CHAPTER I

GENERAL INTRODUCTION

In many respects the knowledge about the extrinsic nervous control of colonic motility and blood flow is incomplete Around the turn of the century gastrointestinal physiology attracted many investigators, and many studies were conducted not the least concerning the function of the large bowel and its nervous control However the apparent finality of the results obtained in animals seem to have discouraged further investigation as relatively few experimental studies have been reported subsequently In addition, the introduction of the opaque meal greatly stimulated clinical research in the field and much of present knowledge concerning colonic function is therefore based on observations in man. However the experimental conditions in such investigations are of necessity often too complex to allow any definite conclusions with respect to the detailed control of colonic function Furthermore only scant information is available concerning the control of blood supply to the colon and its different wall compartments.

The aim of the present study therefore is to explore in cats the extrinsic nervous control of the colon both with respect to motility and blood supply to the different wall compartments. As an introduction a survey will be given concerning present knowledge of the morphology and physiology of the colon, its blood supply and extrinsic nervous pathways.

I. MORPHOLOGICAL CONSIDERATIONS

A. Gross structure of the colon in different species

One may distinguish between two main types of large bowel, one being typical of carnivores and the other of herbivores with that of omniverous animals falling in between (Garry 1934) In *herbivores* the proximal part, apparently designed for cellulose digestion, is large and sacculated and the longitudinal muscle coat is partially absent The intermediate and distal parts are much narrower have a uniform muscle coat and are devoid of sacculation. In *carnivores* the large bowel is usually short with the outer longitudinal muscles constituting a more or less uniform coat with a vestigeal caecum so that the ileo-colic junction forms a nearly straight tube

In the cat used in this study the colon approximates that of man in form and relative size Thus M'Fadden *et al* (1935) described a fairly characteristic radiological picture of the resting colon of the cat where two main flexures one hepatic and one splenic, made it possible to distinguish a vestigeal caecum, a short ascending colon, a transverse part and a descending part The colon of the cat can however freely alter its position often resulting in the disappearance of the mentioned flexures Therefore it is not fully justified to divide the colon of this animal into segments corresponding to those of human anatomy Perhaps it is better to refer to a proximal and a distal segment and to regard the anal canal as that part encircled by the anal sphincters a nomenclature which will be used throughout this study

B The organization of the colonic wall layers

As is the case with the small intestine, the wall of the colon consists of four layers the mucosa the submucosa the muscular coat and the serosa

The mucosa is covered by a single layer of tall columnar epithelial cells which include goblet cells the source of mucus In contrast to that of the small intestine the colonic mucosa is devoid of villi but its surface is punctuated by closely set epithelial crypts, forming the glands of Lieberkühn which are also lined by abundant mucus-laden goblet cells A thin muscularis mucosa separates the mucosa from the submucosa which contains a rich network of blood and lymph vessels.

Whereas the mucosal organization is largely similar in different species, the muscular coat comprising an outer longitudinal and an inner circular layer differs somewhat In the cat the longitudinal muscle layer forms a continuous enveloping coat while it is condensed into three separate taeniae in man

As in other parts of the gastrointestinal tract the intrinsic nervous system is built up by a submucous (Meissner) and an intermuscular (Auerbach) ganglion plexus. Variations in the general organization of the myenteric plexuses in different colonic parts have been described with respect to the size of the meshes, the thickness of the fasciculi and the size shape and cell content of the ganglia (for ref see Schofield 1965) Auerbach plexus is said to be better developed distally than proximally in the large bowel and in man, where the longitudinal muscle coat is gathered mainly into the taeniae neurons are more numerous adjacent to these Concerning the submucous plexus Müller (1901) found large numbers of neurons especially in distal colonic parts whereas Bielschowsky and Schofield (1962) and Schofield (1962) reported that their number was reduced in these parts.

C. Vascular supply to the colon

The colonic vascular supply in the cat comes from two sources; proximally from the superior mesenteric artery and distally from the inferior mesenteric artery These two arteries are interconnected by a long extramural arcade which extends distally along the dorsal wall and penetrates it tangentially The intra pelvic part of the colon the

rectum and the anal canal are further supplied by small arterial branches from the internal iliac arteries. The veins generally follow the arteries but except for minor collaterals at the anus the colonic blood flow is finally drained via the superior mesenteric vein. There is no venous counterpart to the inferior mesenteric artery

