in the most cranial millimetre of L 7 (see Material and Methods). The aim of this estimation and the one at the three-weeks stage (see below) was to compare the bouton population with that in the adult (Conradi 1969 a). As already mentioned, the material (a total of about 50 profiles from two kittens, taken at each stage) is rather small, because of the complicated handling procedure. Despite this, there are several quite consistent general features in regard to the parameters which will be dealt with. The results from the newborn animals are presented in Tables 2—5. The mean values will be used in the following description, although it seems clear that there are some general differences between the two animals; the value for the mean minor diameter of the motoneuron cell bodies is, for example, somewhat bigger in kitten no. 2.

a) *Profiles of motoneuron cell bodies and dendrites.* The mean minor diameter of the motoneuron cell bodies in the newborn was 29 μ. This is about 60% of the corresponding value in the adult (49 μ) (cf. Mellström and Skoglund 1969). The mean diameter of the various dendritic profiles were usually less than half the size of the corresponding values in the adult. The values were 5.9 μ (DA), 3.7 μ (DB), 2.0 μ (d) in the newborn and 11.7 μ (DA), 8.4 μ (DB), 4.8 μ (d) in the adult.

Spinous projections from the cell membrane were rather frequently encountered on both cell bodies and dendrites (Table 2) and seemed to be most common at proximal parts of the motoneuron dendrites. In the adult material,

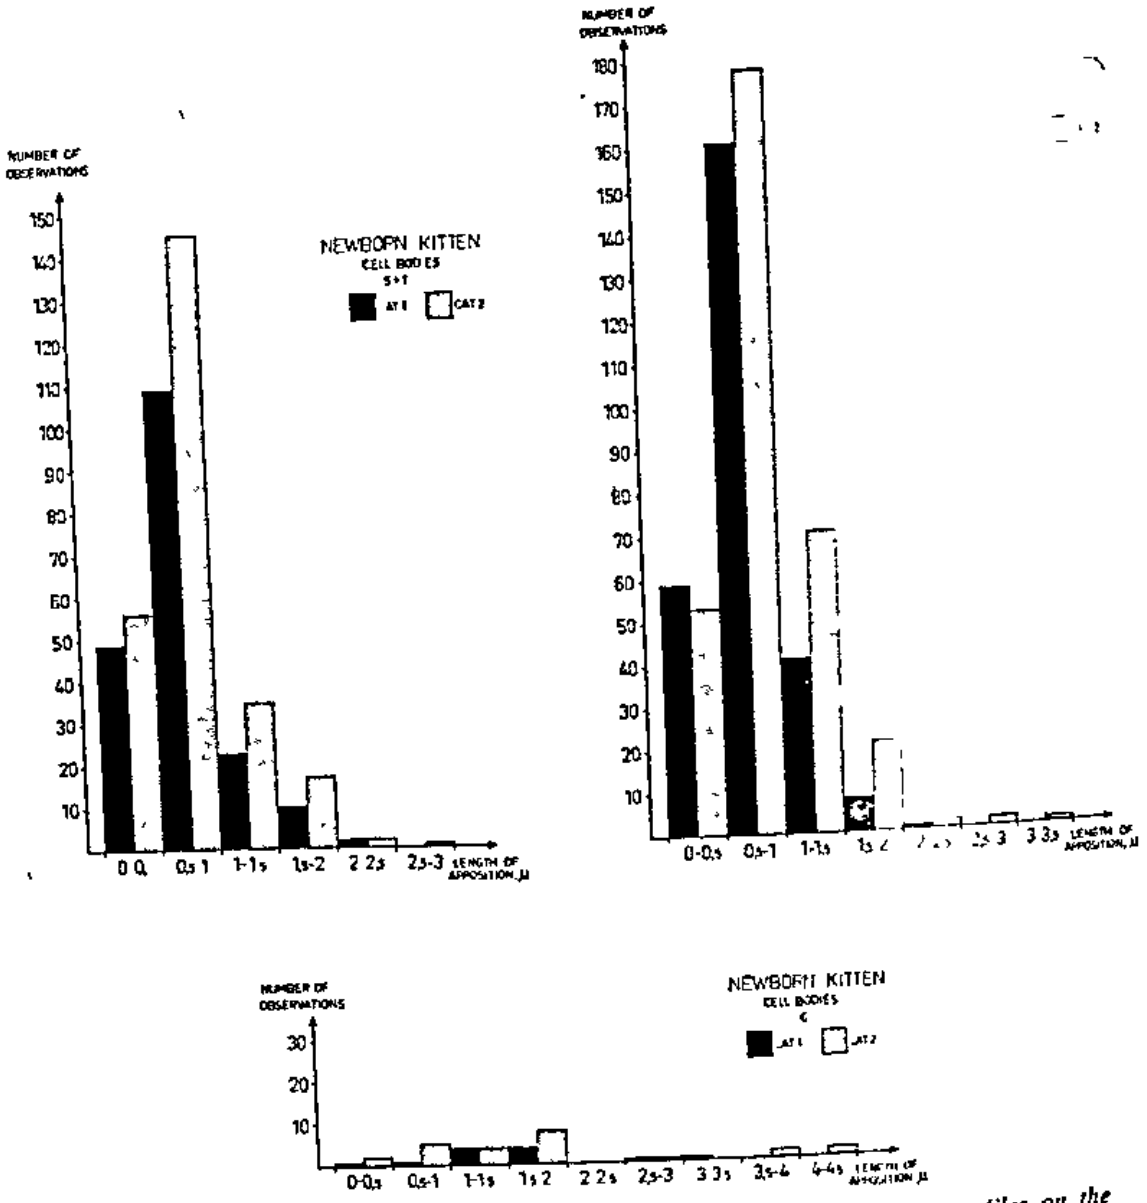
only a few spines were encountered and all of them were found on the dendrites.

The dendro-dendritic apposition regions were also included in the quantitative study. A total of 23 observations of such junctions were made in the quantitative study.

b) *Location of the boutons of different types.* Both S and F boutons were present on the motoneuron cell bodies as well as on the dendrites. As in the adult, profiles of F boutons were most frequently encountered on the cell bodies in single sections with the proportion diminishing with increasing distance from the cell bodies.



The situation for S and particularly T boutons was the reverse. The C boutons seemed to be restricted to the motoneuron cell bodies and proximal parts of the dendrites. Most of the boutons, included in the M and big S column, were situated on proximal parts of the motoneuron dendrites. As already pointed out, these boutons, however, did not completely fulfil the criteria for the M-type and big S-type with axo-axonic contacts, as defined in the adult.

Thus, the location of the different bouton types was very similar to that in the adult. In order to obtain more accurate information on the spectrum of the boutons on different regions of the motoneurons, the bouton covering has to be studied (see below).

c) *Size of the bouton profiles.* The mean length of apposition of the S and F boutons in the neonate is about 0.7—0.8 μ as compared to 1.7—2.1 μ in the adult (adult bigger than newborn for both types at all regions, $p < 1\%$), which means that the two most commonly occurring bouton types in the newborn are about half the size they attain in the adult. There are no significant differences between the mean values on the cell bodies and thin dendrites for the S- or F-type; neither is there any significant difference between the mean values of these two types.

In the newborn, as in the adult, the mean length of apposition of the T boutons seems slightly larger than for S boutons. The mean length of apposition of the C boutons is about twice that of the S and F boutons, as compared to about 2,5 times that in the adult.

The size-range for the length of apposition of both S and F boutons on the cell bodies are shown in text-Fig. 1. The majority of the observations lies near the mean values, and the size-range is noted to be rather small for both types. The calculation of the variances for the length of apposition showed

Text-Fig.: Diagram showing the length of apposition of all the bouton profiles on the motoneuron cell bodies in the quantitative study on the newborn stage.

roughly equal values for S and F boutons, both on the cell bodies and on the thin dendrites. The variance in all cases was much less than in the adult.

d) *Bouton covering (Tables 3 and 4).* The highest total bouton covering of the motoneurons, roughly 60%, was found on the proximal parts of the dendrites. From here on, the covering decreased towards the cell bodies and towards the distal dendrites. These regional differences are significant at the 10%

Table 4. Newborn kitten. Bouton covering, separated for the different bouton types. The developmental change, expressed as difference between adult and newborn, is included

F	27.9	−0.7	10.1	+9.6	30.1	+11.8	20.3	+3.9
C	3.2	+3.8	2.1	+4.0	2.1	+ 2.6	0.2	+0.3
M + big S	0.3	−0.1	1.3	+0.6	1.3	− 0.2	0.1	+0.1

level. In the adult, the highest values for bouton covering were also found on the proximal parts of the motoneuron dendrites, where they are higher than in the newborn. The values for total bouton covering on the cell bodies in the newborn seems equal to, or slightly higher than, in the adult. The differences in total bouton covering between newborn and adult are not significant at any of the four regions.

The values for the covering of the boutons of different types are shown in Table 4; the differences from the adult stage are included. The S and T boutons are included under the same heading, since it was observed in the adult material (Conradi 1969 a, b) that one and the same bouton may establish synaptic complexes of both types.

It must be pointed out at once that the regional differences in the covering of the boutons of different types in the newborn stage are not significant.

Compared to the adult, however, some differences are apparent. The covering of F boutons increases on the dendrites from newborn to adult; on region DA, the rise is significant ($p < 5\%$). On the cell bodies, there is no increase at all for the F boutons. The covering of C boutons seems also to increase, both on the cell bodies and on the dendrites, but the values are not significant. For the S+T boutons, there is a decrease towards the adult stage on the proximal parts of the dendrites and particularly on the cell bodies, where the decrease is significant at the 10% level. Also, a decrease for the ratio between the covering of S+T and F boutons on the cell bodies is significant at the 10% level.

The figures for the mean distance along the cell membrane between the centres of adjacent boutons are included in Table 3. These are further dealt with in connexion with the 3-week stage.

Three-dimensional reconstruction in the newborn

The membrane relationships of the proximal part of a motoneuron dendrite in the newborn kitten were analyzed through serial sections. The mantle surface of the dendrite was illustrated unfolded (Figs. 13—19). The findings were compared with those, obtained from a similar reconstruction from adult animal (Conradi 1969 b).

It can be seen that the largest part of the dendritic cell membrane is covered by boutons (Figs. 15 and 16). Adjacent dendrites and myelin sheaths only small areas, rather narrow intervening astrocytic processes were present at these places. The unlabelled parts of the surface are covered by astrocytic and unidentified processes.

The apposition areas of the boutons seem for the most to be slightly convex. Adjacent boutons are tightly packed at only a few places. Instead, a small space is generally left between the boutons. A large area in Figure 15 is entirely devoid of boutons. All types of boutons were identified, except for F boutons, but three rather big S boutons, obviously exhibiting an axo-axonic synaptic contact, were present (Fig. 15). The size-range of the boutons, both between the different types and within the same type, is not so pronounced as in the adult. S and F boutons seem to be about the same size, while the C boutons are somewhat bigger. No obvious clustering of boutons of the same type was observed.

As shown in Figs. 17 and 18, the preterminal axons, which were always unmyelinated, could not be observed at all the boutons. Some boutons *de passage* were encountered. Granular endoplasmic reticulum was present below the cell membrane at some of the C boutons, but its distribution, apart from this, seemed to be rather random, as was the location of the dendritic spines. Rather many boutons also established synaptic contacts with adjacent dendrites. These boutons with "double synapses" were clustered, since several neighbouring boutons often made synaptic contact with the same adjacent dendrite.

The size and shape of the synaptic complexes and desmosome-like figures are shown for some of the boutons in Fig. 19. Most of the boutons seem to make several desmosome-like contacts with the dendrite. Between every bouton and the dendrite there is often only one synaptic complex, which, in a few cases, nearly reaches the lateral border of the bouton. The synaptic cleft seems to occupy a rather large part of the zone of apposition as compared to the situation in the adult.

When the results of the three-dimensional reconstruction are compared to those obtained in the adult, the following differencies are distinguished: In

the adult, the boutons were bigger and more densely packed. No similar large areas devoid of synaptic contacts, as in the newborn stage, existed, instead the dendrite in the adult stage was covered by myelin at several places. In the adult, some preterminal axons were myelinated, and very few boutons made synaptic contacts with additional adjacent dendrites. Usually several synaptic complexes were found between each bouton and the dendrite in the adult, in contrast to the situation in the newborn.

In the reconstructions analyzed in this study, the number of boutons inside the largest possible square on the dendritic surface were counted. In region A, 106 boutons were present inside 119 μ^2, which corresponds to 89 boutons/100 μ^2. In region B, 100 boutons were situated inside 130 μ^2 or 72 boutons/100 μ^2. Corresponding values for the adult were 17.5/100μ^2 (A) and 22/100 μ^2 (B). Roughly, the extent of regions A and B in the adult and newborn is comparable.

Postnatal changes of the relationships of the motoneuron cell membrane

First three weeks

During the neonatal period, some differences between the animals in the general ultrastructural features of the ventral horn are already apparent. The gestation period for the cat is 65 ± 4 days (Scott *et al.* 1957), which means that kittens are born at different stages of maturation. Individual differences are also met with in the subsequent development; therefore the present description represents a rather rough estimation.

There is a gradual increase in the size of the motoneuron cell bodies, which seems to continue at least during the first two postnatal months (cf. Mellström and Skoglund 1969). The granular endoplasmic reticulum reaches the cell membrane of the motoneuron cell bodies at most places rather soon after birth, and the glycogen-like particles inside the motoneuron cell bodies then disappear. At three weeks the proximal parts of the motoneuron dendrites still look rather thin, as compared to those in the adult, and they still contain relatively little endoplasmic reticulum. In the three-week old kitten, it is moreover often difficult to demarcate the transition between motoneuron cell bodies and proximal parts of the dendrites (Fig. 20). The zone of transition is rather long. The number of spinous projections from the motoneuron cell membrane seems to diminish gradually already from birth on. From studies on developing Purkinje cells there is evidence that the spines disappear in a

centrifugal course from the neuron cell bodies (Larramendi and Victor 1966). Whether this also holds true in the present material was not investigated.

Parallel with the increase in size of the motoneuron cell bodies, the cell/gray coefficient decreases (Mellström and Skoglund 1969). Concomitantly, the number of desmosome-like junctions between adjacent motoneurons decreases rapidly already during the first postnatal week. There is also a rather rapid decrease in the number of boutons making synaptic contact with more than one postsynaptic extension. The diameter of the profiles in the neuropile increases gradually. During the first three postnatal weeks, few axons in the neuropile are myelinated.

As mentioned, glial cells were rather seldom observed to be apposed at the motoneuron cell bodies in the newborn. During the first postnatal weeks both oligodendrocytes and astrocytes were found in such a position to a seemingly increasing extent. Immediate apposition could then also be found between the cell membranes of the oligodendrocytes and the motoneurons. This contrasts to the situation found in mature animals, where a thin astrocytic sheath nearly always was interposed.

As regards the astrocytes, both the degree of ramification of each cell and the total number of cells seemed to increase after birth. The cytoplasm of the astrocytes contained abundant granular endoplasmic reticulum and the Golgi-apparatus was often very prominent. At three weeks, large areas of the motoneuron cell bodies could be found to be covered by astrocytic cell bodies (see below). An increasing amount of astrocytic cytoplasm is also found around the initial axon segment during the same period (Conradi and Skoglund 1969 b). In the adult, astrocytic cell bodies are seldom observed immediately outside the motoneuron cell bodies; instead, large areas of the latter are covered by thin astrocytic sheaths (cf. Conradi 1969 a).

The size of the boutons also increases during the first postnatal month. At one month, boutons are rather infrequently observed to contain glycogen-like particles. One or several mitochondria, instead, are usually seen in most bouton profiles in each single section. Boutons, completely fulfilling the criteria for M boutons in the adult, appear from the third postnatal week.

The development after three weeks

The main ultrastructural changes observed in the ventral horn after 3 weeks were somewhat different from those occurring in the preceding period. The size of the cell bodies continued to increase and the motoneurons were still further separated. The diameters of dendrites, axons and boutons showed a

the adult, the boutons were bigger and more densely packed. No similar large areas devoid of synaptic contacts, as in the newborn stage, existed, instead the dendrite in the adult stage was covered by myelin at several places. In the adult, some preterminal axons were myelinated, and very few boutons made synaptic contacts with additional adjacent dendrites. Usually several synaptic complexes were found between each bouton and the dendrite in the adult, in contrast to the situation in the newborn.

In the reconstructions analyzed in this study, the number of boutons inside the largest possible square on the dendritic surface were counted. In region A, 106 boutons were present inside 119 μ^2, which corresponds to 89 boutons/ 100 μ^2. In region B, 100 boutons were situated inside 130 μ^2 or 72 boutons/ 100 μ^2. Corresponding values for the adult were 17.5/100μ^2 (A) and 22/ 100 μ^2 (B). Roughly, the extent of regions A and B in the adult and newborn is comparable.

Postnatal changes of the relationships of the motoneuron cell membrane

First three weeks

During the neonatal period, some differences between the animals in the general ultrastructural features of the ventral horn are already apparent. The gestation period for the cat is 65 ± 4 days (Scott *et al.* 1957), which means that kittens are born at different stages of maturation. Individual differences are also met with in the subsequent development; therefore the present description represents a rather rough estimation.

There is a gradual increase in the size of the motoneuron cell bodies, which seems to continue at least during the first two postnatal months (cf. Mellström and Skoglund 1969). The granular endoplasmic reticulum reaches the cell membrane of the motoneuron cell bodies at most places rather soon after birth, and the glycogen-like particles inside the motoneuron cell bodies then disappear. At three weeks the proximal parts of the motoneuron dendrites still look rather thin, as compared to those in the adult, and they still contain relatively little endoplasmic reticulum. In the three-week old kitten, it is moreover often difficult to demarcate the transition between motoneuron cell bodies and proximal parts of the dendrites (Fig. 20). The zone of transition is rather long. The number of spinous projections from the motoneuron cell membrane seems to diminish gradually already from birth on. From studies on developing Purkinje cells there is evidence that the spines disappear in a

centrifugal course from the neuron cell bodies (Larramendi and Victor 1966). Whether this also holds true in the present material was not investigated.

Parallel with the increase in size of the motoneuron cell bodies, the cell/gray coefficient decreases (Mellström and Skoglund 1969). Concomitantly, the number of desmosome-like junctions between adjacent motoneurons decreases rapidly already during the first postnatal week. There is also a rather rapid decrease in the number of boutons making synaptic contact with more than one postsynaptic extension. The diameter of the profiles in the neuropile increases gradually. During the first three postnatal weeks, few axons in the neuropile are myelinated.

As mentioned, glial cells were rather seldom observed to be apposed at the motoneuron cell bodies in the newborn. During the first postnatal weeks both oligodendrocytes and astrocytes were found in such a position to a seemingly increasing extent. Immediate apposition could then also be found between the cell membranes of the oligodendrocytes and the motoneurons. This contrasts to the situation found in mature animals, where a thin astrocytic sheath nearly always was interposed.

As regards the astrocytes, both the degree of ramification of each cell and the total number of cells seemed to increase after birth. The cytoplasm of the astrocytes contained abundant granular endoplasmic reticulum and the Golgi-apparatus was often very prominent. At three weeks, large areas of the motoneuron cell bodies could be found to be covered by astrocytic cell bodies (see below). An increasing amount of astrocytic cytoplasm is also found around the initial axon segment during the same period (Conradi and Skoglund 1969 b). In the adult, astrocytic cell bodies are seldom observed immediately outside the motoneuron cell bodies; instead, large areas of the latter are covered by thin astrocytic sheaths (cf. Conradi 1969 a).

The size of the boutons also increases during the first postnatal month. At one month, boutons are rather infrequently observed to contain glycogen-like particles. One or several mitochondria, instead, are usually seen in most bouton profiles in each single section. Boutons, completely fulfilling the criteria for M boutons in the adult, appear from the third postnatal week.

The development after three weeks

The main ultrastructural changes observed in the ventral horn after 3 weeks were somewhat different from those occurring in the preceding period. The size of the cell bodies continued to increase and the motoneurons were still further separated. The diameters of dendrites, axons and boutons showed a

Table 6. Mean number of bouton profiles on the motoneuron cell bodies in the quantitative study on single sections

Age	Cat 1	Cat 2	Mean
Newborn	47	59	53
3 weeks	46	75	60
Adult	34	35	34

probability, still larger. If so, the postnatal increase in diameter is larger for the more distal than for the proximal parts of the dendrites.

The boutons. Since the dimensions of the bouton profiles were not known, the bouton covering could not be calculated. The tight-packing of the boutons had to be expressed as the ratio: $\frac{\text{membrane length}}{\text{number of boutons}}$ which means mean distance along the cell membrane between the centres of adjacent boutons. Despite this limitation, a few comments on the changes in the bouton population from the newborn stage will be attempted.

The mean distance along the cell membrane between the centres of adjacent boutons has increased from the newborn stage on both cell bodies and dendrites. In all instances, the change from newborn to the three week stage is less than the change between the three week and adult stages.

The total number of bouton profiles on the motoneuron cell bodies in the sections has increased slightly by three weeks. However, the values at both the newborn and three week stages are much higher than those found in the adult material (see Table 6). The possible reasons for this decrease are further dealt with in the discussion.

The proportion of bouton profiles of different types as seen in the single sections at three weeks has also changed to some extent from the newborn stage. The comparatively high proportion of profiles of the S+T-type found in the newborn, especially on the motoneuron cell bodies still holds, although it is less pronounced. The values were: SO=40.7% (newborn 41.4%, adult 35.5%), DA=43.2% (newborn 47.1%, adult 39.6%), DB=50.0% (newborn 49.5%, adult 42.0%). In the first animal, the values resemble more those in the adult than those in the newborn, whereas the reverse is true for the second animal.

The M and big S boutons with axo-axonic contacts are present on about the same regions of the motoneuron surface as in the adult. The numerical proportion in the sections of these profiles, which at 3 weeks fulfil the

criteria used in the adult, is comparable to that found in the adult.

In conclusion, it may be stated that the size of the motoneurons and the location of apposing boutons of different types at three weeks, seem to be intermediate between the newborn and the adult stages. The developmental changes in the parameters investigated during the first three postnatal weeks, however, appear to be less prominent than the changes between the three-week and the adult stage.

Neuronal degeneration

From earlier reports (se Levi-Montalcini 1964, Källén 1965, Bodian 1966 a, Wechsler 1966) there is evidence that neuronal degeneration occurs during the development, at least in the early stages of growth. In the present material, large accumulations of contrast-rich material, similar to the structures described by Bodian (1966 a) as fragmented, were observed inside glial cell bodies during the first three weeks (Fig. 21). Profiles of thin dendrites with a dark cytoplasm were also observed at this time (Fig. 22). Similar figures have been observed at retrograde neuronal degeneration in kittens (Grant and Westman 1969), but whether they represent a sign of degeneration in the present material could not be shown. The profiles were often surrounded by stout astrocytic-like processes.

Profiles, similar to degenerated myelinated axons, were rarely noted. However, as reported in the following paper (Conradi and Skoglund 1969 b) projections from the myelin surrounding the motoraxon, or circular myelin bodies with a fragmented interior located outside the motoraxons, were often encountered. At low magnification, they appeared rather similar to degenerated myelinated axons following axon transection in the adult CNS, as described earlier (see Conradi 1969 d).

Special attention was paid to the relationships of the glial cells, which covered large areas of the motoneuron cell bodies and the most proximal parts of the motoneuron dendrites from the first week. Since, in the newborn, the boutons seemed to be rather evenly distributed on the motoneuron cell bodies, the large areas of apposition of astrocytes and oligodendrocytes shortly after birth might indicate that a disappearance of boutons had taken place. Sometimes, profiles of boutons on the motor cell bodies were situated between the motoneuron cell membrane and the cell body of an astrocyte, thus obviously interrupting a long area of apposition of the glial cell to the motoneuron cell body (Figs. 23 and 24). For the most, the interior of these boutons seemed quite normal. At several places, glial processes intervened

Table 6. Mean number of bouton profiles on the motoneuron cell bodies in the quantitative study on single sections

Age	Cat 1	Cat 2	Mean
Newborn	47	59	53
3 weeks	46	75	60
Adult	34	35	34

probability, still larger. If so, the postnatal increase in diameter is larger for the more distal than for the proximal parts of the dendrites.

The boutons. Since the dimensions of the bouton profiles were not known, the bouton covering could not be calculated. The tight-packing of the boutons had to be expressed as the ratio: $\frac{\text{membrane length}}{\text{number of boutons}}$ which means mean distance along the cell membrane between the centres of adjacent boutons. Despite this limitation, a few comments on the changes in the bouton population from the newborn stage will be attempted.

The mean distance along the cell membrane between the centres of adjacent boutons has increased from the newborn stage on both cell bodies and dendrites. In all instances, the change from newborn to the three week stage is less than the change between the three week and adult stages.

The total number of bouton profiles on the motoneuron cell bodies in the sections has increased slightly by three weeks. However, the values at both the newborn and three week stages are much higher than those found in the adult material (see Table 6). The possible reasons for this decrease are further dealt with in the discussion.

The proportion of bouton profiles of different types as seen in the single sections at three weeks has also changed to some extent from the newborn stage. The comparatively high proportion of profiles of the S+T-type found in the newborn, especially on the motoneuron cell bodies still holds, although it is less pronounced. The values were: SO=40.7% (newborn 41.4%, adult 35.5%), DA=43.2% (newborn 47.1%, adult 39.6%), DB=50.0% (newborn 49.5%, adult 42.0%). In the first animal, the values resemble more those in the adult than those in the newborn, whereas the reverse is true for the second animal.

The M and big S boutons with axo-axonic contacts are present on about the same regions of the motoneuron surface as in the adult. The numerical proportion in the sections of these profiles, which at 3 weeks fulfil the

criteria used in the adult, is comparable to that found in the adult.

In conclusion, it may be stated that the size of the motoneurons and the location of apposing boutons of different types at three weeks, seem to be intermediate between the newborn and the adult stages. The developmental changes in the parameters investigated during the first three postnatal weeks, however, appear to be less prominent than the changes between the three-week and the adult stage.

Neuronal degeneration

From earlier reports (se Levi-Montalcini 1964, Källén 1965, Bodian 1966 a, Wechsler 1966) there is evidence that neuronal degeneration occurs during the development, at least in the early stages of growth. In the present material, large accumulations of contrast-rich material, similar to the structures described by Bodian (1966 a) as fragmented, were observed inside glial cell bodies during the first three weeks (Fig. 21). Profiles of thin dendrites with a dark cytoplasm were also observed at this time (Fig. 22). Similar figures have been observed at retrograde neuronal degeneration in kittens (Grant and Westman 1969), but whether they represent a sign of degeneration in the present material could not be shown. The profiles were often surrounded by stout astrocytic-like processes.

Profiles, similar to degenerated myelinated axons, were rarely noted. However, as reported in the following paper (Conradi and Skoglund 1969 b) projections from the myelin surrounding the motoraxon, or circular myelin bodies with a fragmented interior located outside the motoraxons, were often encountered. At low magnification, they appeared rather similar to degenerated myelinated axons following axon transection in the adult CNS, as described earlier (see Conradi 1969 d).

Special attention was paid to the relationships of the glial cells, which covered large areas of the motoneuron cell bodies and the most proximal parts of the motoneuron dendrites from the first week. Since, in the newborn, the boutons seemed to be rather evenly distributed on the motoneuron cell bodies, the large areas of apposition of astrocytes and oligodendrocytes shortly after birth might indicate that a disappearance of boutons had taken place. Sometimes, profiles of boutons on the motor cell bodies were situated between the motoneuron cell membrane and the cell body of an astrocyte, thus obviously interrupting a long area of apposition of the glial cell to the motoneuron cell body (Figs. 23 and 24). For the most, the interior of these boutons seemed quite normal. At several places, glial processes intervened

partly between the motoneuron cell membrane and apposing boutons of an apparently normal appearance (Fig. 25). No boutons were, however, observed to be completely surrounded by glial cytoplasm, as revealed by investigation of series of sections. Some apparently fragmented material was sometimes seen in the glial cytoplasm just outside the motoneuron cell bodies (Fig. 26). Nevertheless, no boutons filled with a contrast-rich material (see Wahlberg 1964, Conradi 1969 d) or neurofilaments (Gray and Hamlyn 1962, Conradi 1969 d) were observed.

DISCUSSION

Glutar aldehyde, dissolved in a 300 mOsm buffer and perfused through the vascular system at a discontinuous pressure, was found to give an acceptable and reproducible fixation of the spinal cord in both the kittens and adult cats. The same is true for the spinal roots (Berthold 1968). The adult animals were more sensitive to the perfusion method than were the newborn kittens, in which it was possible to obtain a good fixation even after perfusions at a high and constant pressure. As pointed out earlier (Conradi 1969 a), the difficulty in obtaining a good perfusion of the spinal cord in the adult cat might be connected with the complicated vascular supply of the cord, and there might well be developmental changes in this respect.

The volume changes in the tissue during the fixation and preparation procedure for ultrastructural work are not known exactly (see Conradi 1969 a). Furthermore, it was not known whether these changes are similar in the kittens and in the adult cats, even if the same fixation method is used. Due to the diminishing water content in the CNS during the development (Friis-Hansen 1957), it might well be that the reaction of the tissue to the fixative varies with age. This has to be borne in mind, especially when comparing the dimensions of various profiles in the different developmental stages (see also discussion by Mellström and Skoglund 1969).

During the earlier stages of development, the motoneurons were rather small and tightly packed. From the lightmicroscopic studies of Mellström and Skoglund (1969), there is evidence that the size-range of all the neurons in Rexed's lamina IX in the newborn is rather small, a differential rate of growth giving rise to neurons of different sizes in the adult. Thus, there are some difficulties in distinguishing the motoneurons from other neurons at younger stages, at least with the lightmicroscope. In the present work, the biggest neurons in the newborn stage were considered to be motoneurons.

They showed similar cytological characteristics, and C boutons were regularly observed on these cells, but did not seem to be present on the smaller neurons, like in the adult (cf. Conradi 1969 a). The dense packing of the cells in the newborn stage also made the recognition of the various motoneuron nuclei somewhat difficult; this could have interfered with the sampling for the quantitative studies.

Membrane relationships of the motoneurons

General appearance

Although there is no earlier report on the membrane relationships of the motoneurons in the cat during the postnatal development, some general features of developing central nervous tissue have been described in several ultrastructural reports during the last few years.

The ultrastructural development, also including earlier maturational stages than investigated here, has namely been studied on neurons (see for ex. Schwartz *et al.* 1968, Voeller *et al.* 1963, Wechsler 1966, Mugnaini and Forströnen 1967, Caley and Maxwell 1968, Del Cerro and Snider 1968), glial cells (see for ex. Vaughn 1969, Mugnaini and Forströnen 1967, Fleischhauer 1968, Caley and Maxwell 1968, Vaughn and Peters 1967), boutons (see for ex. Konishi 1966, Larramendi 1967, Wechsler 1966, Larramendi *et al.* 1967, Mugnaini and Forströnen 1967, Kornguth *et al.* 1968, Glees and Sheppard 1964, Meller *et al.* 1968) and axons (Fleischhauer and Wartenberg 1967, Bunge 1968) in various regions of the CNS (for references, see Wechsler and Meller 1967). The results obtained in these works have been used for the interpretation of the present findings.

Qualitatively, the developmental changes in the relationships of the motoneurons seemed rather slight. Some of these changes also appeared difficult to correlate to the available physiological data. However, the disappearance of glycogen-like particles and the increase in the number of mitochondria, especially in the boutons, during the first postnatal weeks, could point to important biochemical changes in the tissue. Earlier histochemical work has shown that there is a large increase in the amount of oxidative enzymes on and around the motoneurons during the postnatal development (Skoglund 1967, see also Labedsky and Lierse 1968). The finding that glial cells seemed to be apposed to the motoneurons after birth could imply not only changes in the architecture of the extensions on the motoneuron surface, but also chemical changes in the environment of the motoneurons. The great number of desmosome-like junctions between adjacent motoneurons, during the first

postnatal days, and the occurrence of the "double synapses", during the first weeks, could be of importance for the functional interrelationships of the motoneurons. The apparently continuous growth of the boutons and the synaptic complexes, the increase in the number of synaptic vesicles, as well as the myelination of small axons in the neuropile from the second postnatal month on, ought to be of importance for the synaptic activation of the motoneurons.

tative study

here were thus some general features in the ultrastructural develop-
outons, the size and distribution of boutons of different types
rons during development were thought to be of importance in
ological correlates to the physiological maturation. The
gnized in the adult, except for the M-type, were already
pre motoneurons at birth, and the location of the boutons of
as similar in the newborn and the adult. Due to this, the
dist e boutons had to be analyzed quantitatively. Again, it has
to be po at that the quantitative study, performed in this paper, consists
of a limite aterial.

Detailed studies on the development of connexions of the motoneurons require extensive serial sectioning. On the other hand, some of the findings seemed constant throughout the study. The following main findings from the quantitative study will be discussed briefly.

a) Growth of the motoneurons.
b) Growth of the boutons. In the newborn, the bouton profiles were much smaller than in the adult, and the differences between the types were rather small.
c) Postnatal changes in the percentage of total bouton covering of the motoneurons. The covering on the dendrites increased from the newborn to the adult stage, whereas on the cell bodies, the covering remained constant or decreased. The number of bouton profiles on the cell bodies as seen in single sections, was reduced during development. The reduction seemed to be most prominent after three weeks.
d) Distribution of boutons of different types on the motoneurons. The percentage membrane covering of the S and T boutons decreased, most prominently on the cell bodies, from birth. The covering of F and C boutons increased, this was particularly true of the F boutons on the dendrites.

Growth of the motoneurons

There is rather good agreement between the present results and the earlier quantitative light microscopic study (Mellström and Skoglund 1969) in regards to the dimensions of the motoneurons at birth and in the adult. Probably light microscopic studies are the most appropriate for investigations on the growth of the motoneuron cell bodies and dendrites. In the present material, the postnatal increase in diameter was larger for the dendritic profiles than for the cell bodies. If it is assumed that the proportion between the dimension of a profile at one stage of development, compared to the adult, reflects the maturity of the profile (cf. Hines and Emerson 1951) then the finding could indicate that the cell bodies are more mature than are the distant dendritic branches at the earlier developmental stages, a fact which could be of physiologic importance.

With the methods used in the present study, it is impossible to reveal the detailed mode of growth, not only of whole neurons, but also of the different parts. When, for example, only the cell bodies are concerned, it is of interest to know whether there are any movements in the cell membrane and possibly also in the apposing structures, relative to the interior of the cells, which must be of importance for studies on the membrane relationships. The possibilities which exist are: that newly-formed membrane is pushed away from the cell bodies towards the dendrites, and, that the cell body partially incorporates the proximal parts of the dendrites during development. At three weeks, the difficulty in sometimes defining the border between the cell body and the dendrites could be a reflexion of the latter.

The boutons

In the following discussions regarding the boutons it was assumed that the bouton types are retained during development. This means that the boutons with, for example, flattened synaptic vesicles in the newborn stage were believed to contain such vesicles throughout the development. As shown in the adult material (Conradi 1969 a, b) each bouton type showed several characteristics, apart from the shape of the vesicles; hence the assumption seems reasonable.

Growth. In the newborn, most bouton profiles were of similar size. Both the difference in size between the types and the size-range in every type were less in the newborn than in the adult. This can also be seen in the reconstruc-

Reduction in the number of bouton profiles on the cell bodies

The growth of the boutons appeared roughly similar on the cell bodies and on the proximal parts of the dendrites. This, plus the fact that the bouton covering on the cell bodies did not increase, in contrast to that on the dendrites, together with the evidence that the length of the bouton profiles increased faster than the cell body outline, could indicate that there is a reduction in the number of boutons on the motoneuron cell bodies during development. The reduction ought then to involve the S+T boutons, since the covering of these boutons on the cell bodies decreased noticeably. The F boutons might, however, also be affected, since the covering of these did not show the big increase found on proximal parts of the dendrites and the numerical proportion of S+T and F boutons on the cell bodies remained unchanged during development. From developmental studies on the cerebellum, it has been reported that there are contacts between certain boutons and neuron cell bodies at early developmental stages, and that these contacts cannot be found in the adult (Mugnaini and Forströnen 1967, Kornguth *et al.* 1968). The apparent decreasing proportion of S+T boutons on proximal parts of the dendrites in the present material can also be the result of a reduction in the number of these boutons. From the values for the absolute number of boutons on the cell bodies in the single sections from the newborn, at three weeks and in the adult, it might be concluded that such a loss could occur both before and after 3 weeks.

Judging from observations on single transverse sections, the possibilities for the causes of a reduction in the number of boutons on the cell bodies are several: First, the sampling method underlying the comparison between the quantitative studies might have been incorrect, so that different populations of neurons were investigated at different stages. The vertical increase in the diameter of the motoneuron cell bodies might be larger than the horizontal one, implying that a calculated increase in surface, as obtained from measurements of the diameter in transverse sections, is not correct. Thus, the boutons will get more scattered on the surface during development, and the number of bouton profiles found in the single sections will be reduced. In earlier works (Lhermitte and Kraus 1925, Weil 1927, Scheibel and Scheibel 1966) it has been pointed out that the longest diameter of the motoneurons of adult mammals is in the cranio-caudal direction, and that this tendency increases during phylogeny. The earlier-mentioned possible movements of the motoneuron cell membrane during development may also be of importance.

Another possibility is that the "double synapses", during development retain the contact with the thin dendrites and leave the cell bodies. Boutons

might, as suggested, be removed in some way by the astrocyte-like glial cells, which are found to be apposed at big areas of the motoneuron cell bodies from the first or second week. In the adult nervous system, boutons have been reported to be removed by means of glial cells which surround the cell bodies of regenerating motoneurons (Blinzinger and Kreutzberg 1968). In this context, it must also be pointed out that during the first postnatal fortnight, there is removal of all the boutons of different types on the initial motoraxon segment found in the newborn. This seems to occur parallel with an increase in the extent of apposing astrocytes (Conradi and Skoglund 1969 b). Finally, it cannot be excluded that a disappearance of boutons occurs during the normal ageing process. The age of the cats used in the adult material was not known.

In summary, it was concluded that studies on the developmental changes in the connexions of the motoneurons require detailed knowledge of the mode of growth of the motoneuron cell bodies and dendrites. The growth of the boutons differed between the types, the S+T boutons seemed to grow less than other types of boutons. This could explain, at least partly, the decrease in covering of these boutons on, for example, the proximal parts of the dendrites during development. On the cell bodies, there is probably a removal of boutons starting at the newborn stage. This removal, which could comprise both S+T and F boutons might be accomplished by the uncoupling of "double synapses" or by means of the apposing astrocytes.

Physiologic considerations on the size and distribution of boutons

The growth alone of the motoneurons must have physiologic implications. The fact that the dendrites are much thinner in the newborn than in the adult indicates that longitudinal resistance in them is higher in the newborn stage. Thus, the boutons on the cell bodies might have a comparatively greater influence on the impulse-activity of the motoneurons in the newborn than in the adult. Furthermore, the bouton covering on the motoneuron cell bodies is relatively higher in the newborn than in the adult. Due to this, attention is drawn to the boutons on the cell bodies.

As mentioned, there is evidence for a relatively greater bouton covering of S+T boutons on the cell bodies in the newborn than in the adult stage. If these boutons are excitatory (cf. Uchizono 1965), the situation might well correspond to the many observations of an increased excitability of the motoneurons in the newborn stage (see Skoglund 1966). Since there is some evidence (Uchizono 1965, see Conradi 1969 a) that F boutons are inhibitory, the relative increase in the F bouton covering and a decrease of the S bouton

covering at some places confirms the increase of inhibition during postnatal development.

The location of the motoneurons studied in this paper corresponds to the tibial and peroneal nuclei (Romanes 1951), which are physiological flexors. There is a dominance of the flexors against the extensors in the newborn stage (Skoglund 1966) and, as shown by Ekholm (1967), the concealed flexor reflexes are actually dominant in this stage. It might be argued that the morphologic findings presented here are only specific for flexor motoneurons. However, the extensor motoneurons exhibit the same characteristics with regard to excitation and inhibition when tested monosynaptically; they must, therefore, have much in common with the flexor motoneurons, at least with regard to the boutons of dorsal root origin. Further studies (in preparation) might reveal whether there are fundamental differences between flexor and extensor motoneurons with regard to the bouton population during development.

Naturally, there are many other morphologic parameters that can be discussed in connexion with the changing physiology, but rather than venture beyond the realm of facts, the results of the experiments now in progress, using the intracellular recording technique, plus further morphologic studies, will be awaited.

ACKNOWLEDGEMENTS

SUMMARY

The postnatal development of the membrane relationships of the spinal motoneurons was studied on 49 normal kittens from the newborn stage to two months of age. At birth, the motoneurons lie close together and the surrounding neuropile contains glial cells and numerous small profiles of dendrites, unmyelinated axons and boutons. At this stage, the motoneuron cell membrane is covered by glial processes and many small boutons, which sometimes contain glycogen-like particles. The different bouton types found in the adult (Conradi 1969 a, b) are already present in the newborn stage,

except for one type (M-type). During the first postnatal weeks, glial cells seem to be apposed at the motoneuron cell bodies. Myelination of the axons in the neuropile is evident to a marked degree during the second postnatal month.

The size and distribution of boutons of different types on the motoneuron cell bodies and dendrites was studied on single transverse sections through the lateral motoneurons in the most cranial millimetre of segment L 7 in the newborn stage and at three weeks. The results were compared to those obtained earlier in the adult (Conradi 1969 a, b). In the newborn, the percentage bouton covering of the proximal parts of the motoneuron dendrites was less than in the adult, whereas on the cell bodies, the values were equal or possibly higher in the newborn stage. As in the adult, the boutons with flattened synaptic vesicles (F-type) and boutons with a subsynaptic cistern (C-type) were more frequently found on the motoneuron cell bodies than on the dendrites in the newborn. The reverse was true for most of the boutons with spherical synaptic vesicles (S- and T-types), as in the adult. During development, there was a reduction in the percentage membrane covering of the S and T boutons, especially on the cell bodies.

The membrane relationships of the proximal part of a motoneuron dendrite in the newborn stage were analyzed through serial sections. The boutons were distributed roughly as in the adult, but there was a three to four times greater number of boutons inside 100 μ^2 dendritic surface than in the adult.

The findings are briefly discussed against the background of available physiologic data.

Observations on the ultrastructure of the initial motoraxon segment and dorsal root boutons on the motoneurons in the lumbosacral spinal cord of the cat during postnatal development

by

SEBASTIAN CONRADI and STEN SKOGLUND

INTRODUCTION

The present paper describes the ultrastructure of the initial motoraxon segment and the dorsal root boutons on the motoneurons in the kitten. First, the initial axon segment and axon hillock in the newborn stage are described. Some observations on central motoraxon nodes are noted and the findings are compared with those in the adult (Conradi 1969 c). Notes on the development subsequent to the newborn stage are included and finally the ultrastructure of the dorsal root boutons, both in the normal state and following dorsal root section, is elaborated upon.

The initial motoraxon in the newborn is shown to be covered by boutons, which disappear during the first postnatal fortnight. The dorsal root boutons, defined by the same criteria as used in the adult (Conradi 1969 d) are not present until about the third postnatal week. Before this time a few boutons, obviously showing axo-axonic contacts, can be observed and some evidence is presented to show that such boutons degenerate after dorsal root section. The findings are briefly discussed in the light of available physiological data.

MATERIAL AND METHODS

The material of normal kittens, described in the preceding paper (Conradi and Skoglund 1969 a), was used for the study of the initial axon segment and the normal anatomy of dorsal root boutons. Profiles from about 20 initial axon segments, completely or partly cut through, were studied, the majority from the neonatal period.

For the study of the ventral horn after dorsal root section, an additional 28 kittens were used (Table 1). The operation method was roughly the same as the one used for adult cats (Conradi 1969 d), and will be briefly described.

The kittens were anaesthetized intraperitoneally with pentobarbital, 20—40 mg/kg body-weight. Under aseptic precautions and following a wide laminectomy the dura was opened with a mid-line incision. The left dorsal roots L 6, L 7 and S 1 were cut proximal to the ganglion and as distal from the cord as possible. After the operation the spinal muscles and skin were sutured and usually Polymyxin® (Pfizer) unguent was left in the wound. The whole operation lasted for 20—40 min. Postoperatively the kittens were nursed artificially with milk, diluted with water. Treatment with antibiotics was omitted during the postoperative period. Usually the youngest kittens seemed to decrease in weight during the postoperative period and in several cases ascites was noted.

The operated animals were subjected to the same fixation as the majority of the animals in the normal material (Conradi and Skoglund 1969 a). Thus they were perfused through the thoracic aorta with prerinse and fixative at 37° C, and icecold fixative from 1 fusion sets at a discontinuous pressure. The fixative was 5% purified glutaraldehyde, dissolved in 300 mOsm Millonig buffer containing 2.7% Rheomacrodex® (Pharmacia).

Thin, transverse slices of the 7th lumbar segment were made, postfixed in 2% OsO_4 in veronal acetate buffer or 300 OmOsm Millonig buffer and embedded in Vestopal W. In some of the operated animals a slight herniation of the spinal cord occurred. Both in the operated and the normal material, the lateral part of the ventral horn was trimmed out and cut into ultrathin transverse sections, which were collected on one-hole grids. Single sections or short series, comprising 10—50 consecutive ultrathin sections, were studied.

Most of the initial segments studied were continuous with the big neurons in the ventral horn, which were those assumed to be motoneurons (Conradi and Skoglund 1969 a). Some observations were also made on isolated profiles, showing identical

Table 1 Survival time of the kittens

dimensions and characteristics. The description of the myelinated part of the motor axon is based on profiles continuous with the initial segments or isolated profiles in the gray substance, which had the same characteristics and are assumed to be motoraxons (cf. Windle 1930).

The initial motoraxon segment was also studied in longer series of transverse sections through the ventral horn in L 7 from normal newborn animals. The series comprised 50—300 sections, a few random sections were lost. Two initial segments from one of these series were also reconstructed with wax-plates using approximately the same method as was used in the adult animals (Conradi 1969 c). In every second section, the profiles of the initial segments were photographed at a primary magnification of 3 700×. The mean section-thickness in this series was about 670 Å, as calculated from the number of sections required to pass through the longitudinally-sectioned initial segment, which was assumed t be cylindrical. From paper copies with a final magnification of 7,500× the outline of the initial segment and apposing boutons was transferred to 1 mm wax-plates. These were glued together and painted.

One bouton in the newborn stage, which seemed to exhibit an axo-axonic synaptic complex, was also reconstructed with wax-plates. Each section was photographed at a primary magnification of 6 400 and enlarged 3×. The mean section-thickness was here about 600 Å. The bouton was situated on the proximal part of a motoneuron dendrite, analyzed through serial sections (Conradi and Skoglund 1969 a).

RESULTS

The axon hillock and initial axon segment

NEWBORN ANIMALS

Although profiles of many motoneurons are visible in large single transverse sections of the ventral horn in the newborn kitten, it is difficult to recognize the axon hillock and initial axon segment of the motoneurons. The initial axon segment is very thin and does not take a straight course, this explains why complete profiles of longitudinally cut initial segments are almost never observed.

Axon hillock

(Fig. 1) As was the arrangement in the adult, most motoraxons seemed to leave the motoneuron in a horizontal plane. The zone of transition between the parent motoneuron and the axon proper called the axon hillock, usually projected from the motoneuron cell bodies, but in a few cases it was also observed to issue from proximal parts of the motoneuron dendrites (cf.

Strong 1906) In contrast to the situation in the adult the diameter of the hillock was usually not larger than that of the initial segment, therefore the transition between the axon hillock and the cell body was rather abrupt. The cytoplasm in the axon hillock contained scattered ribosomes, longitudinally arranged neurotubuli and neurofilaments some mitochondria and dense bodies The cell membrane of the axon hillock showed the same relationships as the cell membrane of the motoneuron cell body which means that it is covered by astrocytic extensions and boutons. The S- F and C-types of boutons found on the motoneuron cell bodies (Conradi and Skoglund 1969 a) were also present on the axon hillock.

The initial axon segment

The initial motoraxon segment extends from the distal part of the axon hillock to the beginning of the myelin sheath of the motoraxon (Figs 1 and 2) Because the axon hillock is of the same diameter as the initial axon segment, the transition between these two regions was somewhat difficult to distinguish. The cytoplasm of the initial segment contains longitudinally-arranged neurofilaments and neurotubuli the latter often seem to be paired in longitudinal sections, as in the adult (Figs. 3 and 4) Kohno 1964 Peters *et al* 1968 Palay *et al.* 1968 Conradi 1969 c) Mitochondria and dense bodies were observed in some sections and glycogen-like particles may also be found The cell membrane of the initial axon segment showed roughly the same specialization as in the adult (see Conradi 1969 c) At the inner side of the membrane, a 100—300 A thick layer of contrast-rich material is attached Immediately outside the cell membrane there is a rim of granular extracellular material of rather constant thickness, 100—200 A or possibly somewhat less than in the adult (Fig. 3)

The beginning of the myelin sheath

In all instances, the motoraxons were myelinated distal to the initial segment, although the thickness of the myelin sheath varied somewhat (Figs. 1 and 2) As in the adult, the diameter of the axon increased slightly distal to the beginning of the myelin sheath Inside the myelin, the axoplasm contains abundant, mostly longitudinally oriented neurofilaments and numerous mitochondria. The terminal cytoplasmic pockets of the myelin are relatively much larger than in the adult (Fig. 2) as previously found in the ventral root of the newborn kitten (cf Berthold and Skoglund 1968) and they contain a contrast rich cytoplasm They cover about 3 μ of the axon the same as in the adult.

Every pocket reaches the axon membrane which usually is not specialized and ordinarily there is immediate apposition of the cell membranes. Desmosome-like junctions between the cytoplasmic pockets were not found in a number comparable to that observed in the ventral roots (Berthold and Skoglund 1968).

Structural peculiarities of the initial motoraxon segment in the newborn stage as compared to adult

1) As already pointed out, the initial motoraxon segment in the newborn kitten is most often curved. The direction of the deviation occurred in both the vertical and horizontal planes and did not seem to be the same for the different neurons (Fig. 1). (This can also be seen in Fig. 6). In a few cases, profiles quite similar to the granular endoplasmic reticulum of the motoneuron cell bodies were observed in the distal part of the initial segment.

2) There are rather many spinous projections from the initial segment in the newborn. Most often these are found near the beginning of the myelin sheath, either just proximal to this, or at the region where the terminal cytoplasmic pockets (Conradi 1969 c) of the myelin cover the axon (Fig. 2). In a few cases a slender collateral was also observed to arise from the initial segment, often just proximal to the beginning of the myelin sheath. As a rule, these thin extensions from the initial segment could not be followed for any longer distance (Fig. 1 this can also be seen in Fig. 6).

3) Outside the extracellular material surrounding the axon are many thin glial extensions, obviously of astrocytic origin, just as in the adult (Fig. 3). In contrast to the situation in the adult, however no glial cells with a dark cytoplasm, similar to the oligodendrocytes or microglial cells, are observed adjacent to the initial segment in the newborn. (Figs. 1 and 3). Sometimes the initial segment is surrounded by big astrocytic-like glial cells at birth, sometimes this occurs later (Fig. 4 see below).

4) In contrast to the arrangement in the adult, boutons are located on the initial motoraxon segment in the newborn (Figs. 2, 3, 6 and 7). The boutons are rather sparse, but obviously distributed over the entire length of the naked axon. On single sections boutons are not observed on all profiles of initial segments. At the area of apposition of the boutons, the cell membrane specialization of the axon is absent (Fig. 3). the same has been observed to

be true in several regions in the adult (cf Palay *et al* 1968 Peters *et al.* 1968) The boutons have the same ultrastructural characteristics and are of the S- F and C-types, the same as on the motoneuron cell bodies (Conradi and Skoglund 1969 a) (Figs 6 and 7) The boutons were often found at the spinous projections on the initial segment. Sometimes the boutons establish a synaptic complex also with a thin dendrite as did the boutons on the motoneuron cell bodies *In rare instances, the boutons on the initial axon segment* and adjacent boutons on neighbouring dendrites were found to arise from the same preterminal axon. In none of the observed cases were there any axo-axonic contacts on the boutons on the initial axon segment.

Dimensions of the axon hillock and initial motoraxon segment

The dimensions of the axon hillock and initial segment were measured in ten cases. The wax-models (see below) were used in two cases for the rest, the measurements were made on profiles in single sections. Seven of the measurements refer to the newborn stage and three measurements to the three week stage (See Table 2)

Table 3 Number and proportion of boutons of different types on the axon hillock and the initial axon segment in the newborn stage and in the adult (Conradi 1969 c) Two models from each stage.

Bouton type	Newborn animals								Adult animals							
	1				2				1				2			
	AH		IS		AH		IS		AH		IS		AH		IS	
	no.	%	no.	%	no.	%	no.	%	no.	%	no.	%	no.	%	no.	%
S+T	15	36	7	37	8	21	5	33	11	34	—	—	19	40	—	—
F	26	62	8	42	28	74	8	53	21	66	—	—	27	59	—	—
C	1	2	4	21	2	5	2	14	—	—	—	—	—	—	—	—
Sum	42		19	38			15		32				46			

The mean total length of the axon hillock and initial segment in the new born, according to this material, is about 75% of the adult value (Conradi 1969 c) The mean diameter of the initial segment is about half of that found in the adult There seems to be a rather rapid increase in the diameter of the base of the axon hillock after birth

Three-dimensional ultrastructure of the axon hillock and initial motoraxon segment

In order to gain knowledge of the three-dimensional morphology of the axon hillock and initial axon segment, and to get more exact information on the distribution of boutons on these regions, wax-reconstructions were made to illustrate two cases (Figs. 6 and 7) From both figures the following observations were made. the axon hillock and initial segment were of about the same diameter the initial segment was somewhat curved and the motoraxon was myelinated One of the initial segments gave off a thin branch just proximal to the beginning of the myelin (Fig. 6) and boutons of the S- F and C-types were distributed on both the axon hillock and initial axon segment.

The boutons were rather densely packed on the axon hillock, but on the initial axon segment they were scattered In both cases, there seemed to be a random distribution of the different types, except for some possible clustering of F boutons on the axon hillock in both the cases.

The number and proportion of the boutons of the different types on the models are shown in Table 3 The values from the two reconstructions in the adult are included for comparison.

It is understood that the two reconstructed cases from each stage may not be representative however in the newborn stage, boutons containing flattened

synaptic vesicles (F-type) seem to occur more frequently than most of the boutons with spherical synaptic vesicles (S+T type) both on the axon hillock and initial segment. The proportion of the F boutons is similar to or somewhat larger than that on the motoneuron cell bodies (Conradi and Skoglund 1969 a) as in the adult (Conradi 1969 c) The total number of boutons on the axon hillock does not seem to change markedly from newborn to adult. The proportion of F boutons on the axon hillock seems similar between newborn and adult. On the initial segment, several boutons are present in the newborn but could not be observed by the adult stage

The myelinated part of the motoraxon

On the myelinated part of the motoraxons (Figs 5 and 8) the incisures of Schmidt Lantermann are abundant, as in the ventral root in newborn animals (Berthold and Skoglund 1968) The incisures are very prominent, and the glial cytoplasm inside them is much like that in the terminal cytoplasmic pockets (Fig. 8) Usually glial cytoplasm is also found inside of the myelin sheath nearest the axon (Fig. 5) In the newborn this seems to be a typical feature of developing myelin (for references, see Bunge 1968) A layer of contrast-rich glial cytoplasm, obviously of oligodendrocytic origin (Mugnaini and Walberg 1964 Bunge 1968 Vaughn 1969) was also seen just outside the myelin sheath. Often the myelin sheath showed slender evaginations, usually filled with glial cytoplasm, but more frequently rounded myelin bodies not continuous with the myelin sheath (Fig. 5) were found in the oligodendrocytic cytoplasm outside the myelin sheath. The interior of these bodies was often fragmented, giving them an appearance similar to the profiles of degenerating myelin bodies, observed in the Schwann cells in the developing ventral root (Berthold and Skoglund 1968) The profiles could easily be mistaken for profiles of degenerating myelinated axons as earlier described in the adult CNS (for references, see Conradi 1969 d)

The central nodes of Ranvier

At the central motoraxon nodes in the newborn (Fig. 9) the cell membrane of the axon is specialized in a manner similar to that found at the initial segment. There is thus a thin layer of contrast rich material on the cytoplasmic side of the membrane Just outside the nodal axon membrane there is only a narrow rim of extracellular material, in contrast to the situation in the adult (Fig. 9) The length of the node-gap is 0.5—1 μ The big cytoplasmic pockets of the myelin, quite like those found distal to the initial segment, are situated

at both sides of the node (Fig. 9) where they cover about 3 μ of the axon, or about the same distance as in the adult Every cytoplasmic pocket reaches the axon membrane (Fig. 9) as in the ventral root of the newborn kitten (Berthold 1968) The node gap is filled with astrocytic extensions Boutons were sometimes found just outside the nodal axon membrane but none was observed to make synaptic contact with the axon.

In one instance, the profile of a big myelinated axon in the gray substance was observed to send out an apparently short branch from a central node of Ranvier About 5 μ from the parent axon, the branch was somewhat distended, and in the distention were several mitochondria and membrane bound dense bodies (Fig. 10) There was also a desmosome-like junction between the distention and an adjacent dendrite. At the zone of emergence of the branch from the axon there was a well-delimited region containing a granular material (Fig. 10) The granular material also reached a short distance into the branch. Similar regions of granular material could be observed inside some profiles of motoraxons these axons otherwise were completely covered by myelin. At these or other places, the contour of both the axon and the myelin could show evaginations (See Fig. 12)

In the newborn, all the small axons in the neuropile were unmyelinated at birth, which made them difficult to distinguish from other types of extensions, e.g., glial processes and small dendrites Thus, whether there are any boutons and synaptic complexes apposed on the small axons, could not be determined with certainty When unmyelinated axons could be identified, they were never observed to be postsynaptic in a synaptic complex. At three weeks, some of the axons in the neuropile had begun to be myelinated. Rather often, profiles of axons, the length of which was only partly covered by myelin, could then be observed. In such instances, boutons generally did not establish synaptic contact with the naked parts of the axons.

POSTNATAL DEVELOPMENT OF THE INITIAL AXON SEGMENT

Already at birth, or shortly thereafter large areas of the initial axon segment could be surrounded by glial cell bodies and thick glial extensions containing a clear ground substance, in which the granular endoplasmic reticulum and Golgi apparatus were prominent. This is seen in Fig. 4 These cells seemed to be of astrocytic origin (Vaughn and Peters 1967 Vaughn 1969 see also Conradi and Skoglund 1969 a) Glial cells with a dark cytoplasm, similar to oligodendrocytes or microgliacytes in the adult (Vaughn 1969 see also Conradi 1969 c) were not found adjacent to the initial segment until later Even at three weeks, such cells were not regularly observed. From the third postnatal

week boutons were no longer found on the initial axon segment, according to observations on single sections (Fig. 11) It was not possible to obtain any information on the process by which the boutons disappear from the initial segment As pointed out earlier the membrane specialization of the initial segment is absent below the boutons Already in the newborn stage areas of the initial segment can be found which lack the membrane specialization, but which are covered by astrocytic cytoplasm Such areas, which can be seen in Fig. 3 were not observed at three weeks.