Thorough morphological investigations of the extra and intramural colonic vessels have been performed by different techniques both in animals and in humans Brockis and Moffat (1958) using Neoprene latex in the human pelvic colon described how the arteriae rectae after a subserous course pierce the muscle coat sequentially between the mesenteric and anti mesenteric margins These vessels give off small branches to the serosa and form an external plexus for the supply of the outer muscularis. More deeply the arteriae rectae divide into submucosal branches which continue towards the anti mesenteric border Abundant anastomoses are formed with the arteriae rectae of the opposite colonic side A primary and a secondary submucosal plexus is formed the former one supplying inner muscularis parts and the latter one giving rise to numerous mucosal arteries, which take off at more or less right angles. After piercing the muscularis mucosae these arteries form a plexus from which the rich mucosal supply is derived In general the intramural veins accompany the arteries but the venous plexus in the submucosa is placed closer to the mucosa

Thamm (1940) and Ross (1950) suggested the presence of specific arteriovenous anastomoses in the colonic submucosa. This was more recently investigated by Brockis and Moffat (1957) A few submucosal vessels were suggestive of true anastomoses, according to the latter investigators, but the majority of shunt-like vessels were undoubtedly distended capillaries. Boulter and Parks (1960) studying the submucosal vascular pattern in different gastrointestinal compartments of man demonstrated arteriovenous communications with diameters around 30–35 microns in the stomach while such shunt like vessels were seldom seen in the small and large intestines. As an indication of their relative sparseness 12/cm² were found in the gastric submucosa but only 2/cm² in the colon and rectum. Whether they are truly functional shunts i.e. constituting a non nutritional capillary bypass is not known so far (Wiedeman 1963)

D Extrinsic nervous supply

The autonomic nervous pathways to the colon of cats and rabbits were studied in detail by Langley and Anderson (1895) Trumble (1933) emphasized the accuracy of this work, which was also fully confirmed in a similar study by M'Fadden *et al* (1935) (For ref. see Alvarez, 1948)

1 *The parasympathetic supply*

According to the mentioned investigators, parasympathetic fibres are conveyed mainly via *the sacral outflow* forming *the pelvic nerves* (nn erigentes) which usually

arise from the second and third ventral sacral roots. The pelvic nerve ramifications to the colon have been traced in dogs and cats by Schmidt (1933). He demonstrated that after pelvic nerve section degeneration of nerve fibres throughout most of the colon occurred. Whether or not such fibres run to the most proximal colonic parts is not known for sure. In man parasympathetic fibres have been traced from the pelvic plexus upwards along the hypogastric nerves as far as the origin of the inferior mesenteric artery; from here on the fibres may follow the branches of this artery (Telford and Stopford 1934). In similar studies Mitchell (1935) and Lannon and Weller (1947) observed parasympathetic fibres passing upwards in the mesentery to the promontorial level, from where they obliquely crossed the branches of the inferior mesenteric artery. In dogs and cats, on the other hand, Wright *et al.* (1938), M'Fadden *et al.* (1935) and Mizeres (1955) presented strong evidence to indicate that the sacral parasympathetic fibres, rather than being distributed along the extramural vessels with the sympathetic nerves, enter the colonic wall in its pelvic part and from here on run intramurally in the proximal direction.

There are, however, reasons to believe that parasympathetic fibres to the colon are distributed in *the vagal nerves* as well, though few details are available. A junction in the parasympathetic innervation of the colon was actually first suggested by Cannon (1907). He observed in X-ray studies a ring of contraction dividing the cat colon into two portions, which according to Arendt (1945) was supposed to be caused by an overlap of a cranial and a sacral parasympathetic innervation in man. It would thus appear that the vagal influence in the human colon extends only to proximal parts of the transverse colon at most, a concept which is in agreement with the embryological development (Hunter 1928, Hollinshead 1962 and Schofield 1968). Thus, vagal fibres are supposed to reach proximal colonic parts intermingled with postganglionic sympathetic fibres along the arterial supply. However, convincing histological evidence concerning the extent of vagal fibre distribution to the large intestine seems to be lacking so far. For example, after subdiaphragmal vagal section in cats and dogs Schmidt (1933) could trace degenerated nerve fibres in the ascending colon but not in its distal parts. Jayle and Cabanac (1937) and Wollard (1935), on the other hand, claim that vagal fibres also reach the distal parts of the colon. Mitchell (1935) and Lannon and Weller (1947) found it impossible to trace vagal fibres to more peripheral parts of the colon in dissections on man.