As was the case on the motoneuron cell bodies (Conradi and Skoglund 1969 a) some boutons on the initial segment in the neonate period appeared to be surrounded by astrocytic cytoplasm some of which was interposed between part of the bouton and the motoneuron cell membrane However no boutons showing any degenerative changes according to conventional criteria (see Conradi 1969 d) were observed

By three weeks the diameter of the initial axon segment had increased and the diameter of the axon hillock exceeded that of the initial segment (Fig. 11) The course of the initial segment had, however not yet straightened completely The terminal cytoplasmic pockets of the myelin both distal to the initial segment and at the nodes, had grown considerably (Figs 12 and 13) but seemed to cover about the same distance as in the newborn or 3—4 μ Every cytoplasmic pocket reached the axon membrane although the thickness of the myelin sheath had increased considerably as well as the number of cytoplasmic pockets

At three weeks there were still many evaginations of the myelin sheath of the motoraxons and many compact myelin bodies were found just outside the myelin (Fig. 12) as in the newborn and adult stages At the central nodes, the motoraxons still seemed to be covered by only a thin rim of extracellular material and outside this, big astrocytic like extensions were found (Fig. 13) The ultrastructure of the central nodes of the motoneurons during development was not studied in further detail

Dorsal root boutons on the motoneurons

NORMAL MATERIAL

Newborn animals

In a preceding communication (Conradi 1969 d) evidence was presented to show that two specific types of big boutons, both containing spherical synaptic vesicles are of dorsal root origin in the adult. One of the types, de

noted M is characterized by a big size, 4—6 μ and a large synaptic complex, which is irregular in shape and contains a large number of postsynaptic dense bodies. The second type, which was somewhat difficult to distinguish on single sections is of roughly the same appearance as other boutons with spherical synaptic vesicles, but bigger On the convex side of both these types of boutons, small boutons (P-type) containing small irregularly shaped, synaptic vesicles, were always found to be apposed. The P boutons seemed to be presynaptic in a synaptic complex with the bigger boutons.

In the newborn animals no clearcut M boutons could be observed However on the proximal parts of the motoneuron dendrites at this stage, there were profiles of comparatively big boutons, containing spherical synaptic vesicles and having another bouton apposed at the convex side (Figs. 14 and 15) The bigger boutons established one or more synaptic complexes with the motoneuron. The layer of postsynaptic material in these cases was often rather thick, 200—300 A, and irregular in width. In some instances, profiles of small postsynaptic dense bodies could be observed at these boutons (Fig. 15) the same was seen at the boutons, judged to be of the T-type in the newborn (Conradi and Skoglund 1969 a) The boutons apposed at the convex side of these bigger boutons contained synaptic vesicles of a somewhat irregular shape, 250—400 A in diameter (Figs 14 and 15) some of which were apposed at the membrane facing the bigger bouton.

In sections cutting the zone of apposition between the boutons perpendicularly a thin and very small extracellular space could be observed between the membranes at the region of the apposed vesicles. The layers of pre and postsynaptic material were very thin. On the proximal part of the motoneuron dendrite analyzed in the preceding paper there were a few boutons of the types just described Only one apposing bouton was observed in these cases, but it covered a large area of the bouton with spherical synaptic vesicles. The structure similar to a synaptic complex between the boutons seemed to be the only one established by the smaller bouton. A wax reconstruction of one of these cases is shown in Fig. 14 a, together with two of the sections through the bouton.

Postnatal development

From about the third postnatal week, M boutons, quite similar to those in the adult, although somewhat smaller 2—5 μ could be observed on the proximal parts of the motoneuron dendrites (Fig. 16) At that time some big S boutons with axo-axonic contacts also seemed to be present The distribution on the

Table 4 Number of boutons under the heading M and big S in the quantitative studies at different stages.

Age	SO No.	DA No.	DB No.	d No.
Newborn	3	16	5	1
3 weeks	2	19	1	1
Adult	1	16	4	

motoneurons of these two bouton types at the three weeks stage in the adult, seemed quite similar

Whether there are any changes in the number and distribution of these bouton types during the postnatal development is difficult to ascertain In the quantitative estimation on the newborn stage in the preceding paper (Conradi and Skoglund 1969 a) boutons containing spherical synaptic vesicles and showing one large or several smaller profiles of a synaptic complex with postsynaptic dense bodies, were included under the heading, M and big S Under this heading were also included boutons containing spherical synaptic vesicles, with another bouton apposed at the convex side

If the boutons included under the heading M and big S in the newborn are to be regarded as future M and big S boutons with axo-axonic contacts, then the location of these boutons, mainly at proximal parts of the motoneuron dendrites, remains constant throughout development. The number of bouton profiles in this column is rather constant during the development (see Table 4)

It must be pointed out that in the adult, and to some extent also at 3 weeks, the bouton profiles under this heading are considerably bigger than other bouton profiles, thus increasing the chance of these boutons to be included in single sections

OBSERVATIONS AFTER DORSAL ROOT SECTION

In the newborn, as in the adult, the postoperative ultrastructural changes on the operated side were very slight. Since there were almost no myelinated axons in the neuropile during the first postnatal fortnight, neither were there any profiles of degenerated myelinated fibres (cf. Conradi 1969 d) on the operated side This increased the difficulty in distinguishing any signs of neuronal degeneration. As in the adult, just outside the motoneuron cell

membrane, there were rounded, membrane-bound dense bodies inside astrocytic extensions in a few cases and this arrangement was similar to structures earlier described as phagocyted degenerated boutons (Fig. 17) (Colonnier 1964 see Conradi 1969 d) Structures, similar to a postsynaptic membrane specialization were however not observed at the motoneuron cell membrane beneath such profiles; this differed from the situation in the adult. No boutons filled with neurofilaments were observed on the operated side in the newborn

In some newborn animals, boutons with the dense appearance found upon degeneration in various systems in adult animals (see Walberg 1964 Mc Mahan 1967) were found from the 3rd to 5th postoperative day (Figs 18—20) This was not found after dorsal root section in the adult animals.

A rather small number of dense boutons was observed on the operated side and the occurrence of them varied greatly between the sections. A few dense boutons were also observed on the normal side in some of the operated animals this gives grounds for believing that at least some of these boutons on the operated side might be the result of accidental degeneration, due to damage to the cord during the operation. Despite this, the boutons will be described in somewhat further detail since for reasons, given below some of the dense boutons might represent degenerating dorsal root boutons

The interior of the dense boutons was granular and profiles of synaptic vesicles and distended mitochondria could sometimes be observed The boutons were often localized on the proximal parts of the motoneuron dendrites or at medium-sized dendritic profiles in the neuropile, but not on the thinnest dendritic profiles Usually the boutons were surrounded by astrocytic extensions and appeared shrunken, compared to adjacent, normal boutons (Fig. 18) The synaptic complex was often visible and was apparently intact. The layer of postsynaptic dense material was often comparatively thick although no clearcut postsynaptic dense bodies were observed. The thickness and appearance of the postsynaptic dense material were quite similar to that observed at normal boutons with postsynaptic dense bodies, in the newborn (Conradi and Skoglund 1969 a)

In a few instances another bouton, apparently normal, was apposed on the convex side of the dense boutons (Fig. 20) There could be apposition of the synaptic vesicles of the normal bouton facing the region of contact with the dense bouton, thus showing some similarities to a synaptic complex Whether a synaptic cleft existed between the normal and dense bouton was rather difficult to ascertain, since, as pointed out earlier there is often a thin layer of contrast-rich material around dense degenerating boutons, at least in the adult (Holländer *et al.* 1969)

The dense boutons sometimes seemed to be partly invaginated into the postsynaptic profile often at the proximal parts of motoneuron dendrites. Dense membrane-bound profiles quite like the dense boutons were also seen to be completely surrounded by motoneuron cytoplasm judging from observations on single sections (Fig. 19)

There were no clearcut observations of dense boutons on the initial motor axon segment.

After dorsal root section at three weeks, fragments of degenerated myelinated axons were regularly seen. The ultrastructure of these profiles was quite similar to that found in the adult, although the myelin sheath is thinner at three weeks At the stage of development when the M boutons appear about the same pattern of bouton degeneration as observed in the adult (Conradi 1969 d) can be seen, and there are no longer any dense boutons on the operated side

DISCUSSION

As in the preceding paper the largest neurons in the lateral part of the ventral horn were studied. It is likely that these are motoneurons, since the largest neurons in the newborn grow fastest, and the largest neurons in the adult are motoneurons (see Mellström and Skoglund 1969)

During the postnatal development the dimensions of the entire gray substance change (see Mellström and Skoglund 1969) This means that the location of the motoneurons, relative to the zone of emergence of the motoraxons from the gray substance ought also to change If such a change takes place then it might influence the direction of the first part of the motoraxon when it leaves the cell body The observation that the initial motoraxon segment usually is straight in the adult but more often curved in most cases in the newborn, could be a reflexion of these growth changes.

The axon hillock and initial motoraxon segment

The initial motoraxon segment in the newborn exhibits the same membrane specialization as in the adult. From physiologic experiments with the intracellular recording technique on spinal motoneurons in fetal and newborn kittens (Naka 1964) there is evidence that the active impulse of the motoneurons is initiated in the initial axon segment as in the adult animals. The

diameter of the axon hillock in the newborn was of nearly the same size as at the initial axon segment, in the present study In the adult, the axon hillock is much wider at least at the base. The longitudinal resistance of the axon hillock in the newborn would thus be relatively high which could be associated with the difficulty in activating the motoneurons antidromically in the early developmental stages. as noted by Naka (1964)

The boutons on the axon hillock and initial axon segment

The population of boutons of different types on the axon hillock was estimated on only the two models, the same as was done in the adult Therefore, conclusions must be drawn with care At both stages, however the findings were rather similar in the two cases, and since there are no earlier reports on three-dimensional reconstructions of the axon hillock of any types of neurons, at least some remarks might be due Both the total number of boutons and the proportion of different types of boutons on the axon hillock were rather similar between newborn and adult. This might indicate that rather few boutons get apposed at the axon hillock after birth Unfortunately as pointed out in the preceding paper (Conradi and Skoglund 1969 a) the movements of the motoneuron cell membrane during development are not yet known.

Boutons of different types were also consistently found on the initial motoraxon segment in the newborn animals Since there are no boutons at this region in the adult animals—and the same also seemed to be the case at three weeks postnatally—the boutons must somehow leave the initial segment, probably shortly after birth Boutons have also been observed on the initial axon segment of some neurons in the cerebellum during the early developmental stages by Kornguth *et al* (1968) but no information was given in that report on the situation in the adult animals. The findings, as such, that the boutons on the initial segment disappear after birth, lend support to the disappearance of boutons from the motoneuron cell bodies suggested to occur in the preceding paper (Conradi and Skoglund 1969 a) In the absence of direct evidence for the actual mode of disappearance, a further discussion than the one in that paper must pe postponed.

The location of boutons on the initial motoraxon segment ought to have considerable physiologic significance If as suggested, boutons containing flattened synaptic vesicles are inhibitory (Uchizono 1965) and most of the boutons with spherical vesicles are excitatory then the initial axon segment in newborn animals must be subjected to both excitatory and inhibitory influences Assuming that some of the boutons are of dorsal root origin, it

would then be possible to explain the great excitability in the monosynaptic pathway as well as the absence of a subliminal fringe in newborn animals (see Skoglund 1966) However neither any boutons with axo-axonic contacts in the normal material, nor any dense boutons in the operated animals were observed on the initial motoraxon segment in this study Still the possibility exists, that investigations on larger materials than used here might reveal the presence of such boutons and of another yet unidentified bouton type of dorsal root origin. The dorsal root boutons might, namely have another appearance in the newborn stage than in the adult

The motoraxon and the myelin

In the earliest stages, thin and obviously short extensions seemed to project from the motoraxon, both at the initial segment and at the nodes in the lateral part of the gray substance. In later stages and in the adult, no collaterals from the initial segment were observed. From Golgi studies collaterals from the myelinated part of the motoraxons have been reported to leave the latter in the ventral part of the gray substance (see, for example, Scheibel and Scheibel 1966 Szentágothai 1967) It may be that there are transient, short collaterals from the motoraxons during the earlier developmental stages In a Golgi study of the motoraxons of newborn kittens, several collaterals, some apparently short, were noted to leave the motoraxons for the entire course through the gray substance (Prestige 1966)

In a recent study on the postnatal development of the motoraxons in the ventral root of the cat (Berthold and Skoglund 1968) it was concluded that there is a reduction in the number of internodes after birth Bearing in mind that the entire length of the axons is myelinated except at the nodes, this must mean that there is a movement of the myelin along the axon during development. Furthermore there must be a discrepancy between the growth of the myelin and the axon (Berthold and Skoglund 1968) If the latter two mechanisms are also valid for the central part of the motoraxons, there could be an overgrowth of myelin on regions, where collaterals were found during the early developmental stages The bulges of the myelin along with the compact or partly fragmented myelin bodies just outside the myelin could represent morphologic signs of an imbalance between the growth of the motoraxon and the myelin sheath also in the CNS. Contrary to the situation peripherally compact myelin bodies are also found along the motoraxons in the adult (Conradi 1969 c) The myelin bodies observed in this report may be the counterpart of the granules observed light microscopically along the central part of the motoraxon in newborn kittens (Grant 1968)

Normal material

Some evidence was presented, suggesting that axo-axonic contacts were found on some boutons already in the newborn stage The presynaptic boutons showed about the same characteristics as in the adult material but at least in some cases in the newborn animals, the presynaptic bouton was rather big, compared to the postsynaptic bouton. Physiologically there is a strong late inhibition of the monosynaptic reflex in the newborn (see Skoglund 1966) which has been considered to be presynaptic (Eccles *et al* 1963)

Degenerative bouton changes

Due to the small number of them degenerating dorsal root boutons are difficult to identify even in the adult stage (Conradi 1969 d) Two types of boutons disappeared after the operation in the adult. In the newborn kitten, on the other hand, at least the M bouton type could not be clearly identified, thus multiplying the difficulties for investigating the bouton degeneration after dorsal root section. In addition to this difference between newborn and adult, another type of degenerative bouton change seemed to be present, namely the dense type, which occurs commonly in the systems hitherto studied in the adult (see Walberg 1964 Mc Mahan 1966) However a direct conclusion that this type of degeneration is typical of the newborn stage in the system studied is somewhat questionable, since in some cases, similar changes were observed on the unoperated side

Some of the dense boutons found in this study were, in fact, partly invaginated into the postsynaptic extension a process which seemed also to occur in the operated adult animals. Moreover normal boutons apposed at the convex side of dense boutons, could be observed, and this might indicate that at least some of the dense boutons were of dorsal root origin, judging from the observations in the adult animals. Finally the location of the dense boutons might also point to a dorsal root origin agreeing with the findings in the adult.

ACKNOWLEDGEMENTS

We thank Miss Christina Trägårdh and Miss Maj Berghman for skilful technical assistance The work has been supported by grants from Karolinska Institutet (Reservationsanslaget) and from the Swedish Medical Research Council, projects no B69—14X—136—05C and B70—14X—136—06

SUMMARY

The ultrastructure of the axon hillock and initial axon segment of spinal motoneurons in the cat during postnatal development is studied on the normal kittens used in a preceding paper (Conradi and Skoglund 1969 a). At birth, the initial axon segment is covered by boutons of different types, which, however have disappeared by three weeks, but both the internal structure and the membrane specialization of the initial motoraxon segment are similar to those found in the adult. In newborn kittens, the initial segment is often curved and lacks apposition of dark glial cells. The distribution of boutons of different types on the axon hillock and initial segment in the newborn is studied on two wax models made from serial sections. Some observations on the appearance at birth and the postnatal development of the motoraxons in the gray substance are also included.

The postnatal development of the boutons, described earlier to be of dorsal root origin in the adult (Conradi 1969 d) is investigated also on the material of normal kittens. The changes after dorsal root section are studied on an additional 28 kittens, which had been subjected to dorsal root section 1—8 days before fixation. At birth, some boutons with spherical synaptic vesicles and obviously showing axo-axonic contacts are present on the proximal parts of the motoneuron dendrites. Some evidence is presented to suggest that such boutons show the dense type of degenerative change after ipsilateral dorsal root section. From about the third postnatal week, both the normal ultrastructure of the dorsal root boutons and the changes after dorsal root section are similar to those found in the adult.

INTRODUCTION

Knowledge of the process of wound healing and the relevant factors is of great significance to the surgeon. Despite extensive studies in the field of connective tissue regeneration, healing is still an obscure process in many respects. We know general and topical agents that retard wound repair. We also have information about the beneficial effects of various systemic and local applications on healing. In fact, most of these do not speed up the healing but merely restore the rate to normal. Attempts have been made to solve the problem of "supernormal" healing, but no practical way has yet been devised to accelerate normal wound repair.

The present work was prompted by the finding that a hyperoxic atmosphere speeds up the synthesis of collagen *in vitro* (Kao *et al.* 1963) and by the knowledge that wound healing is accelerated in divers living under a high pressure below sea level. The author wished to extend the study to animals living in atmospheres of varying oxygen tension. Preliminary reports on the results of the present study have appeared (Niinikoski *et al.* 1966, Niinikoski *et al.* 1967, Kulonen *et al.* 1967, Kulonen and Niinikoski 1968).

In 1967 J. Englebert Dunphy wrote: "It seems a long way from the operating room to oxygen tension in wound fluid, and even longer to the hydroxylation of proline in an homogenate of chick embryo. But this is the very bridge between surgery and the basic sciences which must be strengthened."

REVIEW OF THE LITERATURE

According t definition, "a wound is a break or solution in continuity of tissue resulting from external force, whether mechanical, physical, chemical or bacterial in origin (Haley and Williamson 1962). Most of the following discussion of wound healing will be in terms of injury by mechanical force and will deal with the healing of skin and connective tissue. Some selected features of current knowledge on wound healing are discussed without any complete review of the available literature. Arey (1936) has published a thorough review of the early literature on wound healing. Edwards and Dunphy (1958a, b). Dunphy (1960). Haley and Williamson (1962). Viljanto (1964). Schilling (1968) and Dunphy and Van Winkle (1969) have reviewed the recent knowledge on wound healing and granulation tissue development.

CLINICAL SEQUENCES OF WOUND HEALING

The clinical division of the healing process into various phases has been based on the rate of gain in wound tensile strength (Fig. 1) or on the rat f contraction of the wound edges (Carrel 1910).

Figure 1 shows that at the beginning there is a quiescent *latent* period of 4—7 days, during which the wound strength does not increase appreciably. The latent period is characterized by the in asion f immature fibroblasts int the wound area. *Proliferation f f broblasts* takes place during the first two weeks. Cellular proliferation is partly accompanied and f llowed by high rates f *synthesis f coll gen* and noncollagenous proteins. During this period the tensile strength rises rapidly. After the third week the rat of collagen synthesis decreases and the tensile strength curve levels ff and there f llows a *period f volution* or maturation that lasts until healing is complete.

DEVELOPMENT OF GRANULATION TISSUE

Cellular aspects

The proliferation f fibroblasts begins from the periphery of the wound and proceeds toward the central regions f the regenerating area. During this proliferation, which is the first stage of fibroblast activity, the young cells vary in size and shape. Th second functional stage is dominated by collagen formation and accompanied by waning growth potential (Schilling *et al.* 1953). In th third, final stage fibroblasts lose their blast potential nd mature into fibrocytes. As maturation progresses, the fibroblasts lengt and orient themselves in parallel patterns between collagen fibers.

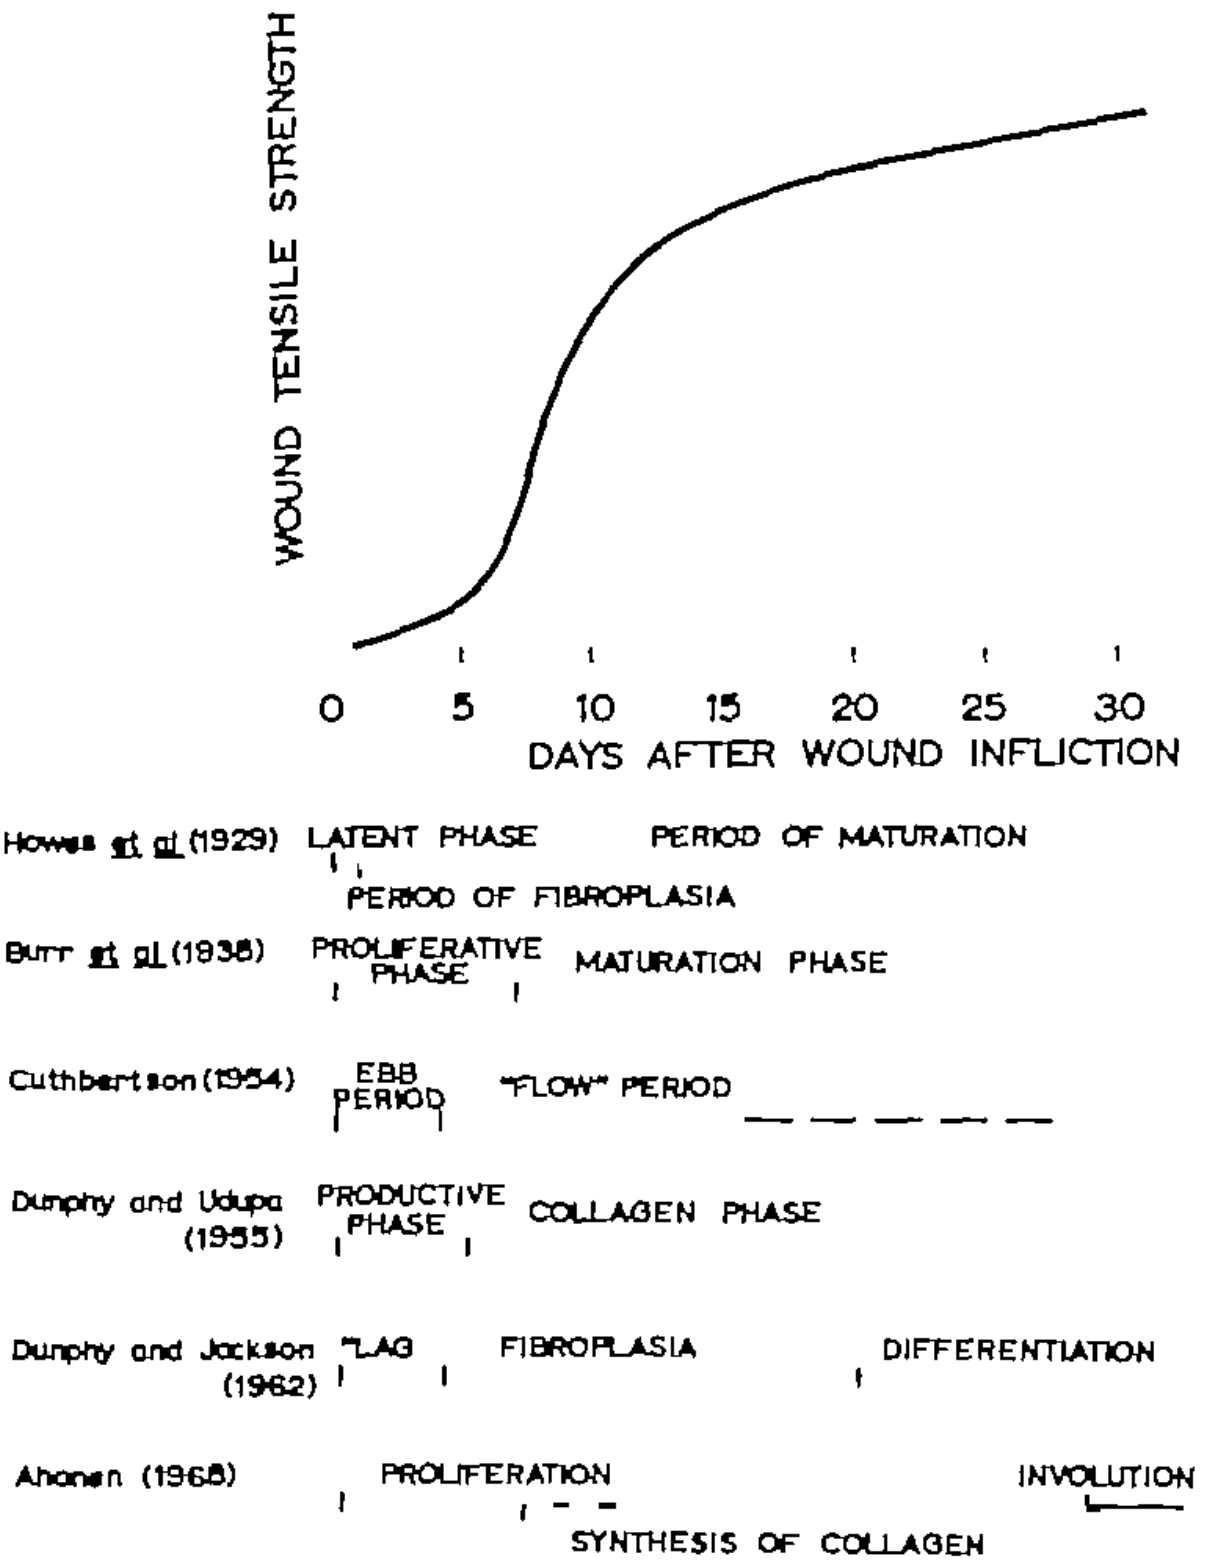

Fig 1 Phases of wound healing as revealed by the increase in tensil strength.

The content of nucleic acids in granulation tissue reflects the number and activity of cells. The contents of DNA and RNA in healing wounds are highest on the 8th day (Hosoda 1960, Williamson and Goschlbauer 1961) In Ivalon and laroue cellulose sponge granulomas, the maximum level of DNA is reached on the 20th day whereafter

the concentration decreases slightly (Woessner and Boucek 1961, Viljanto and Kulonen 196.., Lampiaho and Kulonen 1967) The peak DNA content was attained on the *0th day also in carrageenin granulomas (Boucek and N ble 1961) Chvapil and Cmuchalová (1961) observed the highest level of DNA in carrageenin granulomas already on the 6th— th day probably because of partial resorption of the implants. The peak of fibroplasia was reached in turpentine granulomas on the 5th day as revealed by DNA determinations (*Trnavský et al.* 1961)

The maximum contents of RNA in experimental granulation tissue are attained during the synthesis of collagen (Williamson and Guschlbauer 1961 Viljanto and Kulonen 1962) In granulomas 60—90 days ld the contents of RNA were nearly constant although the synthesis of collagen had almost ceased on the 40th day (Ahonen *et al.* 1964, Lampiaho and Kulonen 1967)

Ahonen (1968) studied the incorporation of ^{14}C-glycine into nucleic acids and proteins during the development of viscose cellulose sponge granulomas. Most of the DNA was synthesized during the first two weeks. Cell proliferation was accompanied and followed by high rates of synthesis of RNA, collagen and noncollagenous proteins.

Connective tissue formation requires the activity of many cell types in addition to fibroblasts. These have been highlighted by Edwards and Dunphy (1958a)

Ground substance

The name ground substance has been given to the amorphous interfibrillar matrix of connective tissue. In healing wound this metachromatically staining material contains acid and neutral mucopolysaccharides, glycoproteins and proteins (Shethar *et al.* 1959, White *et al.* 1961) The metachromasia reaches its maximal intensity on the 5th—6th day and then diminishes (Dunphy and Udupa 1955 Kodicek and Loewi 1955) The accumulation of mucopolysaccharides is connected with the prolifera tion of fibroblasts. Mucopolysaccharides have been suggested to participate in the precipitation and orientation of collagen fibers (Gross *et al.* 1952, Kodicek and Loewi 1955, Loewi and Meyer 1958, Wood 1960)

The content of hexosamine has been used a a measure of mucopolysaccharide content (Dunphy and Udupa 1955, Ahmad 1961) However other evidence has cast doubt on the validity of this. Jackson *et al.* (1960) showed that most of the bound hexosamine in sponge biopsy material is associated with saline-soluble proteins. The ratio of hexosamine to nitrogen in th unextracted sponges indicated that the hexosamine was derived largely from serum glycoproteins rather than from mucopolysaccharides.

Collagen

Structure f collagen. Collagen has a unique amino acid composition with high proportions of glycine, proline and hydroxyproline and low proportions of aromatic amino acids such as tyrosine. The basic structural unit of collagen is called tropo-collagen. Th tropocollagen macromolecule is in the native form an longated, stiff rod 2800 nm long and 14 nm in diameter and its molecular weight is approximately 300,000.

Fibrinogenesis and formation of collagen Tropocollagen molecules are synthesized by fibroblasts and polymerize t fibrils adjacent to these cells. In experimental granula tion tissue the synthesis of collagen begins on the 4th—5th day as judged from the incorporation of proline and synthesis of hydroxyproline by the tissue *i vit o*. The rate f collagen synthesis rises to a peak on the 10th— 1st day and the declines. On the 40th day the incorporation of proline is almost negligible (Lampiaho and Kulonen 1967) In both healing wounds and experimental granulomas the increase of collagen content is paralleled by a gain in tensile strength (*e.g* Dunphy and Udupa 1955, Viljanto and Kulonen 1962)

Hydroxylation of proline in th biosynthesis of collagen. According to current knowledge collagen hydroxyproline and hydroxylysine are formed by a unique process, in which the hydroxylation of proline and lysine takes place after they have been incorporated into a polypeptide precursor *of collagen (Peterkofsky and Udenfriend* 1963, Prockop and Juva 1965, Lukens 1965, Juva and Prockop 1966a, Gottlieb *et al.* 1966, Prockop *et al.* 1966) The proline- and lysine-rich substrate for these hydroxyla tions has been called protocollagen (Juva and Prockop 1966a)

Molecular oxygen is required for hydroxylation (Fujimoto and Tamiya 1962, 1963, Lamport 1963, Prockop *et al.* 1963, Hutton *et al.* 1967) In a nitrogen atmosphere hydroxylation is inhibited (Prockop and Juva 1965) protocollage accumulates inside the fibroblasts (Juva *et al.* 1966) and no collagen is synthesized.

Hutton *et al.* (1967) tested the dependence of the rate f proline hydroxylation *i vitro* on oxygen concentration over the range f 0.5—14.9 volumes per cent. When a partially purified proline hydroxylase was used, a high correlation was found. The Michaelis constant for oxygen was found to be 2.6 volumes per cent.

The hydroxylating activity of a supernatant from an experimental granulation tissue reaches its peak value in 20-day-old granulomas and then declines (Juva 1965) Juva concluded that the hydroxylating activity of granulation tissue reflected the intensity of collagen synthesis and that the hydroxylation reaction might prove to be a regulator of collagen biosynthesis.

PRODUCTION OF EXPERIMENTAL GRANULATION TISSUE

Experimental granulomas induced by various subcutaneous implants offer system for the study of developing granulation tissue. Boucek and Noble (1955) employed nonresorbable polyvinyl sponges implanted under the dorsal skins of rats. The amount of granulation tissue growing into the implant was directly proportional to the size of the sponge. Polyvinyl sponge was employed also by L. C. Edwards *et* L (1957) Schilling *et al.* (1959) R. H. Edwards *et* L (1960) Jackson *et* L (1960) Hruza and Hlavičková (1963) and Sandberg (1964) Viljanto and Kulonen (1962) introduced viscose cellulose sponge as an inductive matrix, and Viljanto (1964) employed it in his comprehensive study on wound repair Experimental granulomas have been induced also by carrageenin (Black 1957 Robertson *et al.* 1959, Chvapil and Cimchalová 1961) stainless steel wire mesh cylinders (Schilling *et al.* 1959) tantalum wire mesh cylinders (Schilling *et al.* 1963) polyurethane (Salvatore *et al* 1961) Dacron-*collagen mixture* (Wesolowski *et* L 1961) silicate powders (W lman and Wolman 1956, Daniel-Mousard and Quesson 1961) agar gel (Kuano and Tetsuka 1964) paraffin (Löhlich

and Arambasic 1961) oil of turpentine (Berenson and Dalferes 1960 Trnavsky *et al.* 1961) alginic acid (Kimoto *et al.* 1960 Mikuochi and Kurume 1960) and cotton pellets (Saikku 1956, Ngy *et al.* 1960)

In experiments where comparisons have been made between different types of experimental granulomas, sponge implants have been found the most useful as they are homogeneous and induce more reproducible granulation tissue formation than, for example carrageenin. In contrast to carrageenin (Viljanto *et al.* 1962) polyurethane (Salvatore *et al.* 1961) and a Dacron-collagen mixture (Wesolowski *et al* 1961) viscose cellulose sponge is not resorbed (Viljanto 1964) The yield of granulation tissue is smaller in wire mesh cylinders than in sponge implants (Schilling *et al.* 1959) Granulation tissue that develops in a viscose cellulose ponge is similar both chemically and histologically to the tissue formed in a healing wound (Viljanto 1964)

"SUPERNORMAL WOUND HEALING

Beneficial effects of various topical or systemic agents on the healing of wounds have been reported, but in many cases continued studies have revealed that the favorable effect has been due to elimination of factors that retard healing

Factors that enhance wound healing are summarized in Table I. It should be noted, however that no factor has attained general clinical significance.

ROLE OF OXYGEN IN WOUND HEALING AND COLLAGEN SYNTHESIS

Wound healing Oxygen tension is much lower in the centers of small muscular wounds than in wound edges nd the surrounding tissue as long as vascularization of the wound is incomplete (Hemensnyder and Majno 1968) Hunt *et al.* (1967) registered respiratory gas tensions and hydrogen ion concentrations in fluid aspirated from developing wire mesh cylinder granulomas. The oxygen tension was 1.. mmHg on the 5th day and rose as healing progressed to 18 mmHg on the 25th day Ten days after metal cylinder implantation, the carbon dioxide tensi n was elevated, probably because of increased production of carbon dioxide by the healing tissue. The low pH values were mostly due to the high carbon dioxide tensions of the wound fluid.

Lundgren and Sandberg (1965) concluded from tensile strength measurements that wound healing was retarded in rats kept intermittently in pure oxygen. However after an cut hemorrhage, oxygen under hyperbaric pressure (OHP) appeared to have stimulating effect on wound healing (Lundgren and Sandberg 1966) Beckham and Hitchcock (1965) obtained quit opposite results. Intermittent exposures to pure oxygen at 2 ATA levated the tensile strengths of wounds in dogs. Repeated skin grafting and OHP together speeded up the closure of open wounds in rats (Shulman and Krohn 1967) A beneficial influence of OHP on ischemi ulcers was observed by Illingworth *et l.* (1961) Boffes *et al.* (1966) Hall *et al.* (1966) and Black *et al.* (1966) on tra matic ischemia by Smith *et al.* (1961) and Black *et al.*

Table I

Factors promoting wound healing

Factor	Effect	References
"Secondary suture"	Increased tensile strength of disrupted and resutured wounds	*e.g.* Calnan *et al.* (1964)
	Enhanced healing from an initially more vascularized tissue	Weiber (1961)
Cartilage powder:		
Locally applied heterologous cartilage powder	Increased tensile strength of wounds	Prudden *et al.* (1957)
	Increased tensile strength of wounds (clinical study)	Prudden and Allen (1963)
Parenterally injected saline extract of cartilage powder	Accelerated closure of open granulating wounds	Sabo *et al.* (1965)
Histamine:		
Intraperitoneally injected histamin and histamine liberator (compound 48/80)	Increased tensile strength of wounds and histologically confirmed acceleration of healing	Boyd and Smith (1939)
Intraperitoneally injected histamine liberators (*compound* 48/80 and polymyxin B)	Increased tensile strength f wounds and enhanced synthesis of collagen	Sandberg (1964)
Elevated temperature	Increased rate of cicatrization	Ebeling (1922)
The first trimester of pregnancy	Increased tensile strength of wounds and enhanced synthesis of collagen	Sandberg and Sandberg (1967)
Locally injected species-specific soluble collagen	Increased tensile strength of wounds and histologically confirmed acceleration of healing	Hernández Richter *et al.* (1965)
Parenterally applied skin extracts	Shortening f the healing period and quicker epithelization of wounds	Teir *et al.* (1951)
Tanning with formaldehyde	Increased tensile strength of wounds	Peacock (1966)
Locally applied hyaluronic acid	Increased tensile strength of experimental granulation tissue	Vilkkinen and Viljanto (1965)
Application of collagen films containing tissue culture cells	Acceleration of skin defect closure	Pappas *et al.* (1961)
Reinforcement of incision by Dacron mesh	Increased tensile strength of wounds	Adler *et al.* (1962)
Orally administered zinc sulphate	Accelerated healing of granulating wounds (clinical study)	Pories *et al.* (1967)
Parenterally injected protamine-zinc insulin	Increased tensile strength of wounds	Rosenthal (1963)
Application of amino-oxidase inhibitors	Stimulated fibroplasia	Scherbel (1961)
Orally administered oxyphenbutazone	Increased tensile strength of wounds	Brunius and Zeder feldt (1965)

(1966) on experimental burns by Marchal *et al.* (1960) and Nelson *et al.* (1966) and on ischemic skin flaps by Perrins (1966) and Niinikoski (1969). Local application of pure oxygen at 1 ATA promoted the healing of burns (Lucedoni *et al.* 1961, 1963) and of torpid ulcers in the lower extremities (Chieregato and Pittoni 1964). Intra-arterial injections of hydrogen peroxide improved the healing of leg ulcers (Balia *et al.* 1964). The closure of excision wounds in dogs was more rapid at sea level than at an altitude of 3000 m (Utkina 1964).

Hyperbaric oxygen affects bacterial growth and may prevent wound infection. Studies conducted with common coliform organisms and staphylococci indicated that *the response of bacteria to OHP both in vivo and in vitro is biphasic as the oxygen* tension increases (Ollodart 1966). Elevating the oxygen tension from normal (pO_2 160 mmHg) to 1 ATA (pO_2 760 mmHg) increases the growth rate of *E. coli*. Pure oxygen at pressures above 2 ATA, however, inhibits bacterial growth.

Collagen synthesis. Kao *et al.* observed in 1963 that *in vitro* synthesis of collagen by sponge biopsy connective tissue was accelerated when the atmospheric oxygen concentration was raised from 21 to 95 volumes per cent. A similar finding was made by Lampinho and Kulonen (1967). Tsurufuji and Ogata (1963) suggested that maturation of collagen and synthesis of tropocollagen depends on aerobic cellular activities. Chvapil *et al.* (1963) found that the synthesis of collagenous and non-collagenous proteins in chick embryo skin slices was stimulated by oxygen at concentrations up to 20 volumes per cent. No effect on protein synthesis was observed at higher tensions. However, as judged from the relative proportion of insoluble collagen hydroxyproline, the maturation of collagen appeared to be a function of pO_2 in the range of 20—95 per cent. Collagen synthesis exceeded its degradation up to an oxygen concentration of 60 per cent but at higher tensions synthesis and degradation of collagen took place at equal rates. The studies of Stern *et al.* (1966) revealed that the rate of collagen synthesis in bone slices increased concurrently with increasing oxygen concentration but that collagen degradation was accelerated even more. Bassett and Herrmann (1961) found that variation of oxygen supply could determine the type of connective tissue that *differentiated in a culture of cells arising from bone; an* oxygen concentration of 35 volumes per cent favored collagen fiber formation. Shaw and Bassett (1967) investigated the effects of various oxygen concentrations on osteogenesis and embryonic cartilage formation *in vitro*. Maximum osteogenesis was achieved at an oxygen concentration of 23 volumes per cent. Osteogenesis and the formation of collagen fibers were retarded by lowering the oxygen concentration to 5 per cent and, to a lesser degree, by elevating it to 95 per cent. High oxygen concentration (95 per cent) caused extensive chondroclasia. Intermediate concentrations of oxygen (40—65 per cent) produced numerous large collagen fibers while some chondrocytes underwent alteration in morphology and came to resemble osteoblasts.

PHYSIOLOGY OF OXYGEN TRANSPORT

After diffusion from the alveoli of the lungs, oxygen is transported to tissues combined with hemoglobin and dissolved in the plasma. At sea level the hemoglobin in arterial blood is about 95 per cent saturated with oxygen, and a hemoglobin value of 15.3 g/100 ml corresponds to 19.5 volumes per cent oxygen in the blood. The oxygen

pressure in arterial blood is normally 90 mmHg The final transport of oxygen to the cell takes place by diffusion and thus depends on the pO_2 in the plasma and the cell. The higher the cellular oxygen consumption, the steeper is the oxygen gradient. The oxygen uptake of the cell is decreased only beyond a critical value of about 1 mmHg (*cf* Tribukait 1963b) The oxygen content in the plasma conforms to Henry's law and depends on the solubility of oxygen in plasma and upon the pO_2 of the gaseous mixture in the alveolar space. Under normal conditions, the dissolved oxygen amounts to 0.26 volumes per cent. In 100 per cent oxygen at sea level, it amounts to 2.2 volumes per cent (Bohr 1903) and in oxygen at 2 ATA to 4.3 volumes per cent. The latter concentration covers sufficiently the oxygen demand f a resting mammal (Haldane 1895) Boerema *et al.* (1960) confirmed this finding by a dramatic demonstration of the possibility of sustaining lif in a bloodless pig perfused with saline solution while the animal breathed oxygen at 3 ATA.

OXYGEN TOXICITY

The pulmonary manifestations of oxygen toxicity involving changes in the lung parenchyma, small arteries, capillaries, alveolar membranes and the pulmonary surface active material are well known (Ohlsson 1947 Bruns and Shields 1954, Pfister *et al.* 1964, Brooksby *et al.* 1966, Cederberg *et al.* 1965, Klatter *et al.* 1966, Spencer *et al.* 1966, Wittner and Rosenbaum 1966 Wood 1969) The changes may be so severe that the pulmonary function fails and the animal dies from paradoxical anoxia and acidosis. Tribukait (1963a) subjected rats to oxygen concentrations f 30—100 per cent for 8—10 weeks. The lungs of the rats were unaffected by oxygen at concentrations up t 80 per cent. According to Hedley Whyte and Winter (1967) however prolonged in halation of 60—70 per cent oxygen can cause lung damage.

The most dramatic and commonly encountered form of oxygen toxicity in short term hyperbaric oxygen therapy at more than 3 ATA is a classic grand mal seizure. This can result in cell destruction in the central nervous system and death.

Increased tolerance to oxygen at 3 ATA (Kaufman *et al.* 1966) and prolonged survival times of animals (Ackerman and Brinkley 1966) were achieved by the use of intermittent hyperbaric oxygenation instead of continuous treatment. Th general safety limit for CHP in human beings is 4 hours' exposure to oxygen t 2.8 ATA (Yarbrough *et al.* 1947) Some investigators, however have stated that probably no absolutely safe threshold can be established for all subjects even in selected group because of the great individual variation in susceptibility (*e.g.* Donald 1947)

Another feature of oxygen toxicity is retrolental fibroplasia in premature infants (*cf* Haugaard 1965)

The mechanism of the toxic actio a high oxygen pressure has been a controversial subject. Complete saturation f hemoglobin in venous blood by oxygen inhibits the transport of carbon dioxide and leads to accumulation of CO_2 in tissues and pH changes. Cellular mechanisms of toxic action of oxygen have been highlighted recently by Haugaard (1968) In 1965 Haugaard summarized the evidence in favor of the view that the toxicity is due to oxidation of sulfhydryl groups in the so-called SH enzymes. On the other hand, Chance *et al.* (1965) observed that oxygen at 11—17 ATA selectively inhibited the energy linked reduction of nicotinamide-adenine dinucleotide

(NAD) by succinate. However Straub (1937) showed that oxygen at 3 ATA had no effect on the energy linked reduction of NAD by succinate in rat liver mitochondria, and so this system does not appear to be the site of the toxic action of oxygen at this pressure.

Low temperature prevents the development of oxygen toxicity whereas an elevated temperature has the opposite effect (Hulpieu and Cole 1944, Smith *et al.* 1960) Increased thyroid activity is an important factor in oxygen toxicity because accelerated metabolism augments the toxic effects of oxygen (Smith *et al.* 1960)

Young individuals are less susceptible to oxygen toxicity especially as manifested by convulsions, than older individuals. This has been ascribed to the immaturity of the adrenals (Bean 1965)

Hulpieu and Cole (1944) observed that the ambient humidity is important in the control of oxygen toxicity At a relative humidity of 30 per cent the toxicity is weaker than at relative humidities below 20 per cent or above 90 per cent.

OBJECTS OF THE PRESENT STUDY

The purpose of the present work was to study the effect of oxygen supply on wound healing and the development of experimental granulation tissue in the rat. The following were the main objects of study:

(I) The influence of various respiratory oxygen tensions on the tensile strengths of healing skin wounds and experimental granulomas.

(II) The relation of various respiratory oxygen tensions to the chemical composition of experimental granulomas.

(III) Mechanism of the action of oxygen in the synthesis of various granulation tissue components.

(NAD) by succinate. However Straub (1967) showed that oxygen at 3 ATA had no effect on the energy linked reduction of NAD by succinate in rat liver mitochondria, and so this system does not appear to be the site of the toxic action of oxygen at this pressure.

Low temperature prevents th development of oxygen toxicity whereas an elevated temperature has the opposite effect (Hulpieu and Cole 1944 Smith *et al.* 1960) Increased thyroid activity is an important factor in oxygen toxicity because accelerated metabolism augments the toxic effects of oxygen (Smith *et al.* 1960)

Young individuals are less susceptible to oxygen toxicity especially as manifested by convulsions, than older individuals. This has been ascribed to the immaturity of the adrenals (Bean 1963)

Hulpieu and Cole (1944) observed that the ambient humidity is important in the control of oxygen toxicity At a relative humidity of 20 per cent the toxicity is weaker than at relative humidities below 70 per cent or above 90 per cent.

VARIATION OF THE SUPPLY OF OXYGEN

Experiments in various oxygen nitrogen mixtures at 1 atm absolute pressure. The experimental setup is shown schematically in Fig 2. After the first postoperative night, Wistar rats were housed two to a box. The boxes were opened once every day for a period of about 5 min for feeding cleaning and ventilating The oxygen nitrogen mixtures (containing 15 21, 50 and 100 volumes per cent of oxygen) were supplied by AGA Oy Turku, Finland. When the gas flows were adjusted to 6 l/h, the final concentrations of oxygen in the boxes were 12 ± 1, 18 ± 1 35 ± 3 and 70 ± 5 % v/v respectively as measured with Scholander s apparatus (Scholander 1947) The final oxygen tension was reached within 8 hours. The carbon dioxide concentration inside the boxes rose to a level of about 3—5 % during the 24-hour period (Fig 3 next page)

Higher oxygen concentrations were obtained by raising the gas flow This decreased the carbon dioxide concentration When small con

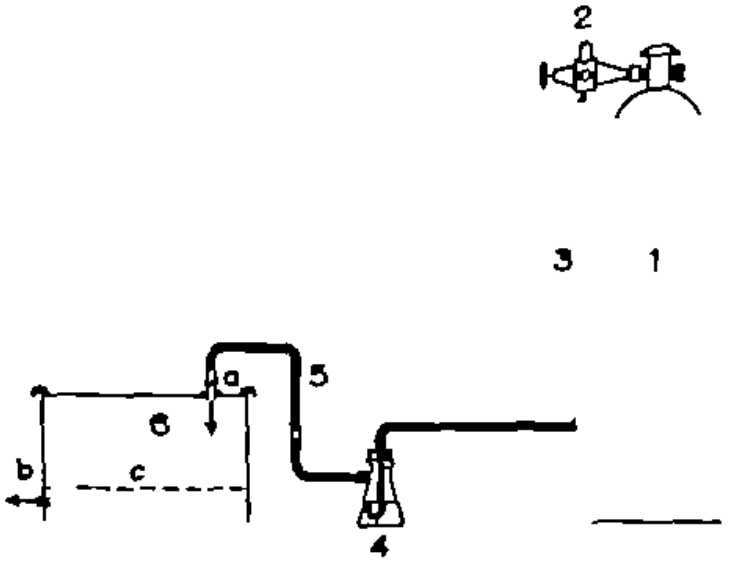

Fig 2 Experimental arrangement. The oxygen-nitrogen mixture flows from a gas cylinder (1) through a reducing valve ( ) and 5 mm tubing (3) to a wash bottle (4) which serves both as crude flow-meter and humidifier and then through further tubing (5) to box (6) where two rats are kept. The air-tight box (volume about 23 l) with transparent cover is made of Perspex and has two small holes of diameters 5 and 3 mm for the entry (a) and exit (b) respectively of the gas. The rats live on a removable mesh floor (c) of stainless steel wire nd the bottom of the box is covered with saw dust which is replaced every third day

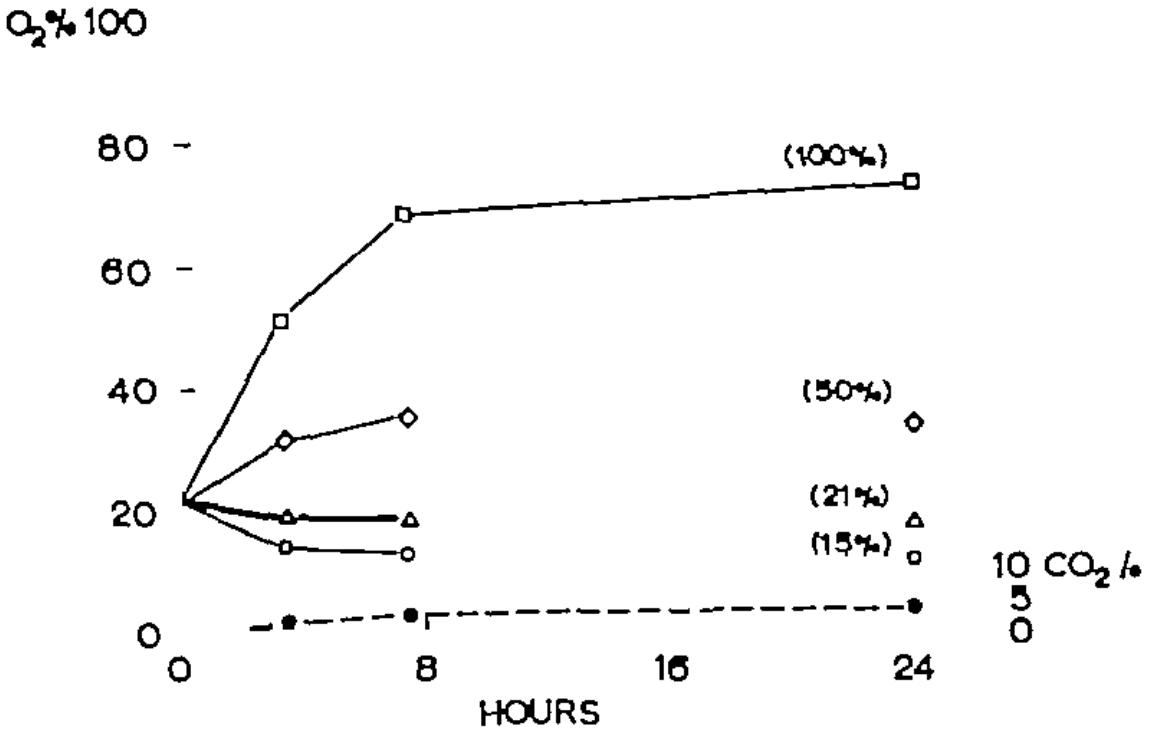

Fig 8 Actual O and CO concentrations inside the boxes during the 24-hour period. The respective O_2 concentrations in the gas cylinders are given in parentheses. Gas flow = 6 l/h.

tainers of soda lime (Sofnol® 5—10 mesh, A G Field & Co Great Britain) were employed as absorbers inside the boxes, the carbon dioxide concentration remained under 1 % Table II reveals the correlations between the flow rates of the oxygen-nitrogen mixtures and the final oxygen and carbon dioxide concentrations inside the boxes. The relative humidity in the boxes was about 90 % and the temperature 2—3 C above room temperature.

Table II

The flow rates of the oxygen-nitrogen mixtures and the O and CO concentrations (volumes per cent) inside the boxes after the 24-hour period

Gas cylinder O_2 %	Gas flow l/h			
	6	8	12	15
15	1[illegible] % O_2/4 % CO_2	14 % O_2/< 1 % CO_2	—	13—14 % O_2/3 % CO_2
21	1[illegible] % O_2/4 % CO_2	19 % O_2/< 1 % CO_2	19 % O_2/[illegible] % CO_2	19—20 % O_2/3 % CO_2
50	3[illegible] % O 4 % CO_2	40 % O_2/< 1 % CO_2	40 % O_2/2 % CO_2	45 % O_2/3 % CO_2
100	1[illegible] % O 4 % CO_2	75 % O_2/< 1 % CO_2	—	90 % O_2/3 % CO_2

CO_2 absorbed by soda lime

The following discussion of the concentrations of oxygen and carbon dioxide will be in terms of volumes per cent reached inside the animal boxes during the 24-hour period if not stated otherwise.

Experiments under hyperbaric oxygen After the first postoperative night, Sprague-Dawley rats were exposed to oxygen at 2 atm absolute pressure for a period of 2 hours twice every day (at an interval of 2 hours) The hyperbaric treatment was extended to the 3rd or 9th day after wounding The rats were killed 4 or 10 days after the implantation. The exposures to compressed oxygen took place in a hyperbaric animal chamber (volume about 33 l) manufactured by Vickers Research Establishments, Sunninghill, Berks., England. Ten rats were housed in the chamber Compression and decompression were carried out at the rate of 3 psi/min i.e in 5 minutes. The flow of oxygen was 1 l/min/rat. The highest carbon dioxide content in the breathing gas during the experiments, as ascertained with a Luftanalysator Type K 1/64 (the Laboratories of Aviation and Naval Medicine, Karolinska Institutet, Stockholm, Sweden) did not exceed 0.1 % The temperature in the chamber increased by 2°C and the relative humidity decreased from about 50 % to 35 % during the 2-hour exposure. The control rats were housed in ordinary cages in the animal room.

Experiments in air at ½ atm absolute pressure These experiments were carried out in an altitude chamber (volume about 10 m) After the first postoperative night, Wistar rats were subjected to ½ atm absolute pressure corresponding to an altitude of 5500 meters for 9 days. Decompression was accomplished in 5 minutes and the reduced pressure was maintained in the range at altitudes of 5300—5700 meters. Recompression also took 5 minutes. For feeding the rats, the pressure was elevated to normal once a day for a period of 20 minutes. Fresh air was pumped into the chamber three times every day Sixteen rats were housed simultaneously in the chamber The relative humidity in the chamber was approximately 50 % and the temperature 1—3 C above room temperature during the experiments. The control rats were housed in ordinary cages in the animal room. All the rats were killed 10 days after the implantation.

TENSILE STRENGTH MEASUREMENTS

Wounds. The rats were anesthesized with ether and killed by a blow on the neck. The tensile strengths of the skin wounds and the granulomas were measured as described by Viljanto (1964) The wound with its environment was cut away and the sutures were removed. One skin strip 1 cm wide was cut at right angles to the wound incision with a razor blade

with the aid of a Perspex sheet containing two parallel slits. The tensile strength was determined by a flowing water method The effect of static stress was avoided by adjusting the height of the water level and the diameter of the rubber tube so that one assay took 20—40 sec. The skin strip was fixed between two clamps with the jaws of the clamps parallel to the wound and suspended at the end of the beam of a triple beam balance. Water was allowed to flow at a uniform rate (250—500 ml/min) into a plastic container on a scale pan When the wound edges were torn apart, the wound strength was calculated from the weight of water that had flowed into the plastic vessel. From the 5th day on the wounds became so strong that 2 thread stitches were made at each end of the skin strip and the wound strength was tested by pouring small lead shot (3 mm in diameter and weighing 50 mg) at an even rate into the plastic container to tear the wound open within a period of 20—40 sec.

Granulomas The granulomas were removed from the subcutaneous space and freed from the connective tissue capsules surrounding them The cotton thread holding the halves of the implant together was cut and removed. The granulomas were fastened to the two serrated clamps of the tensile strength apparatus with the jaws exactly parallel to the section surfaces. The tensile strengths of the granulomas were assayed by the flowing water method in the same way as the tensile strengths of the wounds. After the granulomas had been torn apart, they were cooled in test tubes on crushed ice and stored frozen until analyzed. On the 15th day after implantation, the granulation tissue in the sponges was so strong that the halves could no longer be torn apart and the granulomas broke near the clamps. For this reason reliable tensile strength determinations could be carried out on the granulomas only on the first ten days.

INCUBATION OF GRANULOMA SLICES

For the *in vitro* experiments, the granulomas were removed from the rats under light ether anesthesia, decapsulated and cooled on crushed ice, after which the pieces were cut into thin slices with a Stadie-Riggs microtome in the cold room. If not stated otherwise, the incubations were carried out in air or 40 % oxygen in a thermostated shaker (Compensiat, Gallenkamp & Co. London England) at 37 C The nutrient medium was the Krebs Ringer phosphate solution, pH 7 4 (Cohen 1957) supplemented with glucose (5 4 mM) No antibiotics were added to the medium In the incorporation experiments, 20 ml of the medium and the slices

from 4 granulomas (wet weight about 4 g) were added to a 100-ml flask. After a preincubation period of 30 min a radioactive compound was added to the medium and the incubation was continued with vigorous shaking of the mixture. The atmospheres inside the flasks were renewed every second hour.

Studies on energy metabolism. The experiments on glucose utilization and lactic acid production of the slices of granulation tissue were carried out entirely in air. Slices from half a granuloma (wet weight about 0.5 g) and 3 ml of the medium were added to a 25-ml flask and incubated for 3 hours. No preincubation was used. Immediately after the incubation, the slices were separated from the medium by centrifuging in a refrigerated centrifuge (MSE High Speed 17. Measuring and Scientific Equipment Ltd., London, England) at 10 000 *g* and 0°C for 10 min.

Incorporation of ^{3}H proline. ^{3}H L-Proline (TRA. 82, 100—1000 mCi/mM, The Radiochemical Centre, Amersham Bucks., England) was added in a dose of 80 μCi in 0.22 ml of 0.9 % sodium chloride solution to the incubation mixture. The incorporation was stopped by centrifuging the incubation mixture at 30 000 *g* and 0°C for 10 min and discarding the supernatants.

Incorporation of ^{3}H-cytidine. ^{3}H-Cytidine (TRK. 198. >15 000 mCi/mM, The Radiochemical Centre) was added in an amount of 30 μCi in 0.30 ml of 0.9 % sodium chloride solution to the incubation mixture. The incorporation was stopped by addition of ice-cold perchloric acid to give a final concentration of 0.5 N.

INCORPORATION OF ^{3}H THYMIDINE AND ^{32}P PHOSPHATE IN VIVO

Incorporation of ^{3}H-thymidine. A dose of 100 μCi of ^{3}H-thymidine (TRK. 61. >10 000 mCi/mM, The Radiochemical Centre) in 1.0 ml of 0.9 % sodium chloride solution was injected intraperitoneally into anesthetized sponge-bearing rats on the 8th and 9th postimplantation day and the implants were removed 48 and 24 hours later respectively. The rats were kept in an atmosphere containing 19 or 40 % O_2. On the 10th day the sponge implants were decapsulated and cooled on crushed ice.

Incorporation of ^{32}P phosphate. A dose of 1.0 mCi of ^{32}P phosphate (Sodium Phosphate-^{32}P Injection, PBS. 2P. phosphorus content 1 mg/ml. The Radiochemical Centre) in 1.0 ml of 0.9 % sodium chloride solution was injected intraperitoneally into anesthetized sponge-bearing rats exposed

to 19 or 40 % oxygen On the 10th postimplantation day after incorpora tion periods of 1—19 hours, the implants were removed decapsulated and cooled on crushed ice

ANALYSIS OF GRANULOMAS

Extraction and fractionation of collagen from granulomas

The extraction and fractionation procedures were carried out as described by Viljanto (1964) except that the acid-soluble collagen was extracted with 0.5 M acetic acid solution instead of a 0 1 M citrate buffer pH 3.5 The collagen of the granulation tissue was divided into three fractions according to solubility neutral salt-soluble acid-soluble and insoluble collagen The detailed extraction procedure is presented in Fig 4

Fig 4 Extraction a d fractionati f collagen from granulomas.

The specimen consisting of 4 granulomas (all the implants from one rat) was homogenized in 20 ml of water in revolving blade homogeniser (Omni Mixer®, Type OM, Ivan Sorvall Inc., Norwalk, Conn., U.S.A.) at 20 000 rpm and 0 C for 1 min. The homogeniser cup was rinsed with 5 ml of water The mixture was centrif ged in a refrigerated centrifuge (MSE Super Speed 50S, Measuring and Scientific Equipment Ltd., London, England) t 35 000 *g* and 4 C for 30 min.

Sediment extracted with 10 ml of 1 M sodium hloride solutio by shaking t 4 C for 2 hrs, centrifuged at 35 000 *g* and 4 C fo 30 min extra tion, shaking and centrifugation repeated.

Supernatant:
Hemoglobin
Hexosamine
Hyd oxyproline
Nitrogen

Combined supernatants
Hydroxyprol and n itrogen f vaporized extral salt-sol ble collagen

Sediment extracted by shaking igorously with 10 ml of 0.5 M acetic acid solution at 4 C for 2 hrs mixture centrifuged at 35 000 *g* and 4 C for 30 min extraction, shaking and centrif gation repeated.

Combined supernata t
Hydroxyprol ne and itrogen f vaporized acid-sol ble ollage

Hydrolysis of sediment in 6 N hydrochloric acid at 130 C f 3 hrs.

Hydrolysate:
Hydroxyproline and nitrogen f vaporized insoluble collagen

Processing of incubated granuloma slices after the incorporation of H proline

The method employed has been described by Juva (1968) A detailed scheme of the process is presented in Fig 5 Because proline and hydroxy proline occur in collagen in nearly equal amounts, the radioactivity of non collagenous protein was calculated from the total activity assuming that the radioactivity of collagen was twice that of the hydroxyproline.

Fig 5 Management of incubated granuloma slices after the incorporation of H proline

Four sliced granulomas were washed twice with 20 ml of ice-cold distilled water a d the mixture centrifuged at 30 000 *g* nd 0 C for 10 min.

↓

The sediment was homogenized in the Omni Mixer® homogenizer at 20 000 rpm and 0°C for 1 min in 20 ml f ice-cold distilled water Half a milliliter of toluene and 10 mg of carrier proline were added t the homogenate, which was then dialyzed gainst running tap water for 48 hrs.

↓

The dialysate was hydrolyzed in 6 N hydrochloric acid at 120°C for 12—16 hrs.

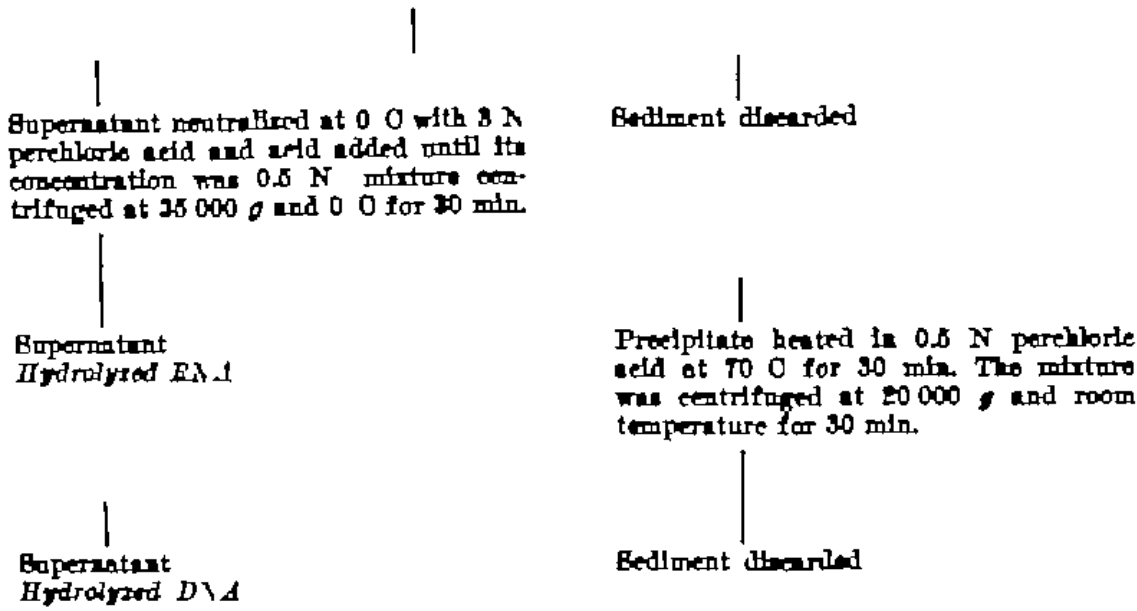
↓

The hydrolysate was evaporated to dryness on a boiling water bath and the residue was dissolved in 4 ml f distilled water

↓

0.2 ml was taken for the determination f total radioactivity

3.8 ml was used for the assay f labeled hydroxyproline.



Extraction of nucleic acids from granulomas

The method was a modification of the original Schmidt-Thannhauser procedure (Schmidt and Thannhauser 1945) The detailed extraction scheme is presented in Fig 6 (next page)

Extraction of nucleic acids from incubated granuloma slices

Four sliced granulomas were washed twice with 20 ml of ice-cold 0.5 N perchloric acid and centrifuged in the MSE High Speed 17 cen trifuge at 35 000 *g* and 0 C for 20 min The granulation tissue was homogenized in 20 ml of 0.5 N perchloric acid in the Omni Mixer® homogenizer

Fig 6 Extraction of nucleic acids from granulomas

at 20 000 rpm and 0 C for 1 min. The homogenate was centrifuged at 35 000 *g* and 0°C for 30 min. The sediment was washed twice with ice-cold 0.5 N perchloric acid and centrifuged at 35 000 *g* and 0°C for 30 min. The sediment was hydrolyzed in 10 ml of 0.3 N potassium hydroxide solution at 37 C for 20 hours. After the hydrolysis, the procedure was continued as described in Fig 6

Extraction of extranuclear lipids from granulomas

Two granulomas removed from the same side of a rat were homogenized in 24 ml of chloroform methanol (1 1) in the Omni Mixer® homogenizer at 20 000 rpm and 0 C for 2 min. To remove the nuclei, the homogenate was centrifuged in the MSE High Speed 17 centrifuge at 600 *g* and 4 C for 15 min The sediment was extracted further with 2 × 4 ml of chloroform-methanol (1 1) and centrifuged at 20 000 rpm and 0 C for 2 min. The supernatants were combined and a volume of 8 ml was taken for the isolation and purification of total lipids by the procedure described by Folch *et al* (1957) Other aliquots were taken for the measurement of total and specific radioactivity of lipid-bound phosphorus.

ANALYTICAL METHODS

Hemoglobin was extracted from granulomas as described in Fig 4 The opalescence of the aqueous supernatant was removed by centrifugation at 100 000 *g* and 4 C for 30 min in the MSE Super Speed 50S centrifuge. The hemoglobin was determined as cyanmethemoglobin as recommended by the European Society of Haematology (1965) The coefficient of variation of the method was ± 3.8 %

Water-soluble hexosamine was estimated by Blix's (1948) modification of the original Elson Morgan procedure (Elson and Morgan 1933) The sample was first hydrolyzed in 2 N hydrochloric acid in sealed tubes at 100°C for 17 hours. Hexosamines were separated from interfering substances on a Dowex-50 column by the method of Boas (1953) The coefficient of variation of the method was ± 3 4 %

Hydroxyproline was determined as described by Pikkarainen (1968) The procedure was based on the method of Stegemann (1958) as modified by Woessner (1961) Extraction with benzene was not used. The coefficient of variation of the method was ± 2.5 %

Radioactive hydroxyproline was assayed according to Juva and Prockop (1966b) The coefficient of variation of the method was ± 2.6 %

The amino-acid composition of the granuloma collagen was kindly determined by Dr J Pikkarainen from the gelatin extracts (Pikkarainen 1968)

Nitrogen was estimated as described by Pikkarainen (1968) The method originated from the methods of Stegemann (personal communication to Dr Nänti) and Minari and Zilversmit (1963) The coefficient of variation of the method was ± 2.0 %

DNA was determined by the diphenylamine reaction (Burton 1956) The standard was prepared from DNA ("ex herring sperm L. Light & Co. Ltd., Poyle, England) The coefficient of variation of the assay was ± 1.1 %

RNA was assayed as ribose by the method of Ceriotti (1955) The coefficient of variation of the assay was ± 1.8 %

Lactic acid in the incubation medium was determined as described by Barker and Summerson (1941) The coefficient of variation of the assay was ± 2.8 %

Glucose in the incubation medium was assayed enzymatically with glucose oxidase (Glox® AB Kabi Stockholm, Sweden) The coefficient of variation of the assay was ± 1 5 %

Lactate dehydrogenase (LDH) After decapsulation four 10-day-old granulomas were homogenized in 20 ml of distilled water in the Omni Mixer® homogenizer at 20 000 rpm and 0°C for 1 min. The homogenate was centrifuged at 35 000 *g* and 0°C for 30 min in the MSE High Speed 17 centrifuge. The electrophoresis of the LDH isoenzymes in the supernatant was performed on cellulose acetate according to Barnett (1964) The supernatant was diluted 1 50 with distilled water and the total activity of LDH in the supernatant was measured by the UV method (C P Boehringer & Soehne G.m.b H Mannheim, Germany Biochemical Test Combination, TC-G) using a Beckman DU spectrophotometer

Lipid-bound phosphorus was assayed by the method of Bartlett (1959) with the exception that the digestion reagent employed was that proposed by Svanborg and Svennerholm (1961) The coefficient of variation of the assay was ± 0.8 %

Measurement of radioactivity Radioactivities were assayed usually with a Packard Tri-Carb® liquid scintillation spectrometer Model 3214 (Packard Instrument Company Inc., Downers Grove, Ill., U.S.A.) The solvent system (Prockop and Ebert 1963) consisted of 6 ml of ethylene glycol monomethyl ether (methyl cxitol, Shell) and 10 ml of scintillation liquid containing 15 g of 2.5-diphenyloxazole and 50 mg of 4-methyl 5-phenyloxazolylbenzene (Packard) in 1000 ml of distilled toluene. In the measurement of radioactive hydroxyproline, the solvent system did not contain methyl cxitol. The aliquot for the assay of radioactivity was chosen so that the measured counts were at least ten times the background. H-counting efficiencies were individually estimated with tritiated water (specific activity $^{9}72 \times 10^{6}$ dpm/ml, Packard) as an internal standard. ^{32}P radioactivities were assayed with a Packard Tri-Carb® liquid scintillation spectrometer Model 3320 ^{32}P-counts were corrected for decay by *measuring the radioactivity of a standard solution at the same time as* the radioactivities of the sample solutions.

STATISTICAL CALCULATIONS

The statistical calculations were carried out on an IBM 1130 computer in the Department of Applied Mathematics, University of Turku, by Mr Matti Grönroos, B.Sc. The statistical significance of the results was determined by the analysis of variance or by the *t* test.

RESULTS

I. EFFECT OF OXYGEN SUPPLY ON THE TENSILE STRENGTHS OF A HEALING SKIN WOUND AND EXPERIMENTAL GRANULATION TISSUE

Effect of various oxygen nitrogen mixtures at 1 ATA

Treatment started one day after implantation

Figure 7 reveals the effect of various respiratory oxygen concentrations on the tensile strengths of healing wounds and granulomas during the first 15 postimplantation days. Reliable tensile strength values of the granulation tissue were obtained only up to the 10th day. The favorable effect of a high oxygen concentration was clear from the 5th day on, especially in the range of 18—35 % O_2. The tensile strength rose to a maximum in 70 % O. The healing rate was lower in 12 % O than in 18 % O_2. The increase of the tensile strength was greatest for wounds on the 5th—7th day and for granulomas on the 7th—10th day. On the 10th day the tensile strengths of the wounds in rats exposed to 70 % O were 35 % and the tensile strengths of granulomas 108 % greater than in the rats exposed to 18 % O. In the analysis of variance on the 7- 10- and 15-day values, statistically significant differences were observed between the tensile strengths of both wounds and granulomas in rats exposed to different oxygen concentration, $p < 0.001$. Removal of carbon dioxide did not influence the tensile strengths of the wounds essentially.

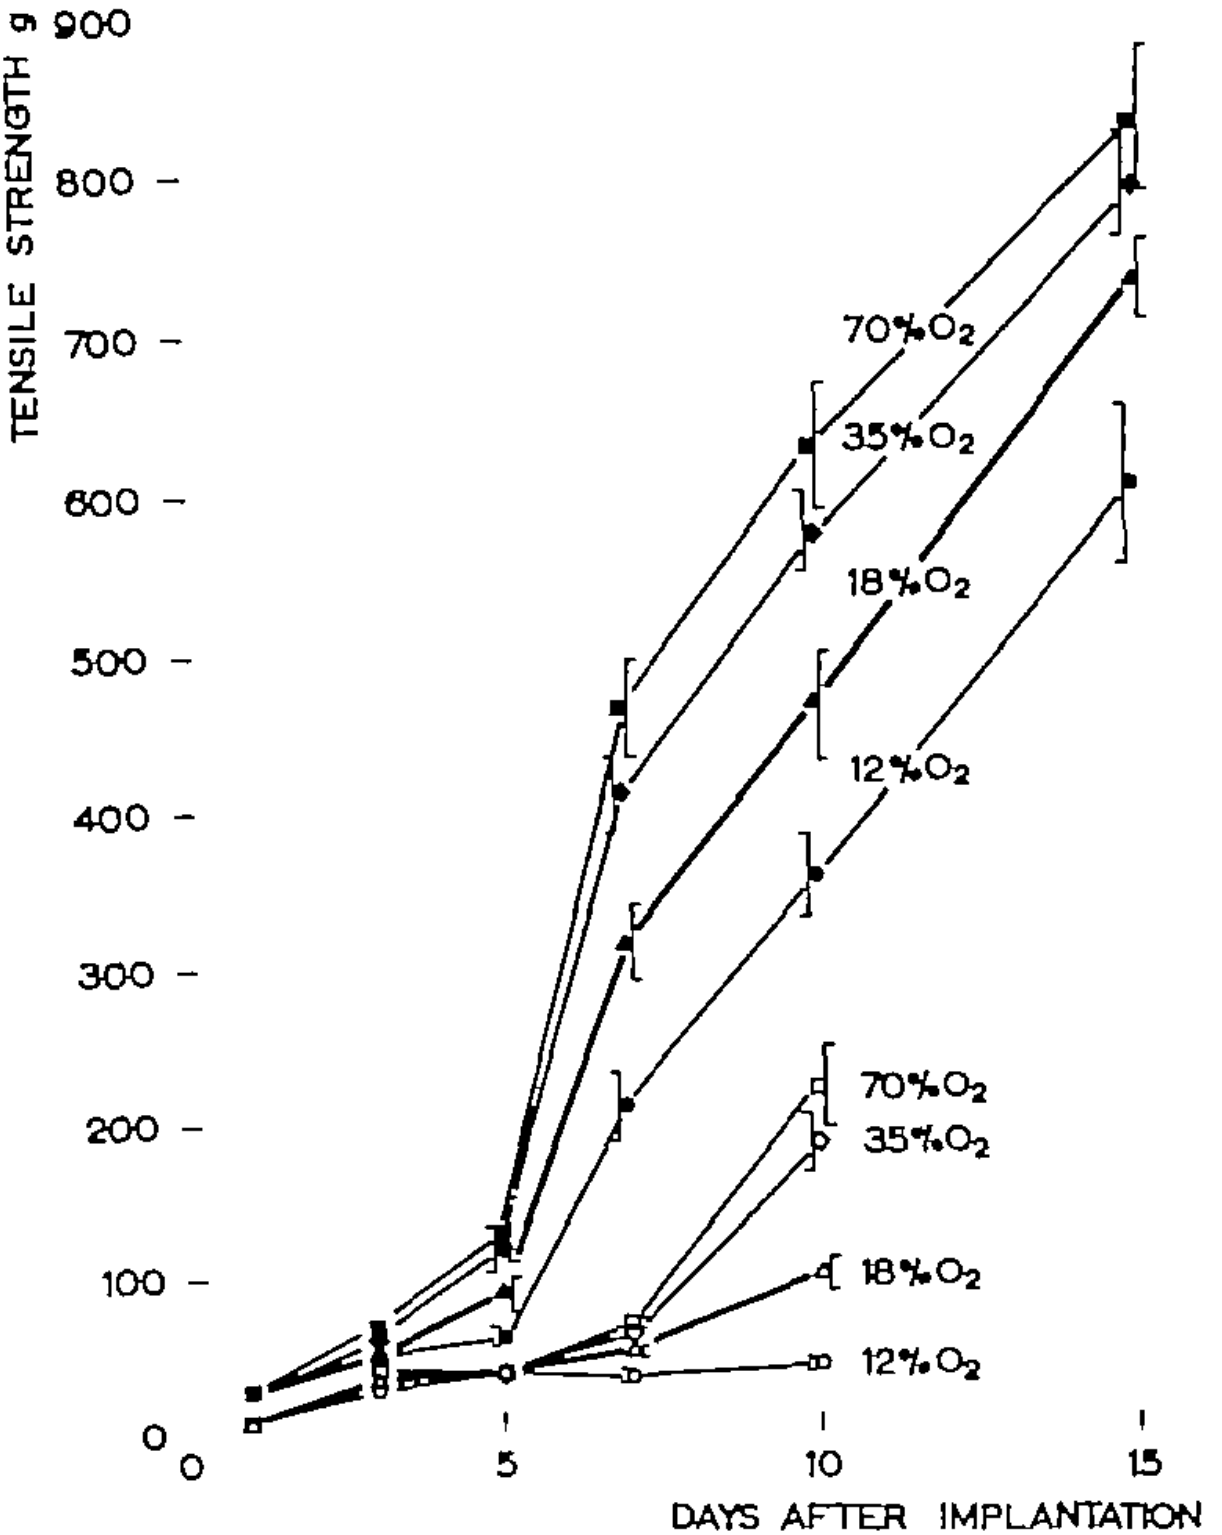


Fig. 7. The tensile strengths of skin wounds and experimental granulomas in rats exposed to different oxygen concentrations during the first 15 postoperative days. The tensile strengths of the skin wounds (dark symbols) are given in g/cm of healing wound width and the tensile strengths of the granulomas (open symbols) in g/cm² of cross-sectional area. All values are means for 8—29 rats or 83—116 granulomas. The length of each vertical bar represents twice the standard error of the mean.

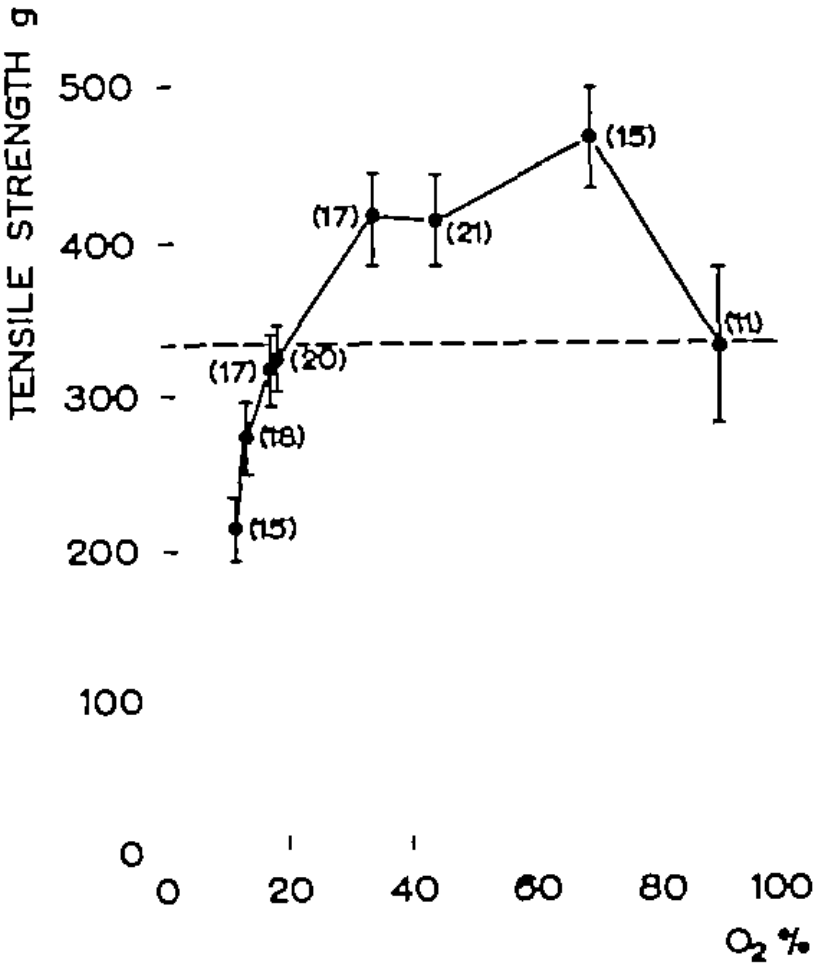

Fig 8 The tensile strengths of 7-day-old skin wounds in rats exposed to different oxygen concentrations. All values are means for 11—31 rats as indicated in the parentheses. The length of each vertical bar represents twice the standard error of the mean.

From Fig. 8 it is evident that the concentration of oxygen in inspired gas for optimal wound healing is 35—70 %. When the oxygen concentration was 90 % the tensile strengths of the 7-day-old wounds were on the same level as in air. In the *t*-test,, the difference between the tensile strengths of the wounds in rats exposed to 70 and 90 % O_2 was statistically significant, $p < 0.05$

Treatment started five days after implantation

To evaluate the significance of the oxygen supply during the latent phase of healing, rats (7—8 in each group) were kept in normal air instead of various oxygen concentrations for the first 5 days after operation

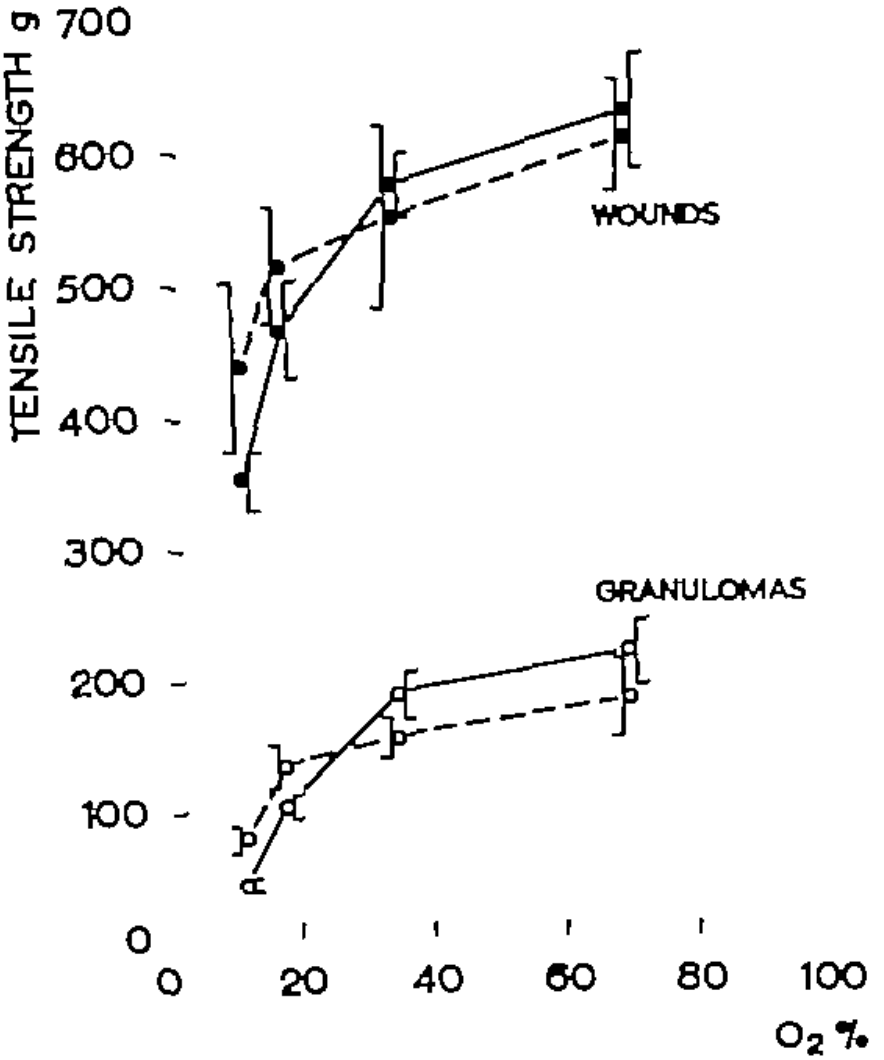

Fig 8 The tensile strengths of 10-day-old skin wounds and experimental granulomas in rats exposed to various oxygen concentrations either from the 2nd (continuous lines) or from the 6th (dashed lines) postoperative day onwards. The length of each vertical bar represents twice the standard error of the mean.

and, then in different oxygen tensions for the following 5 days. Ten days after implantation the rats were killed and the tensile strengths of the wounds and granulomas were measured.

When the inhalation of various oxygen concentrations was started first during the proliferative phase, the relative changes in the tensile strengths of wounds and granulomas of rats exposed to different oxygen tensions were much smaller than in the preceding experiments (Fig 9). Exposure to 12 % O_2 from the 6th day onwards led to lower tensile strengths than exposure to 18 % O_2 (in the t test, $p < 0.05$ for wounds and $p < 0.01$ for granulomas). No statistically significant differences were observed between mean tensile strengths for rats exposed to normal or higher oxygen tensions.

Effect of hyperbaric oxygenation

As seen in Fig 10 the optimal oxygen tension in the breathing atmosphere is passed when the oxygen treatment is extended to hyperbaric conditions. The tensile strengths of wounds and granulomas were clearly lower in rats exposed intermittently to oxygen at 2 ATA than in control rats after both 4 and 10 days. The results were statistically significant (in the analysis of variance, $p < 0.001$ for both wounds and granulomas)

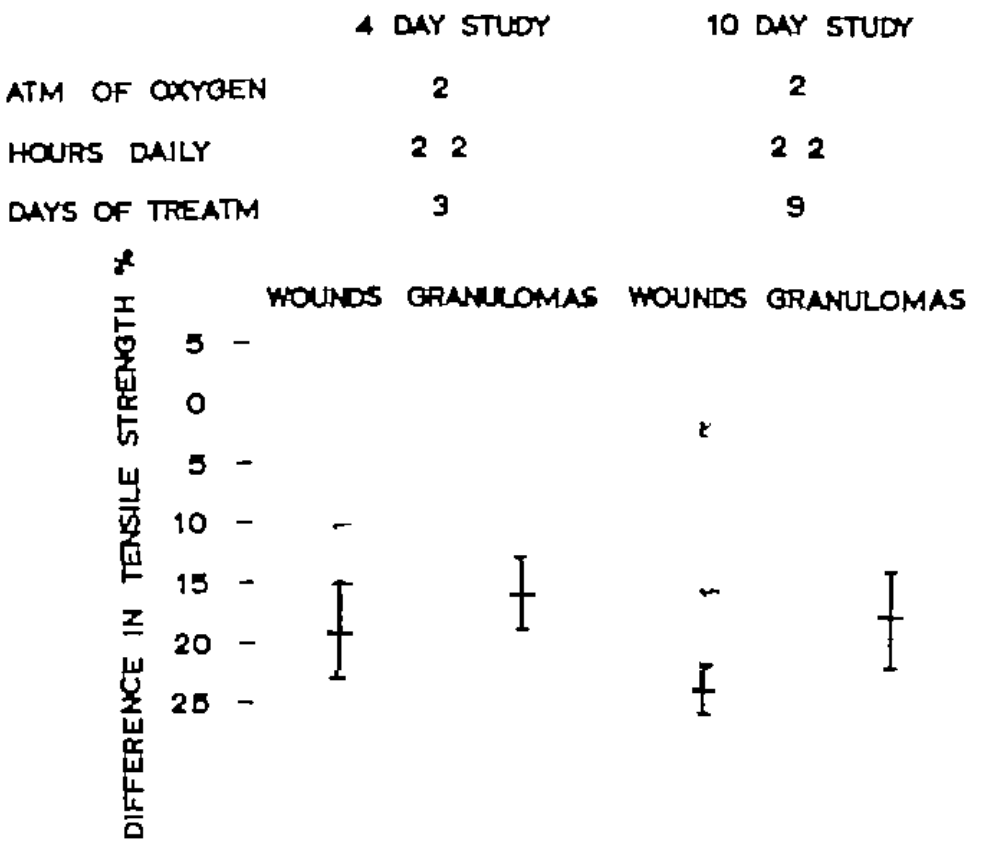

Fig 10 Effect of hyperbaric oxygenation on th tensile strengths of skin wounds and experimental granulomas. The heights of the columns are relative differences (in per cent) between the mean tensile strengths of the experimental and control wounds or granulomas. A decreased tensile strength is indicated by a negative percentage. The length of each thin bar represents twice the relative standard error of the mean (in per cent) for the experimental group. Each group consisted of 16—20 rats.

Effect of reduced barometric pressure

Studies conducted in air at $\frac{1}{3}$ ATA revealed that wound healing was distinctly retarded in unacclimatized animals at a pO of 80 mmHg (Fig

11) Ten days after implantation the mean tensile strength of the skin wounds was 30 % and that of the granulomas 35 % lower than the respective control values (in the t test, $p < 0.01$ for the wounds and $p < 0.05$ for the granulomas)

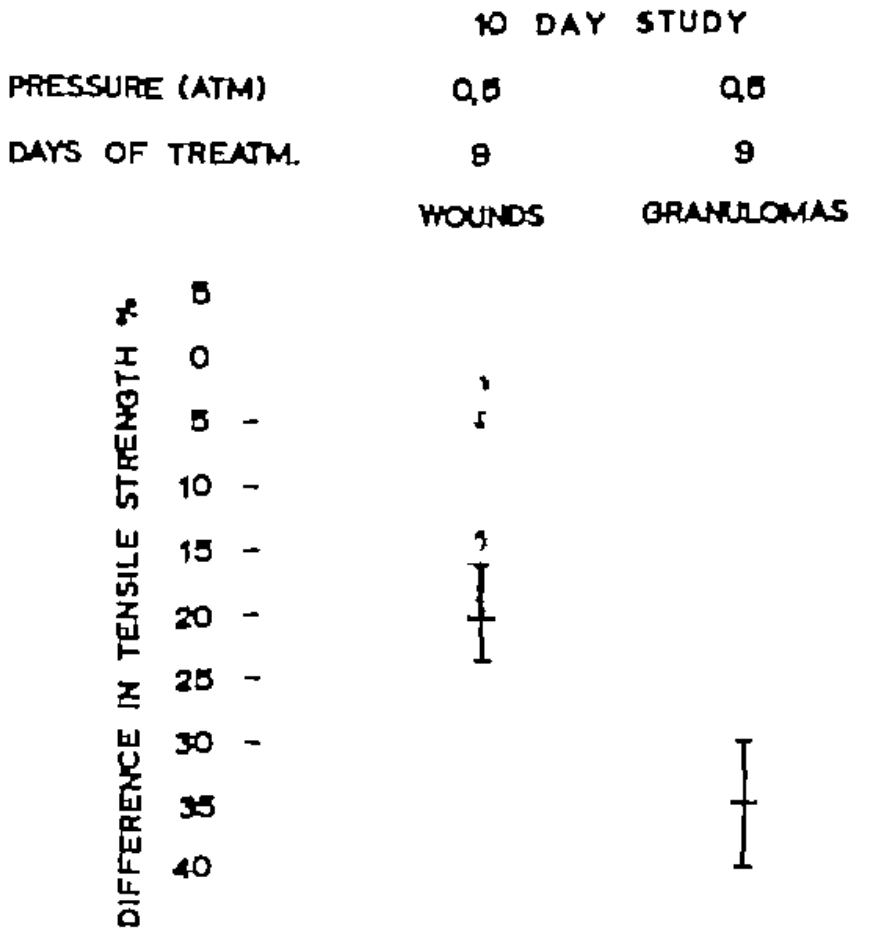

Fig 11. Effect of reduced barometric pressure (½ ATA) on the tensile strengths of skin wounds and experimental granulomas. The heights of the columns are relative differences (in per cent) between the mean tensile strengths of the experimental and control wounds or granulomas. A decreased tensile strength is indicated by negative percentage. The length of each thin bar represents twice the relative standard error of the mean (in per cent) for the experimental group. Both groups consisted of 15 rats.

The reduced pO_2 distinctly accelerated erythropoiesis in the rats. During the 10-day study the mean blood hemoglobin rose from 12.0 g/100 ml to 16.8 g/100 ml ($p < 0.001$) and hematocrit from 45 % to about 65 %.

As a general conclusion, air at a reduced pressure of ½ ATA has an effect similar to that of a hypoxic oxygen nitrogen mixture of 1 ATA (Figs. 7 and 8) and delays healing.

II. EFFECT OF OXYGEN SUPPLY ON THE CHEMICAL COMPOSITION OF EXPERIMENTAL GRANULATION TISSUE

Effect of various oxygen nitrogen mixtures at 1 ATA

Treatment started one day after implantation

Hemoglobin Hemoglobin analyses were carried out to get information on the extent of vascularity in the granulation tissue (Fig 12) A clear increase in the amounts of granuloma hemoglobin occurred in all oxygen tensions from the 1st to the 7th day The highest content was reached in 18 % O on the 7th day Already on the 10th day the hemoglobin contents were clearly lower No marked differences were observed in the amounts of hemoglobin in the 15-day granulomas Throughout the series, the lowest hemoglobin contents were found in granulomas from rats exposed to 12 % O_2.

The contents of hemoglobin determined in the present work are lower

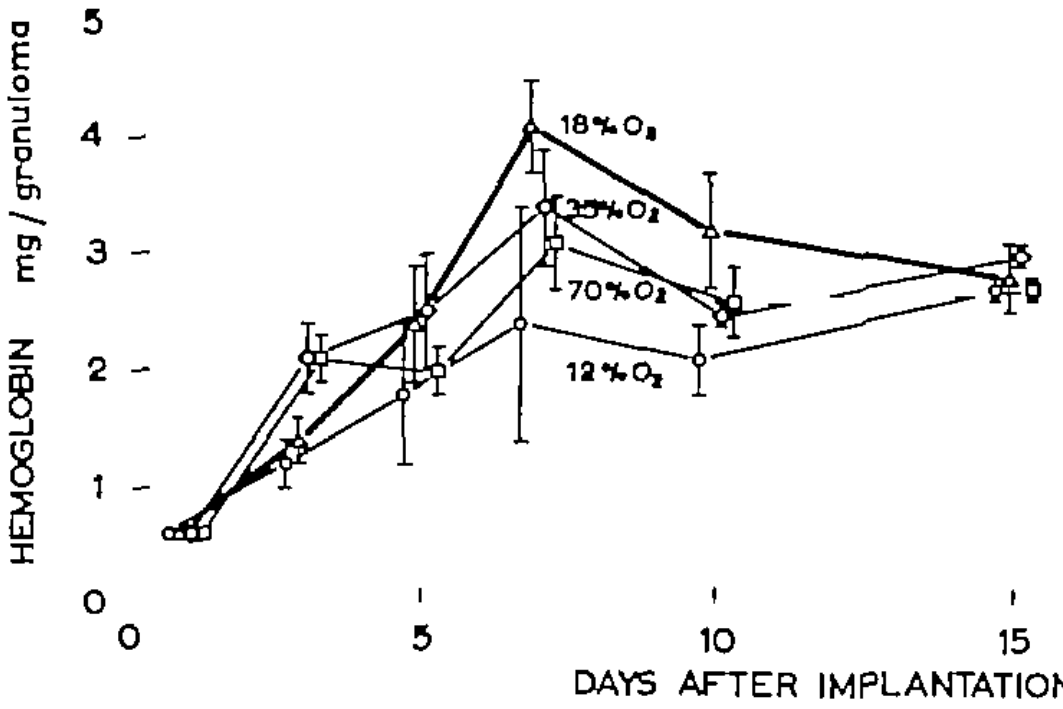

Fig 12. Effect of various respiratory oxygen concentrations on the content of granuloma hemoglobin. All values are means for 4—7 samples (16—23 granulomas) The length of each vertical bar represents twice the standard error of the mean.

than the values reported by Viljanto (1964) This can be due to a different porosity of the viscose cellulose sponge or to loss of granuloma exudate during the decapsulation of the implants.

In addition to vascularity the content of hemoglobin in blood affects the hemoglobin content of the granulomas. On the 15th day blood hemoglobin was 2.8 g/100 ml higher in rats exposed to 12 % O than in rats exposed to 18 % O_2, but no marked changes in blood hemoglobin took place in rats exposed to the other oxygen tensions.

Water soluble hexosamine The formation of mucopolysaccharides in granulomas is partly reflected in the content of hexosamine. As shown in Fig 13, the accumulation of water-soluble hexosamine in the granulomas took place in two phases. In the first phase the hexosamine content rose to

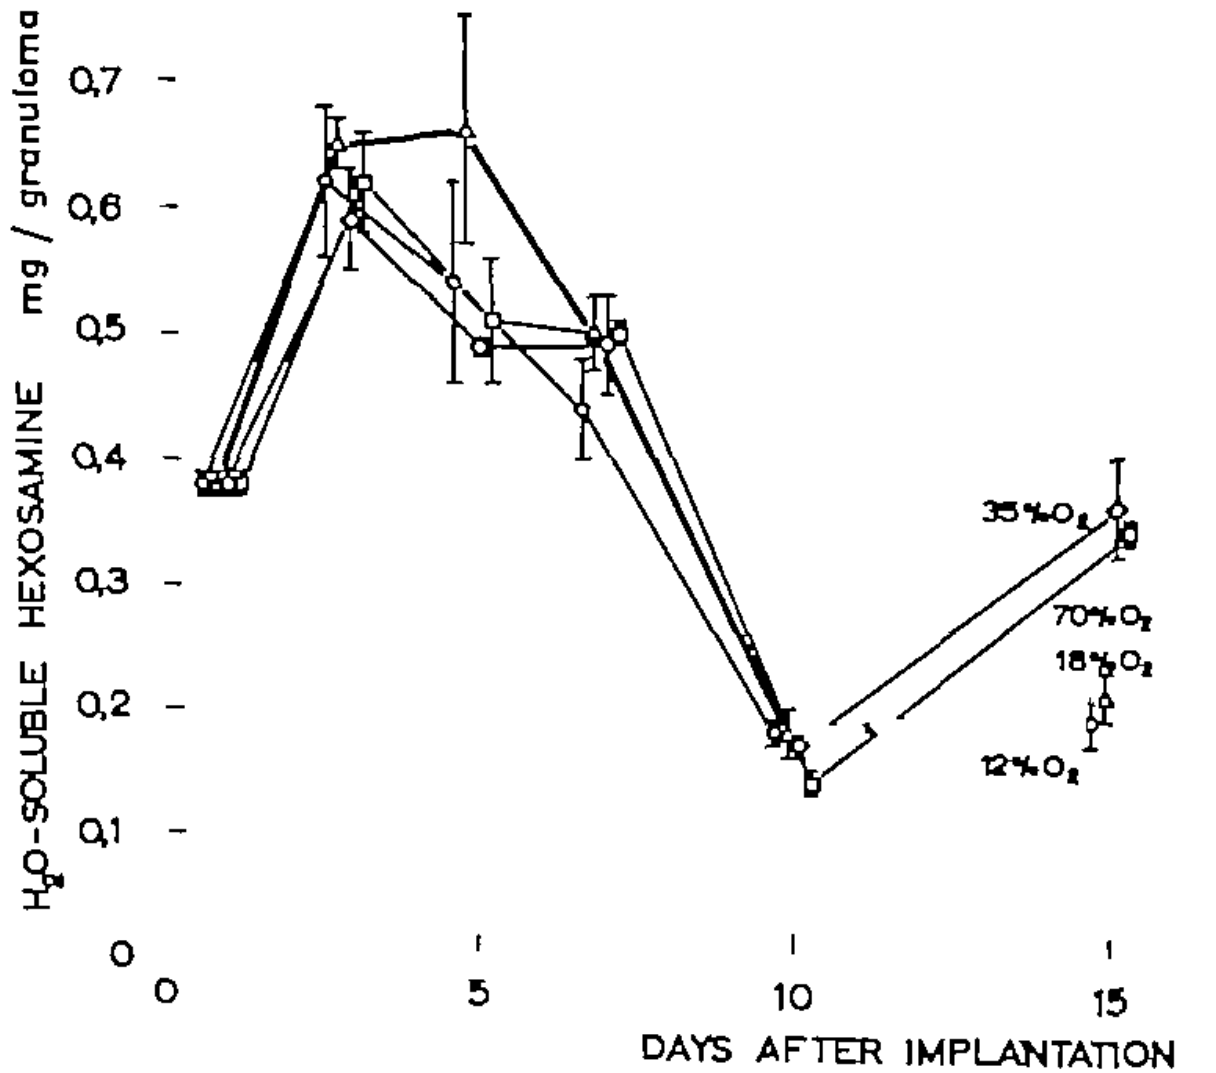

Fig 13 Effect of various respiratory oxygen concentrations on the content of water soluble hexosamine granulation tissue. All values are means for 4—8 samples (16—32 granulomas) The length of each vertical bar represents twice the standard error of the mean.

a maximum already on the third day and then fell steeply to a minimum on the 10th day In the second phase from the 10th to the 15th day the low concentration was maintained in 12 % O and 18 % O_2, whereas a statistically significant increase of the hexosamine content occurred in 35 % O and 70 % O (in the *t*-test, $p < 0.01$)

Nitrogen of unpurified collagen fractions Four fractions were obtained (Fig 4) The total nitrogen contents of the granulomas and of the unpurified collagen fractions are plotted in Figs. 14 and 15

The *water-soluble fraction* originated mainly from the exudate absorbed by the implant on the first few days and from plasma proteins which entered the sponge with circulating blood. The fraction contained also the water soluble nitrogenous compounds synthesized within the implant itself. From the 1st to 7th day the content of nitrogen in the water-soluble fraction was approximately the same in granulomas of rats exposed to different oxygen tensions. From the 10th day onwards, the mean values for rats exposed to 35 % O and 70 % O were higher than those for rats exposed to 12 % or 18 % O (in the analysis of variance $p < 0.001$ on the 15th day)

Nitrogen in the *fraction soluble in 1 M sodium chloride* rose evenly from the 1st to the 15th day From the 10th day onwards, the mean value rose concurrently with increasing oxygen pressure (in the analysis of variance $p < 0.01$ on both the 10th and the 15th day)

The amount of nitrogen in the *acetic acid-soluble fraction* rose from the 1st-day value of 0.25 mg/granuloma to a level of 0.5 mg/granuloma on the 15th day irrespective of the atmospheric oxygen concentration.

The nitrogen in the *insoluble fraction* rose slowly from 1.4 mg/granuloma on the 1st day to 3.5—5.0 mg/granuloma on the 15th day In the 15-day granulomas, the mean value rose with increasing oxygen tension in the hyperoxic environment (in the analysis of variance, $p < 0.01$)

Hydroxyproline in unpurified collagen fractions Chemical analyses on the granulomas confirmed that the tensile strength increased with the content of collagen hydroxyproline (Fig 7 as compared with Figs. 16 and 17) Generally the hydroxyproline contents of the different fractions remained almost unchanged during the first 5 days at various oxygen tensions. After 5 days, however the hydroxyproline contents rose sharply An elevated oxygen concentration accelerated the formation of hydroxyproline whereas a low oxygen concentration retarded collagen synthesis.

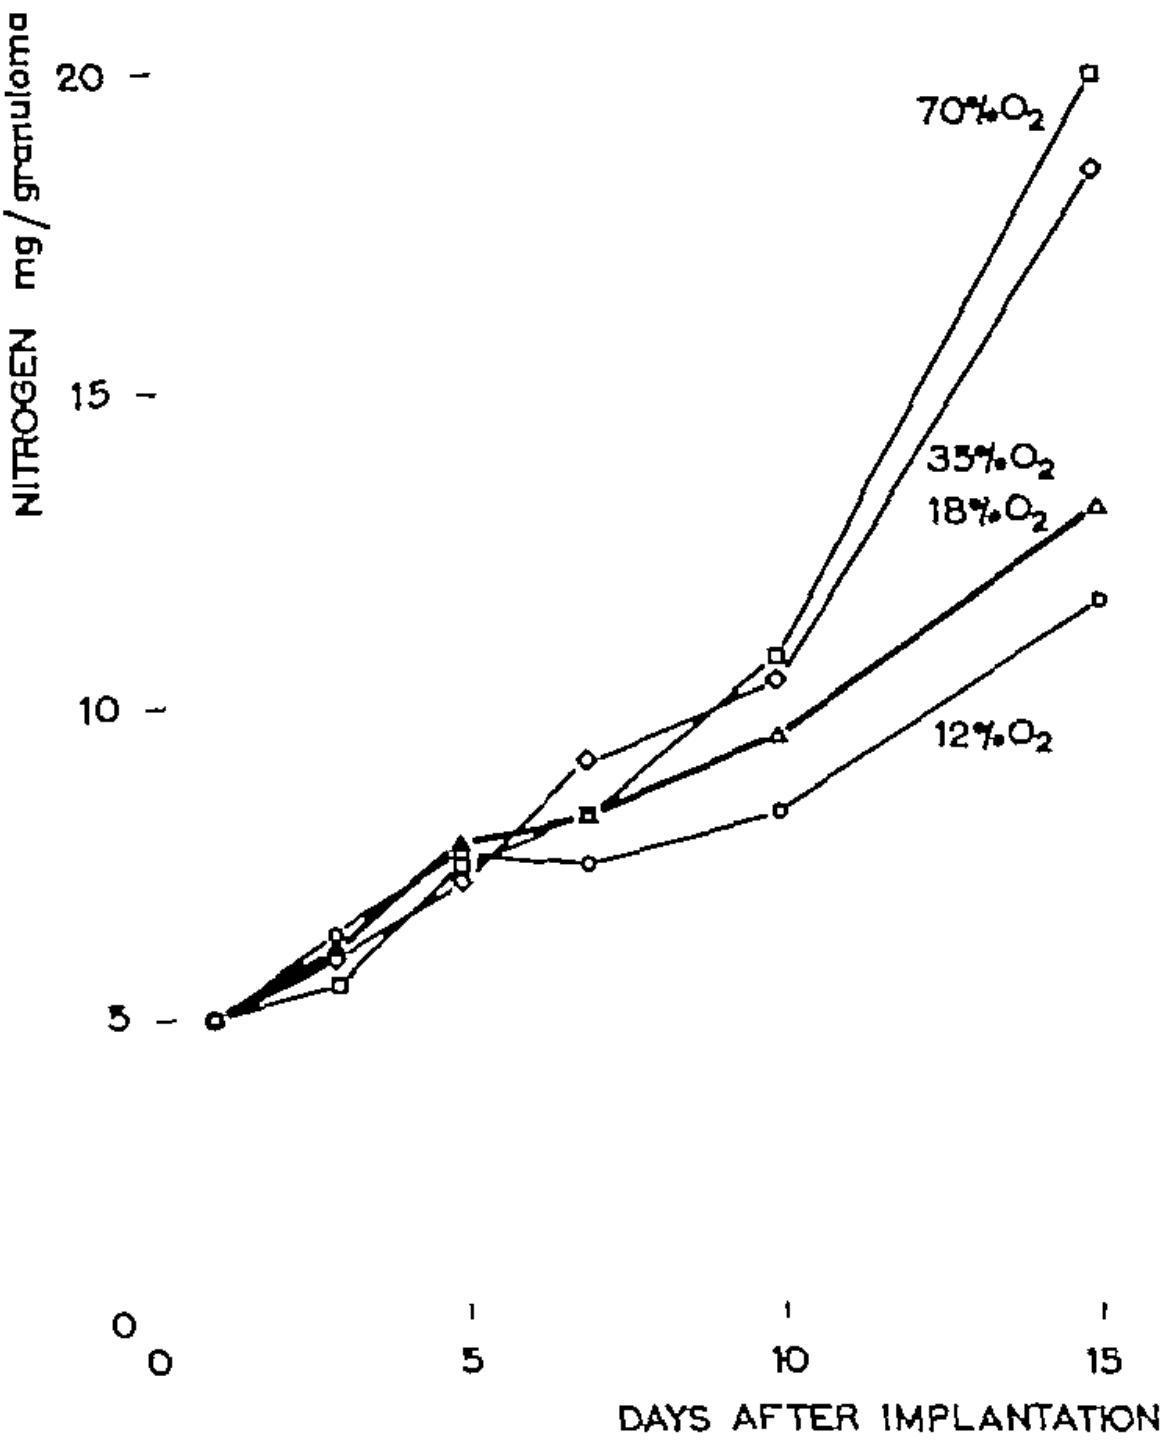

Fig 14 Effect f various respiratory oxygen concentrations on the content f total nitrogen in granulation tissue

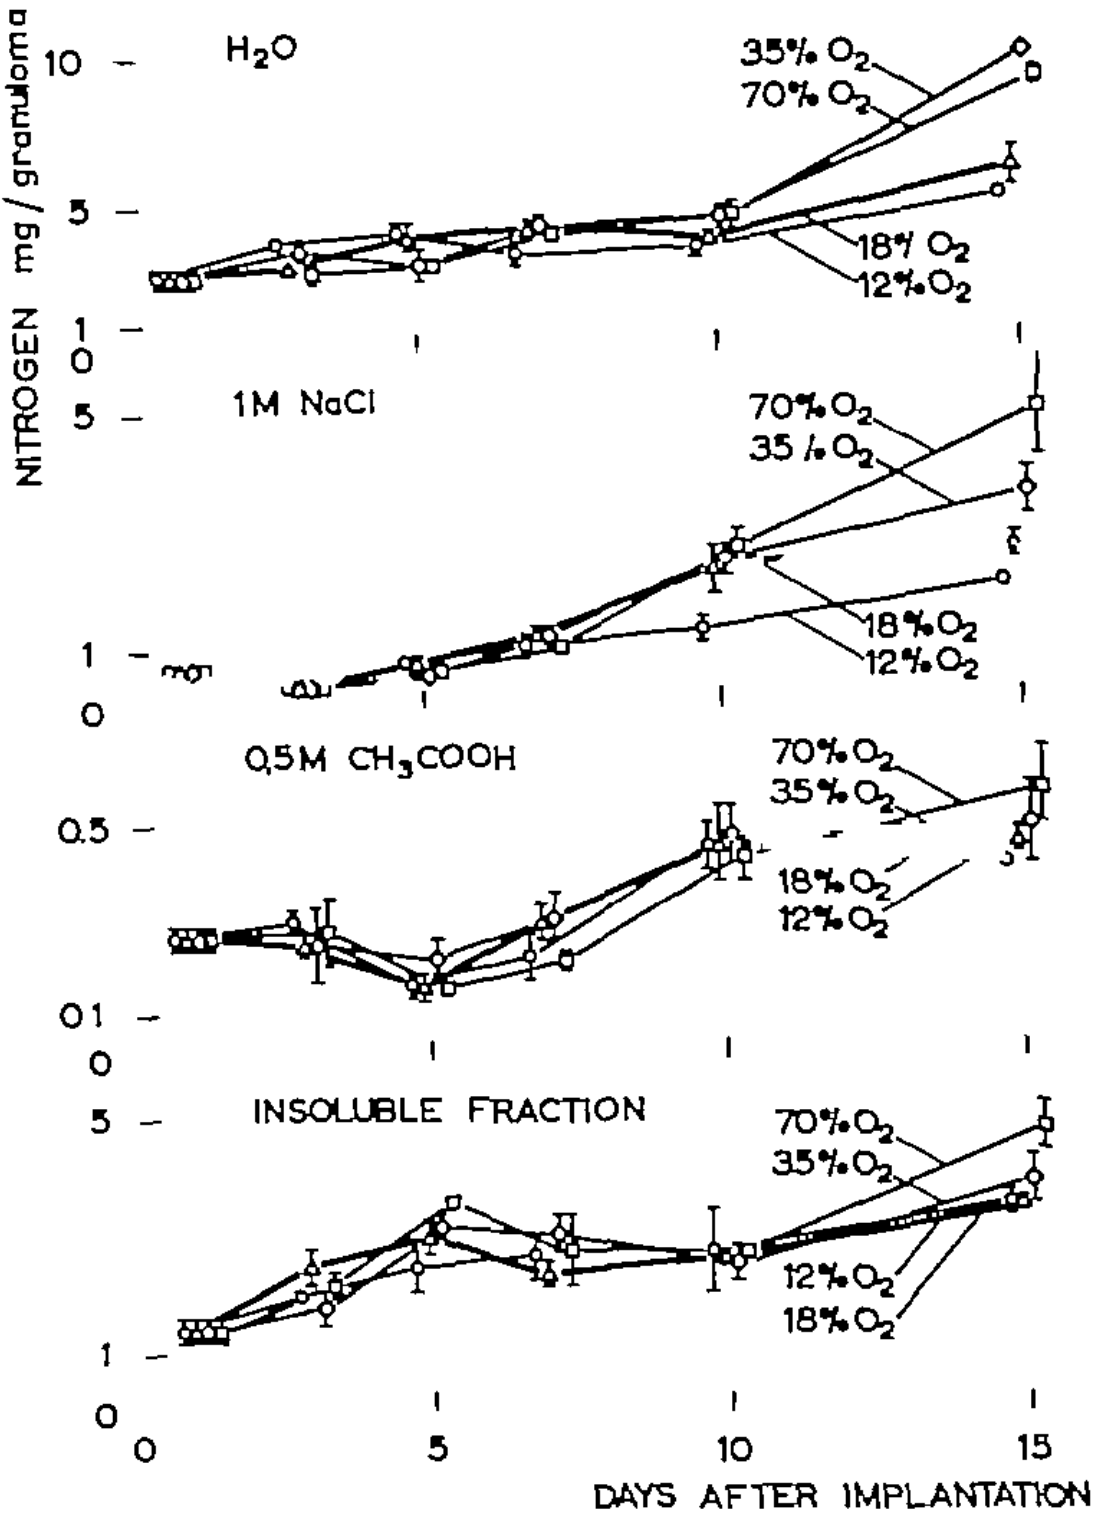

Fig. 15 Eff t various re pirat ry oxygen concentrations on the total nitrogen i unpurified colla fra tions f om gr ulation tissue All alues are means for 4—8 samples (16—1 granulomas) The length of each vertical bar represents twice the standard error the mean. The fractions were obtained as described in Fig 4.

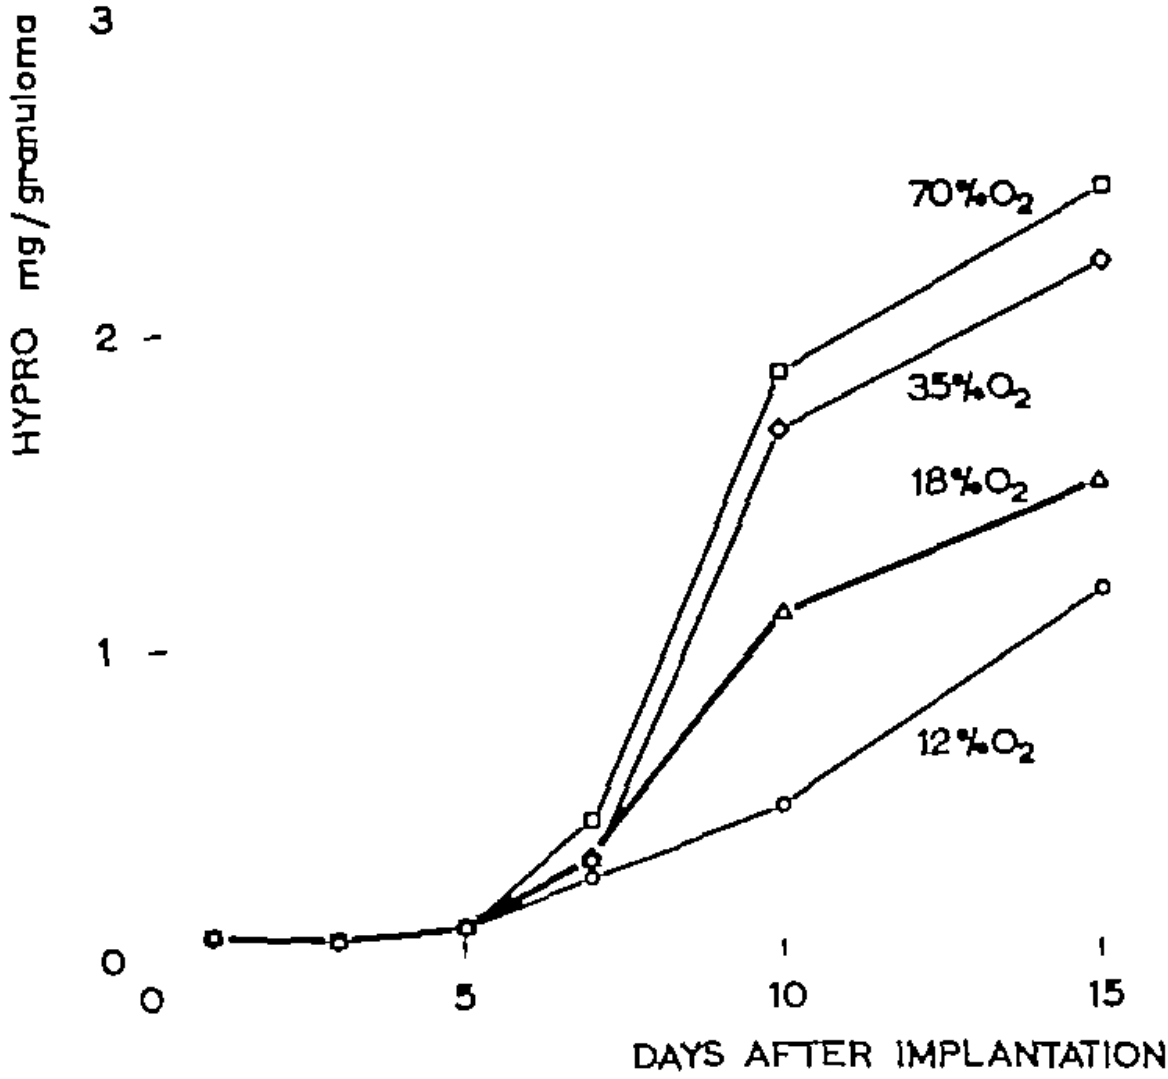

Fig 16. Effect of various respiratory oxygen concentrations on the content f total hydroxyproli in gran lation tissue.

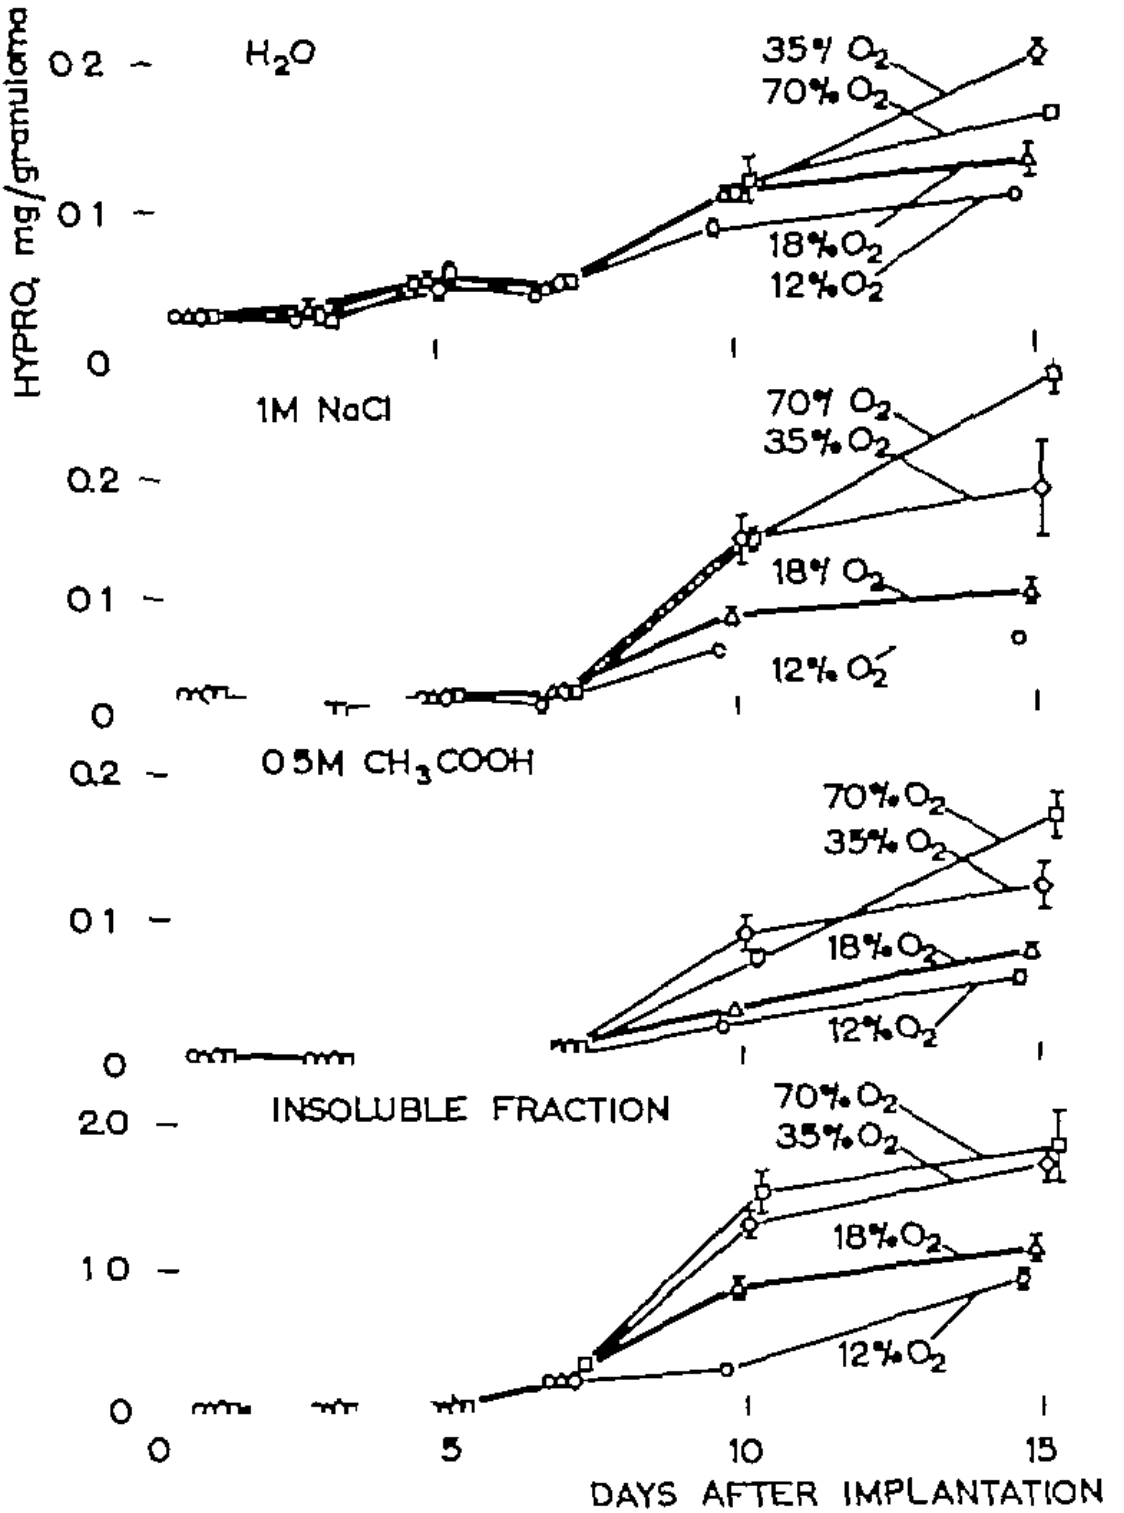

Fig 17 Effect of various ambient oxygen concentrations on the contents of hydroxyproline in unpurified collagen fractions from granulation tissue All values are means for 4—8 samples (16—3 granulomas) The length of each vertical bar represents twice the standard error of the mean. The fractions were obtained as described in Fig 4.

An increase in respiratory oxygen tension elevated significantly the content of *water-soluble hydroxyproline* in the 10- and 15-day granulomas (in the analysis of variance $p < 0.05$ and $p < 0.001$ respectively). According to Viljanto (1964) half of the water-soluble hydroxyproline is free hydroxyproline in normal conditions.

The hydroxyproline of the *neutral salt soluble fraction* rose distinctly faster from the 7th day onwards in 70 % and 35 % O_2 and more slowly in 12 % O than in 18 % O (in the analysis of variance, $p < 0.001$ on both the 10th and the 15th day). Seventy per cent oxygen and 35 % O accelerated and 12 % O retarded the formation of hydroxyproline in the *acid soluble fraction* as compared with the rate of formation in 18 % O (in the analysis of variance, $p < 0.001$ on both the 10th and the 15th day).

The level of hydroxyproline in the *insoluble fraction* began to rise on the 5th day. The greatest increase occurred in 70 % O_2. The formation of hydroxyproline was also accelerated in 35 % O_2, whereas in 12 % O_2 it was retarded as compared with the rate of formation in 18 % O (in the analysis of variance $p < 0.001$ for the 10-day values and $p < 0.01$ for the 15-day values).

Hydroxyproline-proline ratio. For the determination of the hydroxylation ratio of the imino acids, the amino acid composition of gelatin extracted by hot trichloroacetic acid solution and exhaustively dialyzed was assayed by an automated method developed by Spackman *et al.* (1958). The amino acid composition of collagen varied insignificantly in granulomas from rats exposed to different oxygen tensions. The content of glycine was approximately one third of the total amino acid content. Varied oxygenation did not influence the amounts of hydroxy amino acids. The hydroxyproline proline ratio was the same (about 0.7) in the different groups.

Maturation of collagen. The maturation of collagen occurred similarly in the different oxygen concentrations as judged from the ratio of insoluble collagen hydroxyproline to total collagen hydroxyproline. The proportion of insoluble collagen hydroxyproline rose from the 1st-day value of 45 % to 80—90 % on the 7th day and remained unchanged thereafter.

Deoxyribonucleic acid. The DNA contents of the granulomas from rats exposed to various oxygen tensions are shown in Fig. 18. The contents remained nearly constant during the first 5 days. From the 7th to the 10th day the formation of DNA in granulomas of rats exposed to 35 % O was clearly accelerated in comparison with the formation in granulomas of rats exposed to 18 % O (in the *t*-test, $p < 0.05$ on the 10th day). The DNA content in granulomas of the rats exposed to 18 % O rose evenly

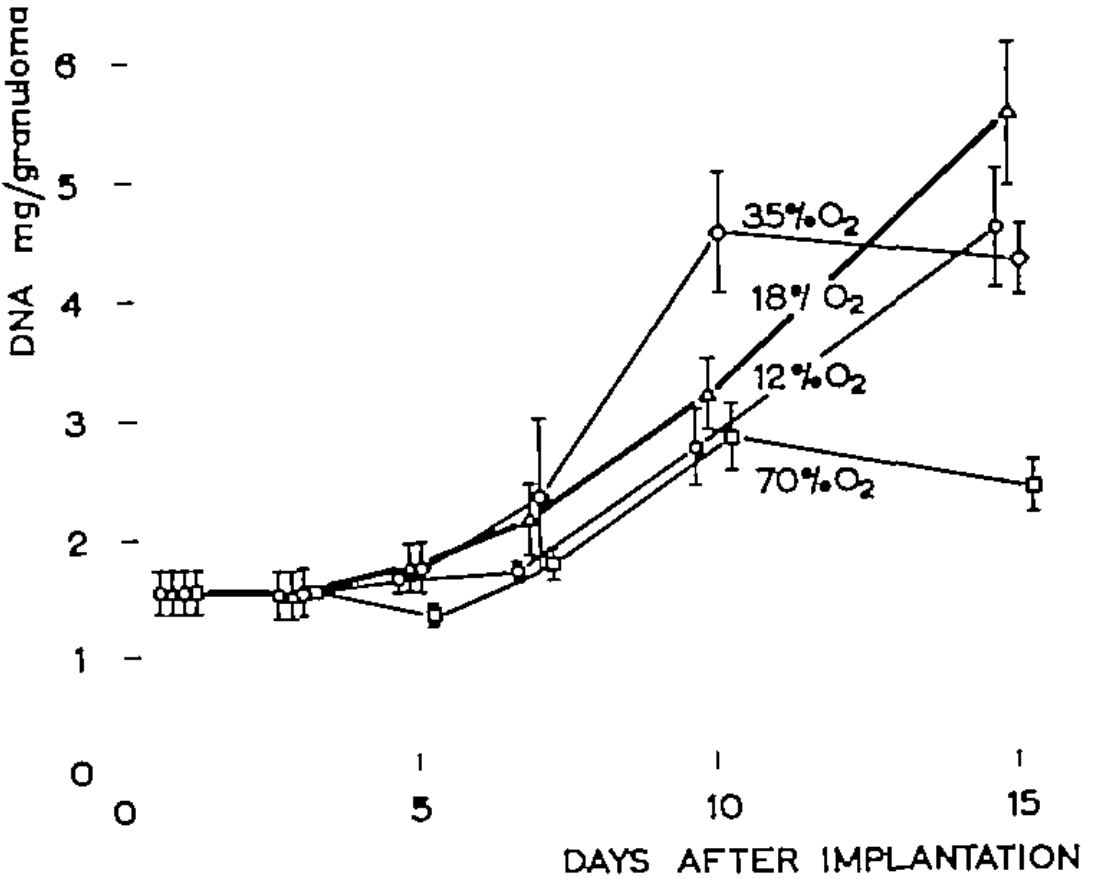

Fig 18 Effect of various respiratory oxygen concentrations on th content f deoxyribon cleic acid in gran latio tissue. All values are means for 4—8 samples (16—83 granulomas) The length of each vertical bar represents twice the standard error of the mean.

from 1 74 mg/granuloma on the 5th day to a maximum of 5 51 mg/granuloma on the 15th day Also in 12 % O_2, the content of DNA increased continuously from the 5th day but to a smaller extent than in 18 % O_2. It is remarkable that the formation of DNA was clearly retarded in 70 % O as compared with the rate of formation in 18 % O (in the *t*-test $p < 0.01$ for the 15-day values) The changes between the 10th and 15th lay were checked by replicate experiments and analytical determinations.

Ribonucleic acid. RNA was assayed as ribose. The changes in RNA ribose content of granulation tissue at various oxygen concentrations are shown in Fig 19 During the first three days the contents were approximately the same in granulomas from rats exposed to different oxygen tensions. This level was maintained in 12 % O until the 7th day The highest RNA ribose contents from the 5th to the 15th day were attained in 3o % O (in the *t*-test as compared with the results for granulomas from rats exposed to 18 % O_2, $p < 0.001$ on the 10th day) The content of RNA

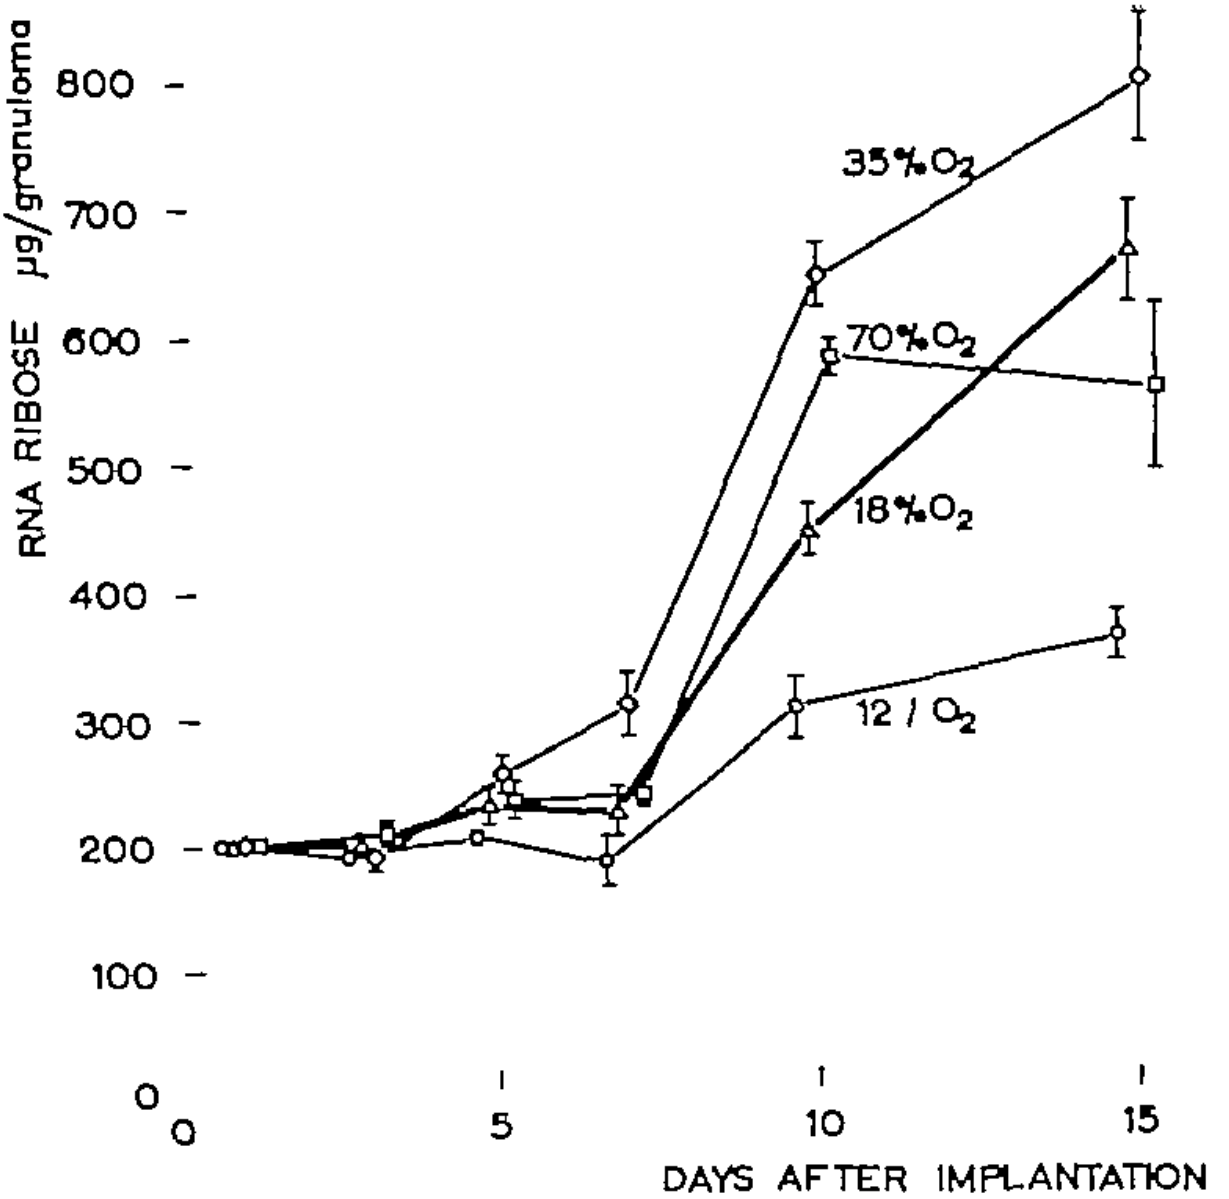

Fig 13 Effect of various respiratory oxygen concentrations on the content of RNA ribose in granulation tissue All values are means for 4—8 samples (16—32 granulomas) The length of each vertical bar represents twice the standard error of the mean.

was greater on the 10th day in rats exposed to 70 % O than in rats exposed to 18 % O (in the *t* test, $p < 0.001$) In 18 % O_2, the RNA ribose rose evenly from the 7th day onwards on the 15th day the mean exceeded the mean in 70 % O Formation of RNA was distinctly retarded at a low oxygen tension (12 % O) as compared with the formation in 18 % O (in the *t*-test, $p < 0.001$ on both the 10th and 15th day) The changes between the 10th and 15th day were checked by replicate experiments and analytical determinations.

RVA ribose.DNA ratio In granulation tissue the ratio of RNA ribose to DNA reflects the potential of fibroblasts to synthesize protein. Furthermore, the ratio can be regarded as an index of cellular differentiation.

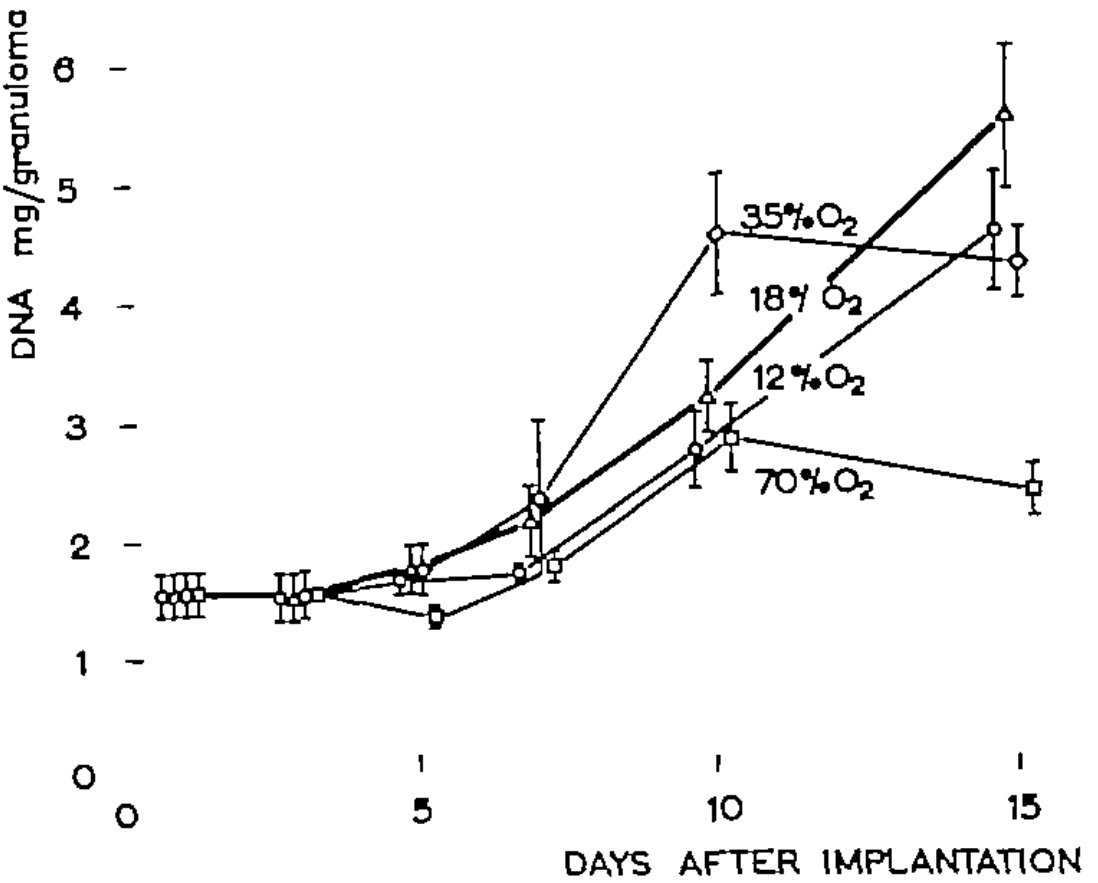

Fig 18 Effect f various respiratory oxygen concentrations on the content of deoxyribonucleic acid granulation tissue All values are means for 4—8 samples (16—33 granulomas) The length of each vertical bar represents twice the standard error of th mean.

from 1 74 mg/granuloma on the 5th day to a maximum of 5.51 mg/granuloma on the 15th day Also in 1° % O_2, the content of DNA increased continuously from the 5th day but to a smaller extent than in 18 % O It is remarkable that the formation of DNA was clearly retarded in 70 % O as compared with the rate of formation in 18 % O (in the *t*-test, $p < 0.01$ for the 15-day values) The changes between the 10th and 15th lay were checked by replicate experiments and analytical determinations.

Ribonucleic acid RNA was assayed as ribose. The changes in RNA ribose content of granulation tissue at various oxygen concentrations are shown in Fig 19 During the first three days the contents were approximately the same in granulomas from rats exposed to different oxygen tensions. This level was maintained in 12 % O until the 7th day The highest RNA ribose contents from the 5th to the 15th day were attained in 3o % O (in the *t* test as compared with the results for granulomas from rats exposed to 18 % O_2, $p < 0.001$ on the 10th day) The content of RNA

Treatment started five days after implantation

Supply of oxygen during the latent phase seems to be important for the subsequent synthesis of collagen and RNA. A low oxygen concentration during the first 5 days inhibited the formation of granuloma hydroxy proline and RNA ribose (Table III) The values for the animals exposed to a normal oxygen tension differ from those for animals exposed to a low oxygen concentration during the latent phase. At high oxygen pressures, differences in the hydroxyproline and DNA contents arose only in granulomas of rats exposed to 35 % O_2. A high oxygen concentration during the latent phase seems to retard the formation of capillaries as judged from the hemoglobin contents. No apparent changes were observed in the nitrogen contents when these were compared with the nitrogen contents after treatment with different oxygen pressures from the second day onwards.

Table III

The chemical compositions of 10-day-old granulomas from rats exposed to various oxygen concentrations from the 6th postimplantation day onwards

The values are means for 4 samples (16 granulomas) The standard errors of the means are also given. The results are compared with those obtained on exposure of rats to various oxygen tensions from the second postimplantation day onwards. The mean relative differences in per cent between the results for the two groups are enclosed in parentheses. A value greater than that obtained after treatment from the second day onwards is indicated by a positive percentage, and *vice versa*. The statistical significance has been tested by the analysis of variance; NS denotes not significant.

Variable (per granuloma)	O_2 % 12	18	35	70	P
Hemoglobin (mg)	2.17±0.60 (+3 %)	2.86±0.04 (+11 %)	3.81±0.7 (+59 %)	4.78±0.6 (+81 %)	<0.05

Effect of hyperbaric oxygenation

Analysis of granulomas confirmed that the tensile strengths of wounds and granulomas in rats exposed intermittently to hyperbaric oxygen (Fig 10) decreased with the contents of hydroxyproline and nitrogen (Table IV) The reduction of the hemoglobin level was probably due to a diminished vascularity The amount of water-soluble hexosamine was not affected by OHP The slight decreases in the amounts of DNA and RNA ribose were not statistically significant.

Table IV

Effect of hyperbaric oxygenation on the chemical composition of experimental granulomas

The numbers of rats are given in parentheses. The figures express means ± the standard errors of the means. The statistical significance was determined by the *t* test.

Variable (per granuloma)	4-day study		10-day study	
	Control	Experiment	Control	Experiment
Hemoglobin (mg)	2.48±0.1(6)	1.60±0.20(6)	3.04±0.26(5)	1.83±0.38(5)

RNA-ribose (μg)	198±9(9)	184±8(9)	494±18(8)	477±23(9)

Significantly different values, $p < 0.03$.

Effect of reduced barometric pressure

As seen in Table V the formation of all components of granulation tissue was retarded when rats were kept in air at ½ ATA. Low pO retarded the formation of capillaries in the granulation tissue as judged from the content of hemoglobin (by the *t* test, the difference was almost significant, $0.05 < p < 0.1$) A statistically significant decrease was observed in the content of water-soluble hexosamine. The content of collagen hydroxy

proline decreased to approximately half of the control value. The total nitrogen content changed accordingly The decreased contents of DNA and RNA ribose at ½ ATA indicate retarded cellular proliferation

Table 7

Effect of reduced barometric pressure (½ ATA) on the chemical composition of experimental granulomas.

The numbers of rats are given in parentheses. The figures are means ± the standard errors of the means. The statistical significance was determined by the *t*-test; NS denotes not significant.

III. IN VIVO AND IN VITRO STUDIES ON THE MECHANISM OF THE ACTION OF OXYGEN IN THE SYNTHESIS OF VARIOUS GRANULATION TISSUE COMPONENTS

Studies on energy metabolism

Utilization of glucose in vitro

During the first 10 days, glucose uptake *in vitro* by slices of granulation tissue removed from rats exposed to various oxygen concentrations followed a similar course as the formation of collagen hydroxyproline in granulomas (Fig 71) After a latent period of 7 days, the higher the availability of oxygen *in vivo* the greater was the amount of glucose utilized *in vitro* by the slices of granulation tissue (in the analysis of variance, $p < 0.001$ for the 10-day values) Statistically significant changes were no longer observed on the 15th day The utilization of glucose by slices of granulation tissue was not correlated with the DNA content of the granuloma (Fig 18)

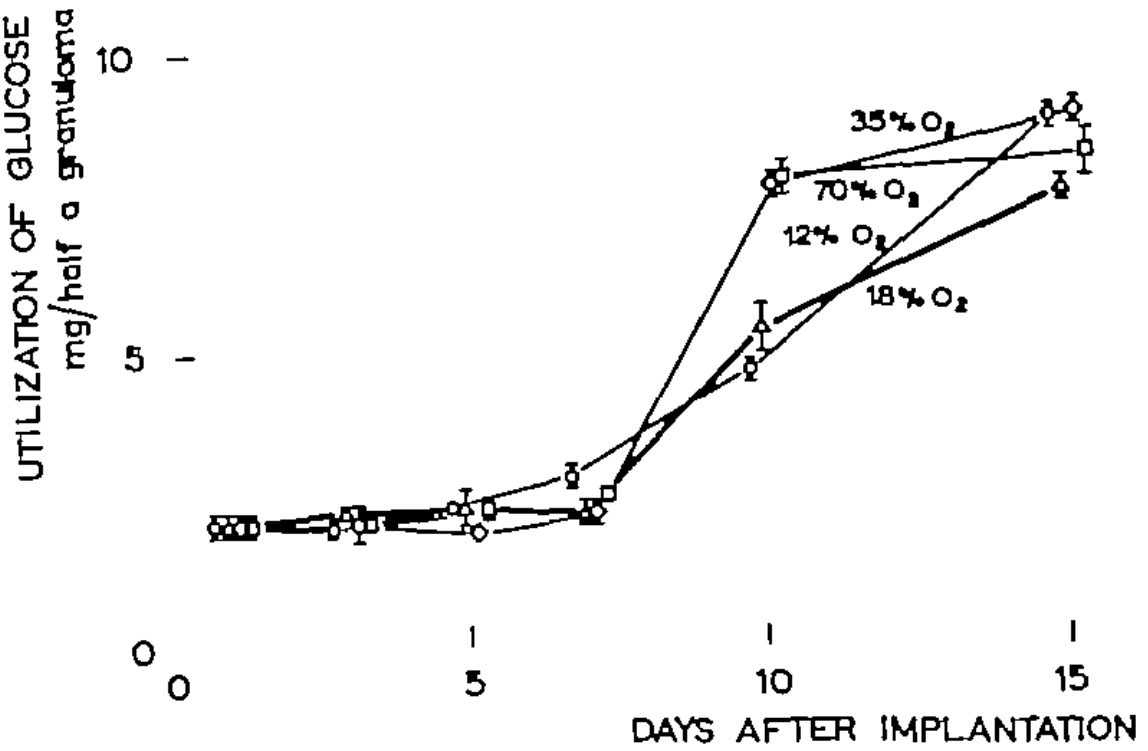

Fig 21. Utilisation of glucose by slices of granulation tissue removed from rats exposed to various oxygen concentrations. Slices of granulation tissue were incubated for 3 hours in a Krebs-Ringer phosphate medium containing glucose. The values are means from 4—12 experiments. The length of each vertical bar represents twice the standard error of the mean (for details, see pp. 20—21)

Formation of lactic acid in vitro

In contrast to the uptake of glucose formation of lactic acid by slices of granulation tissue from rats exposed to various oxygen concentrations had no latent period. As seen in Fig 22, the higher the availability of oxygen *in vivo* the greater was the amount of lactic acid produced by the granuloma slices *in vitro* already from the third day onwards (in the analysis of variance $p < 0.01$ on the third day $p < 0.001$ on the 5th day $p < 0.05$ on the 7th day $p < 0.001$ on the 10th—15th day). However mixtures containing 35 % O_2 and 70 % O_2 had almost the same effect. Again, differences exist between the patterns of granuloma DNA (Fig 18) and the rates of lactic acid formation by the slices.

The utilization of glucose and the formation of lactic acid by slices of granulation tissue reflect the rate of growth of the tissue. The results concur with those of Lampiaho and Kulonen (1967) according to whom glycolysis is a prominent feature in the metabolism of granulation tissue, and especially in the synthesis of collagen.

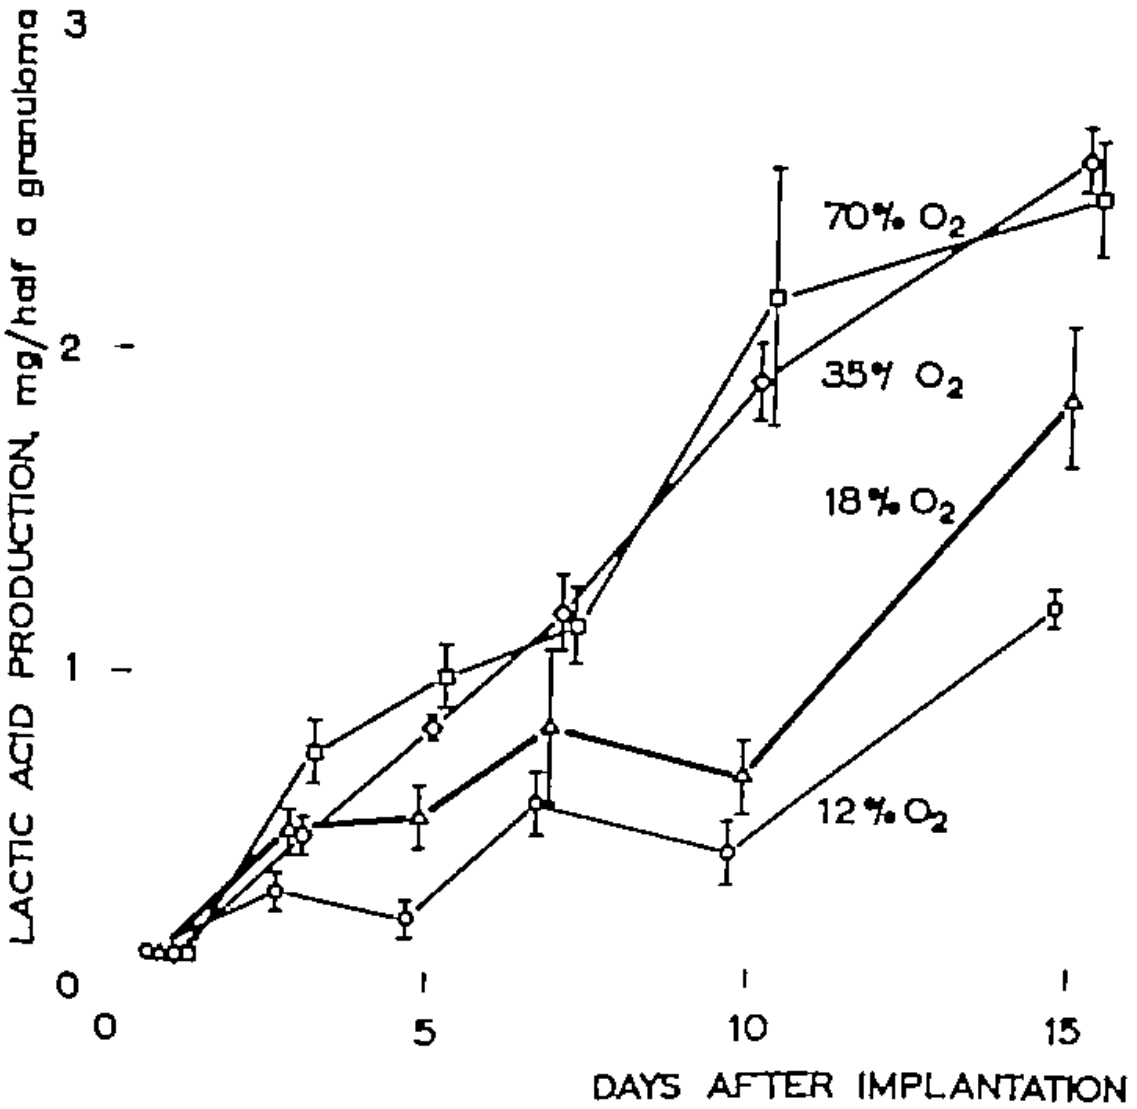

Fig 22. Production of lactic acid by slices of granulation tissue removed from rats exposed to various oxygen concentrations. The experimental conditions were the same as in Fig. 21. All values are means of 4—12 experiments. The length of each vertical bar represents twice the standard error of the mean.

Lactate dehydrogenase in vivo

The lactate dehydrogenase activity of the granuloma supernatant was not dependent on respiratory oxygen tension and varied between 7600 and 11000 mU/granuloma on the 10th postimplantation day. The electrophoretic patterns of the LDH-isoenzymes underwent no changes. Only one anaerobic isoenzyme typical of a tissue in which a glycolytic metabolism prevails was observed.

Incorporation of ^{3}H proline in vitro

Accelerated synthesis of collagen in high oxygen concentrations (Fig 16) was observed also by the incorporation of H proline into collagen of incubated granuloma slices (Table VI) Exposure to 40 % O_2 in vivo or during subsequent incubation had effects which were approximately additive In experiments 1 and 3 40 % O_2 accelerated the synthesis of collagen more than the synthesis of noncollagenous protein as judged from the ratio of H-collagen to noncollagenous H protein. In experiment 2, the ratio was almost the same in the different groups.

Table VI

Effect of oxygen supply on the levels of incorporated H proline and H-hydroxyproline in slices of granulation tissue

The granulation tissues had developed during 10 days in rats breathing the indicated atmospheres. The incubations were carried out in air or 40 % O_2. After preincubation period of 30 min, 80 μCi of ^{3}H proline was added to the medium and the incubation was continued for 4 hours. In the test controls trichloroacetic acid was added to the medium to a final concentration of 5 % to prevent the incorporation (for details, see pp. 20—21 and Fig 5)

Incorporation of ^{3}H thymidine in vivo

Preliminary tests showed that H thymidine was not incorporated *in vitro* into the DNA of slices of 10-day-old granulomas that had developed in rats exposed to 19 or 40 % O_2. This indicated that the proliferation of fibroblasts in the slices had ceased or had greatly slowed down

The total amount of H-thymidine incorporated into granuloma DNA on the 10th postimplantation day *in vivo* was essentially the same in 19 and 40 % O (*Table VII*)

Table VII

Effect of oxygen supply on the incorporation of H thymidine into the DNA of granulation tissue in vivo.

The experimental procedure is described on p. 21. DNA was extracted from the granulomas as described in Fig 5. Both experiments were run in duplicate

Sample	Oxygen supply	
	10 % O_2	40 % O_2
Experiment 1		
Total ^{3}H (dpm × 10^{-4})	59	64
Spec. ^{3}H/mg of DNA (dpm × 10^{-4})	8.6	9.5

Spec. H/mg of DNA (dpm × 10^{-4})	3.1	6.7

Incorporation of ^{3}H-cytidine in vitro

Data on the incorporation of H-cytidine into the RNA of granuloma slices at various oxygen concentrations are presented in Table VIII. The rate of RNA formation was over twice as great in the granulation tissue that developed *in vivo* in 40 % O as in controls. The highest labeling was usually found in granulation tissue exposed to 40 % O both *in vivo* and *in vitro* The lowest incorporations and specific activities were observed in the granulation tissue that had grown in 19 % O *in vivo* and then in air *in vitro*

T ble VIII

Effect of oxygen supply on the incorporation f H-cytidine into the RNA in slices f granulation tissue

Th granulation tissues had formed during 10 days in rats inhaling the indicated gas mixtures. The experimental conditions during the incubations were the same as in Table VI except that in the test controls perchloric acid was added t a final concentration of 0.5 N to prevent the incorporation. After a preincubation period of 30 min, 30 μCi of ³H-cytidine was dded and the incubation continued fo 4 hours *(for details, see pp. 20—31)*

Oxygen supply *in vivo/in v tro*	Total ³H dpm × 10^{-4}	Spec. ³H/μg of RNA ribose dpm × 10^{-4}
Experiment 1

40 % O_2/air	61	3.8
40 % O_2/40 % O_2	71	4.8
Test control	0.8	0 6

As already shown in Table III adequate oxygenation, especially during the first 5 days, is of great importance for the synthesis of RNA. Ten days after sponge implantation 40 % O stimulated the incorporation of H-cytidine into the RNA of granulation tissue but had no marked effect on the incorporation of H thymidine in.o the granuloma DNA. These data support the finding that the RNA DNA ratio in granulation tissue becomes greater in a hyperoxic environment than in air (Fig 20)

Incorporation of ³²P phosphate in vivo

The experiments with ³²P-phosphate were undertaken to obtain infor mation on the formation of *cytoplasmic membranes of granulation tissue*

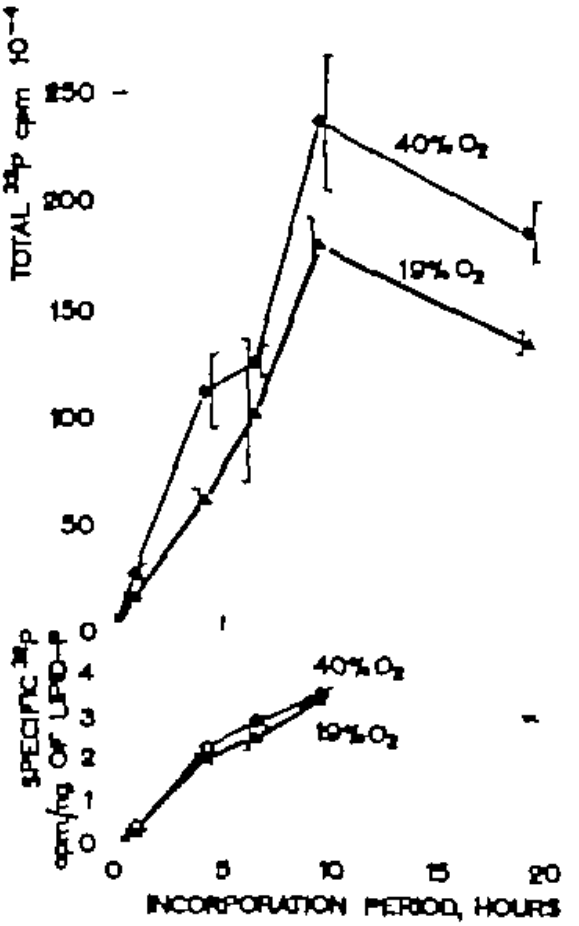

Fig 23 Effect of oxygen supply on the incorporation of ³²P phosphate into extranuclear phospholipids of granulation tissue in vivo. All values are means for 3—8 samples (6—16 granulomas) The length of each vertical bar represents twice the standard error of the mean. The experimental procedure is described on pp. 21—22.

cells in various oxygen tensions. The specific and total radioactivities of the extranuclear lipid bound phosphorus were determined after various incorporation periods. The atmospheres employed contained 19 % O and 40 % O_2.

As shown in Fig 23 the synthesis of extranuclear phospholipids in 10-day-old granulomas was distinctly more rapid in 40 % O than in 19 % O (in the *t* tests, $p < 0.001$ except for the 6.5-hour values which were not significant) It is remarkable that no differences were observed in the specific activities of the extranuclear lipid bound phosphorus at different oxygen tensions. The data indicate that the formation of extranuclear phospholipids took place during the incorporation periods at rates attained already before the injection of ³²P phosphate. The maximum labeling occurred during a period of 9.5 hours.

To conclude, enhanced synthesis of extranuclear phospholipids [illegible] in granulation tissue of rats exposed to 40 % O_2, where also the formation of RNA was augmented (Table VIII)

DISCUSSION

COMMENTS ON MATERIAL AND METHODS

Gas tensions in the breathing mixtures In the experiments at 1 ATA, the oxygen concentrations were lower in the animal boxes than in the gas cylinders (Table II) This was due to entry of air through the exit hole to the oxygen consumption of the animals, and to accumulation of carbon dioxide When the rate of gas flow was 6 l/h the oxygen concentration in the boxes housing the control rats varied between 21 and 18 % O During a 24-hour period, the two rats in each box produced a carbon dioxide concentration of about 4 % (Fig 3 Table II) which caused some hyperventilation However the short term increase of the carbon dioxide concentration had no disturbing effect on the rats as judged from the even rise of the weights of the animals during the experiments and from the fact that the removal of carbon dioxide effected no essential changes in the tensile strength values of the healing wounds. In the experiments in hyperbaric oxygen and at reduced barometric pressure the accumulation of carbon dioxide inside the pressure chambers was almost negligible

Partial pressure of oxygen in the arterial blood and granulation tissue Hunt *et al* (1967) found that the pO in wire mesh cylinder granulomas was 11—17 mmHg but from measurements like these it is not possible to decide if the oxygen tension in granulation tissue cells is below the critical value for respiration. In the present study the pO in the granulomas was not measured. As calculated from the data of Tribukait (1963b) the arterial pO is 175 mmHg in 35 % O_2, 215 mmHg in 40 % O_2, 425 mmHg in 0 % O 570 mmHg in 90 % O and 1500 mmHg in oxygen at 2 ATA In all these conditions, the cellular oxygen pressure should also rise but certainly not proportionately (*cf* Hunt 1965)

Signs of oxygen toxicity Prolonged inhalation of 70 % O_2 caused death of four of about 100 animals on the 10th—15th day At autopsy the lungs of the four animals exhibited diffuse hemorrhagic consolidation and edema. Histologic sections (hematoxylin-eosin or hematoxylin van Gieson stain) revealed patchy consolidation and congestion throughout the lung field,

perivascular edema exudate in the alveolar space and thickened alveolar walls. Histologic sections of lungs from rats exposed to 70 % O for 9—14 days showed perivascular edema around the small vessels. All these findings are signs of oxygen toxicity (Pfister *et al.* 1964 Spencer *et al.* 1966 Wittner and Rosenbaum 1966) No rats exposed to OHP or 35—40 % O showed any signs of oxygen toxicity (such as convulsions or histologic changes in pulmonary tissue)

DISCUSSION OF RESULTS

Effect of oxygen supply on the tensile strengths of a healing skin wound and experimental granulation tissue

The oxygen concentration in breathed gas for optimal wound healing appeared to be 35—70 % O (Figs. 7 and 8) As compared with the controls, an increase of almost 40 % in the tensile strength of a healing wound had taken place in 70 % O on the 7th day after incision. The increase in strength appeared to slow down during the later course of the healing process. The increase in strength on the 10th day was approximately 30 % and on the 15th day no more than about 10 % Prolonged inhalation of almost pure oxygen (90 % O) did not affect the tensile strength of a healing wound (Fig 8) Intermittent short term exposures to hyperbaric oxygen at 2 ATA led to reduced wound strength (Fig 10) as also did prolonged inhalation of mixtures of low oxygen content (Figs. 7 8 and 11) The variation in tensile strength of experimental granulation tissue correlated well with that of the healing wounds.

In the study of Lundgren and Sandberg (1965) hyperbaric oxygenation started on the day of wound infliction retarded wound healing in rats significantly The unfavorable effect of OHP seemed to display a dose response pattern. However when the treatment was started on the second day the tensile strengths of healing skin wounds were the same in the experimental and control groups. This does not agree with the results of present investigation. In 1965 Beckham and Hitchcock established that OHP at 2.5 ATA can influence beneficially the rate of healing of clean surgical wounds in dogs. Two facts cast doubt on the general validity of this finding (1) even the longest observation period of the study was only 4 days, which is too short for reliable tensile strength measurements (2) the dogs were under anesthesia during the whole observation period.

Effect of oxygen supply on the chemical composition of experimental granulation tissue

Hemoglobin The content of granuloma hemoglobin can be regarded as indicative of the volume of circulating blood only after the 5th day when the implant has developed its own vascularity (Viljanto 1964) The peak content of granuloma hemoglobin was attained in 18 % O on the 7th day (Fig 12) Low pO retarded the formation of capillaries. The decrease in hemoglobin content with increasing oxygen tension (Fig 12, Table IV) indicates a decreased vascularity caused by higher oxygenation of tissues, but even vasoconstriction should lead to a lower hemoglobin content Variations in the hemoglobin content of the blood do not seem to be important in this connection

Water-soluble hexosamine The high contents of water-soluble hexosamine during the latent phase originated most likely from plasma glycoproteins that accumulated in the granulomas after sponge implantation (L. C Edwards *et al.* 1957 Schür 1957 Jackson *et al* 1960) The clearly increased hexosamine contents on the 15th day in granulomas of rats breathing 35 and 70 % O probably reflected an accelerated synthesis of mucopolysaccharides (Fig 13)

Collagen Analyses of the granulomas confirmed that the tensile strengths in optimal oxygen tensions were positively correlated with the amounts of collagen synthesized (Figs. 16 and 17 Tables IV and V) Varying the oxygen tension did not affect the amino acid composition of collagen (p 41) The nitrogen contents of the unpurified collagen fractions merely reflected the amount of collagen (Figs 14 and 15)

Maturation of the granuloma collagen was not affected by an elevated or lowered oxygen tension (p 41) The result does not agree with the findings of Chvapil *et al* (1968) and Tsurufuji and Ogata (1965) but concurs with that of Heikkinen (1968) who observed that the formation of insoluble collagen in radioactive skin slices *in vitro* was not affected by anaerobic conditions.

Nucleic acids There is evidence that fibroblasts are more resistant to a subnormal oxygen tension than other cell types. Powell (1959) pointed out that diethyl dithiocarbamate influenced oxidation reduction reactions and thus prevented cell respiration and that it affected sarcoma tumor cells more than fibroblasts. Clark (1964) showed that the growth of adult mouse fibroblasts in tissue culture at oxygen concentrations above 3 % did not differ from the growth in air Kenny and Fink (1966) established that the optimal pO (60 mmHg) for the growth of fibrogenic cells in tissue culture is below the normal oxygen tension of the atmosphere (152

mmHg) Maximum growth of the L strain mouse fibroblasts occurred at oxygen concentrations from 10 to 30 % (Brosemer and Rutter 1961) This finding is in good agreement with the results of present study where the highest levels of DNA *in vivo* were attained at oxygen concentrations from 12 to 35 % (Fig 18) The maximum formation of DNA and RNA took place in 35 % O during the first 10 days (Figs. 18 and 19) In 70 % O the synthesis of DNA was retarded throughout the experiments. However the granulation tissue cells in the rats exposed to 70 % O_2 had rather high contents of RNA (Fig 19) and synthesized protein more efficiently than cells at a lower pO_2 (Fig 20)

Histologic examination of granulomas Microscopic examination of slices of granulomas stained with hematoxylin-eosin revealed changes in the total number of cells, erythrocytes, capillaries and collagen formation at various oxygen pressures which agreed fully with the results of the biochemical studies (the data of the histologic study are not presented)

The mechanism of the action of oxygen in wound healing

Chronic superficial ischemic ulcers in man have been induced to undergo more rapid healing by intermittent exposures to hyperbaric oxygen (Illingworth *et al.* 1961 Baffes *et al.* 1966 Hall *et al* 1966 Slack *et al.* 1966) Skin flaps with impaired circulation have survived with intermittent short-term exposures to hyperbaric oxygen (Perrins 1966 Niinikoski 1969) The favorable effect of adequate circulation has been attributed to an elevation of temperature an increased supply of nutrients and an adequate supply of oxygen (Sandblom 1944)

Wound margins are separated by a minimal fibrin layer at the beginning of the healing process. It is reasonable to assume that increased phagocytosis and fibroblast activity require more oxygen than surrounding normal tissues.

In the present study inhalation of 35—70 % O at 1 ATA had the most favorable effect on wound healing In the presence of excess oxygen, *e.g* at OHP the energy metabolism in the healing wound may be controlled by adenosine diphosphate (ADP) phosphate or substrates, and the kinetics of oxygen utilization will be independent of the oxygen concentration. At decreased oxygen tensions, hemoglobin becomes deoxygenated, large gradients of oxygen tension develop in the tissue and eventually cytochrome oxidase is reduced. The electron flow diminishes. Adenosine triphosphate (ATP) production decreases and the energy transfer is then controlled by the diffusion of oxygen to the respiratory enzymes in the mitochondria.

The increase in ADP and the decrease in the energy reserves may evoke glycolytic activity (Chance 1965)

The oxygen supply is important for healing since collagen cannot be synthesized in the absence of molecular oxygen (Fujimoto and Tamiya 1962, 1963 Prockop *et al.* 1967 Lamport 1963 Hutton *et al* 1967) An increased supply of oxygen can cause (1) an accelerated hydroxylation of proline bound in the collagen precursor or (2) a less specific stimulation of the growth of granulation tissue. Attempts were made to decide between these two alteratives.

Action of oxygen in the synthesis of collagen hydroxyproline The formation of hydroxyproline appeared to be a special target of oxygen Forty per cent oxygen promoted the formation of hydroxyproline both *in vivo* and *in vitro* (Table VI) The effect of increased oxygen tension on the synthesis of noncollagenous protein was much smaller perhaps insignificant In *in vitro* studies reported elsewhere (Niinikoski *et al* 1967) a maximal proline-hydroxylating activity (Juva 1968) was observed in granulomas removed from rats exposed to 18 % O_2 It is interesting to note that oxygenation during the latent phase seems to be important for certain synthetic activities, especially the synthesis of collagen (Table III)

Retarded synthesis of granuloma collagen resulted from exposure to a hypoxic environment (Fig 16 Table V) A low pO_2 probably caused a relative deficiency of oxygen required in the hydroxylation of proline and, in addition inhibited cellular growth during the first ten observation days (Table V)

The results of the present study agree well with the data of Kao *et al* (1963) and of Lampinho and Kulonen (1967) who found that the synthesis of collagen was stimulated *in vitro* when the atmospheric oxygen concentration was raised from 21 to 95 % A different result was obtained by Chvapil *et al* (1968) collagen synthesis in chick embryo skin slices was promoted by oxygen only up to a content of 20 % v/v

Intermittent exposures to hyperbaric oxygen at 2 ATA tended to reduce the formation of collagen hydroxyproline in granulomas (Table IV) This was possibly due to toxic effects of oxygen such as the inhibition of SH enzymes (Haugaard 1965) to suppression of the growth of fibroblasts (Brosemer and Rutter 1961 Clark 1964 Kenny and Fink 1966) to activation of lysosomal proteolytic enzymes (Sledge 1965) to suppression of glycolysis by oxygen, i.e the Pasteur effect (*cf* Cruickshank and Trotter 1956) or to the changes in pH and carbon dioxide levels.

Action of oxygen in the development of granulation tissue Changes in respiratory oxygen tension affected profoundly the RNA DNA ratio in granulation tissue (Fig 20) The most noteworthy effect of oxygen

was its effect on the incorporation of labeled cytidine into RNA and the availability of oxygen was decisive during the growth of the granuloma *in vivo* (Table VIII) In contrast, an elevated oxygen pressure had no effect whatsoever on the incorporation of labeled thymidine into DNA (Table VII)

Because the finding relating to RNA suggested that the metabolic apparatus for the synthesis of collagen is a special target of the action of oxygen the incorporation of radioactive phosphate into the extranuclear lipid fraction was studied. It was found that the formation of extranuclear phospholipids was enhanced in 40 % O as compared with the formation in 10 % O (Fig 23) *These results indicate an augmented ability of* fibroblasts to synthesize protein as well as an enhanced rate of cellular differentiation at an increased oxygen tension. Supporting evidence was given by Bassot and Herrmann (1961) who noted that variation of the oxygen tension profoundly affects the differentiation of multipotent mesenchymal cells in tissue culture and that collagen fiber formation was favored by 35 % O

The increased activity of fibroblasts in granulomas led to the utilization of more glucose (Fig 21) and to the production of more lactic acid *in vitro* (Fig 22) These findings agree with those of Lampiaho and Kulonen (1967) who found that the consumption of oxygen and glucose and the formation of lactic acid by slices of granulation tissue increased almost linearly during the first 20 days of development of granulation tissue. They observed also that the proliferative phase was characterized by a relative high activity of the pentose phosphate cycle whereas glycolysis dominated during the synthesis of collagen.

In the present study no changes in the total activity or in the isoenzymes of lactate dehydrogenase were observed when the oxygen supply was varied. A different result was obtained by Lindy and Rajasalmi (1966) with chick embryos incubation of the embryos at various oxygen concentrations affected the relative amount of subunit M

To conclude, the action of oxygen in wound healing resolves itself into the following main functions

(1) Oxygen concentrations between 35—70 % at 1 ATA stimulate the synthesis of collagen hydroxyproline, whereas a hypoxic environment retards collagen formation.

(2) A hyperoxic atmosphere (35—70 % O) accelerates both the formation and function of the metabolic apparatus of the fibroblast for protein synthesis.

(3) An elevation of oxygen tension beyond the optimum retards healing probably because of toxic effects on cellular metabolism

contents of hemoglobin were found in granulomas that developed in subnormal oxygen tensions (Fig 12, Table V) High concentrations of oxygen as well as hyperbaric oxygen retarded the accumulation of hemoglobin into the granulomas (Fig 12, Table IV)

The high content of water-soluble hexosamine during the latent phase of the healing originated probably from plasma glycoproteins. The increased contents of hexosamine in 15-day granulomas from rats exposed to 35 and 70 per cent oxygen indicated stimulated formation of mucopolysaccharides (Fig 13) Low pO retarded the formation of hexosamines (Table V)

Adequate respiratory oxygen tension (pO at least 150 mmHg) during the latent phase appeared to be important for the formation of collagen and RNA, but high oxygen concentrations during the latent period retarded the formation of capillaries (Table III)

III. *The mechanism of the action of oxygen in the synthesis of various granulation tissue components*

An increased synthesis of collagen was indicated also by the incorporation of H proline into collagen of incubated granuloma slices. The administration of 40 per cent oxygen either *in vitro* or afterwards during the incubation had effects which were approximately additive. Furthermore a hyperoxic atmosphere appeared to stimulate to some extent the formation of noncollagenous protein (Table VI)

Granulomas that developed *in vivo* in 40 per cent oxygen synthesized more RNA *in vitro* than those which developed in 19 per cent oxygen (Table VIII) The incorporation of ^{3}H thymidine into granuloma DNA *in vivo* was essentially the same in 19 and 40 per cent oxygen (Table VII) The rate of formation of extranuclear phospholipids in granulomas *in vivo* was significantly higher in 40 per cent oxygen than in 19 per cent oxygen (Fig 23)

Granulomas that developed *in vivo* in 35 or 70 per cent oxygen had a greater ability to utilize glucose and produce lactic acid *in vitro* than granulomas that developed *in vivo* in 18 or 12 per cent oxygen (Figs. 21 and 22) No significant variation of the total LDH-activity was observed. Only one LDH isoenzyme typical of a glycolytic tissue was detected.

ACKNOWLEDGEMENTS

This investigation was conducted in 1966—1969 at the Department of Medical Chemistry University of Turku. I sincerely appreciate the expert help my colleagues have given on days and nights at the department.

It gives me particular pleasure to acknowledge my indebtedness to my chief, Professor Pino Kulonen M.D., the Head of the Department for introducing me to the problems of connective tissue research, for his close guidance and for the use of working facilities.

I want to express my deep gratitude to Dr Per Olof Barr M.D M. Eng the Laboratories of Aviation and Naval Medicine Karolinska Institutet, Stockholm who organized my visit to the Karolinska Institutet in 1967 I am greatly indebted to Dr Bernhard Tribukait M.D., Head of the Department of Medical Radioprotection Stockholm for the use of the hyperbaric chamber for valuable criticism of the manuscript and for his generous hospitality during my visit in Stockholm.

I am grateful to Professor Torgny Sjöstrand M.D Head of the Department of Clinical Physiology Karolinska Sjukhuset, Stockholm, to Professor Gunnar Birke M D., Head of King Gustav V Research Institute, Karolinska Sjukhuset, Stockholm to Professor Knarlo Hartiala, M.D., Head of the Department of Physiology University of Turku, and to Professor Mikko Niemi, M.D Head of the Department of Anatomy University of Turku, for the use of the facilities of their departments.

Mrs. Hilleri Rannikko, Mrs. Riitta Bergman, Mrs. Marita Potila and Miss Tuula Marja Aho gave competent technical assistance Miss Irja Montonen and Mrs. Pirkko-Liisa Holmas did the secretarial work and preserved to my great astonishment, their good temper even after the sixth version of the manuscript. Mr Vilho Hytonen and Mr Jorma Lauti nen constructed various apparatus necessary for this investigation. To all of them I want to express my deep gratitude.

I owe my thanks to Mr E R. Korte Ph.L, for revising the language of my manuscript. My thanks are also due to Mrs. Aili Ryynänen, Ph.L Custodian of the library of the Medical Faculty University of Turku, and her assistants for their help in the search for relevant literature

This work was supported by a personal grant from the Emil Aaltonen Foundation and a grant awarded by the Sigrid Juselius Foundation to the Department of Medical Chemistry University of Turku.

Turku, November 1969