2. *The sympathetic supply*

Little is known whether splanchnic postganglionic fibres reach the colon along the superior vascular supply (Kilee 1913). The main source of sympathetic fibres is therefore supposed to be derived from *the lumbar preganglionic outflow* arising from the second, third, fourth and *sometimes fifth* ventral lumbar roots (Langley and Anderson 1895, Trumble 1933). All or most of these preganglionic fibres pass without interruption through the sympathetic chains and run as *four or five thin strands* to

the inferior mesenteric ganglia forming the spinal rami of the inferior mesenteric ganglia In addition two or more bundles arising from the coeliac or superior mesenteric ganglia pass downward entering the inferior mesenteric ganglia as their coeliac root

The inferior mesenteric ganglia, usually four in number lie close together forming a ring around the inferior mesenteric artery not far from its aortic origin. From these ganglia the postganglionic *lumbar colonic nerves* arise which accompany the inferior mesenteric artery to the colon. Furthermore the paired hypogastric nerves which are also derived from these ganglia run caudally to join the pelvic plexus and give off branches to the ureter bladder internal genital organs and to the sphincter muscles in the anal canal (Learmonth and Markowitz 1929 Trumble 1933)

The literature on the distribution of the extrinsic nervous supply to the large bowel is thus contradictory in several respects especially concerning vagal and splanchnic nerve supply

II FUNCTIONAL CONSIDERATIONS

A. The motility pattern of the large bowel

According to earlier studies the acutely denervated colon in cats exhibits two types of "spontaneous motility rhythmic contractions travelling downwards on which are superimposed shortlasting contractions (Bayliss and Starling 1900) In unanaesthetized cats Cannon (1902) found in X ray examinations that antiperistalsis occurring about every 15 minutes and lasting some 5 minutes constituted a common type of motility in the proximal parts of the colon. The contents were then churned and mixed in a semi-closed sac as the ileocaecal valve prevented reflux Similar observations were made on the proximal portion of the exteriorized colon in dogs by Barcroft and Steggerda (1932) The importance of colonic antiperistalsis was also emphasized by Elliot and Barclay Smith (1904) and it was supposed to arise as a myogenic response to distension These investigators also distinguished a coordinated peristaltic activity moving the contents downwards. This was found especially in middle colonic parts and was supposed to be due to intramural reflexes as a response to distension. The main activity of the distal colon, on the other hand consisted of powerful contraction waves moving downwards and thus emptying the reservoir This latter activity seemed to be largely dependent upon the central nervous system and conveyed by the pelvic nerves. It could be reflexly elicited by distension. According to Cannon (1902) and M'Fadden (1935) defaecation in cat was usually initiated by a powerful wave of constriction starting in middle colonic parts and pulling the shortened bowel towards the pelvis by the recto-coccygeal muscles. This motility pattern was associated with the characteristic defaecation posture contraction of the diaphragm and abdominal muscles, and with relaxation of the anal sphincters.

Colonic motility is known to be affected by activity in more proximal gastrointestinal compartments (Youmans 1949) Thus food intake usually increases colonic activity within few minutes (Hertz and Newton 1913 Welch and Plant 1920 Barcroft *et al* 193?) and initiates a mass peristaltic contraction that often leads to defaecation. The exact pathways of this gastro-colic "reflex" is unknown Douglas and Mann (1930) observed that it was largely unaltered by vagotomy suggesting that neither afferent nor efferent vagal fibres were needed. In fact they suggested that the response might be mediated by a humoral mechanism In experiments on dogs and humans Logan (1967) and Connell and Logan (1967) presented evidence to show that gastrin may play a role in the mediation of the gastrocolic "reflex (For ref see Connell 1968)

It has further been observed that topical stimulation of the lower brain stem close to the vomiting centre causes defaecation (Hatcher 1923 Koppanyi 1930 Wang *et al* 1940) and afferent vagal stimulation is claimed to elicit the same response (Lehman 1913) possibly by activating the bulbar defaecation centres It is also well known that *stress and emotions* considerably affect colonic motility and presumably also colonic secretion and blood flow (e.g Friedman and Snape 1946 Almy *et al* 1949 and Grace *et al* 1951) According to these studies, performed on humans, reduced colonic motility and mucosal pallor occurs in association with overwhelming life situations provocative of abject fear and dejection while situations provocative of conflict with anger resentment and anxiety were associated with increased motor activity and mucosal flushing The sight or smell of food brought about increased motor activity and reddening or engorgement of the mucosa

B Extrinsic nervous control of colonic motility

1 *The vagal supply*

It is still controversial as to what extent vagal fibres reach the colon and certainly as to what an extent they influence motility blood flow and secretion. Thus upon electrical stimulation of the vagal nerves in dogs and rabbits Bayliss and Starling (1900) Elliott and Barclay-Smith (1904) and Klee (1912) were unable to detect any *effects on colonic motility* Carlson (1930) and Wells *et al* (194_) came to the same conclusion in experiments on dogs but the former investigator noted motor effects in proximal colonic parts in monkeys. Gray *et al* (1955) recording motor responses from consecutive sections of the small and large intestines in dogs observed that vagal stimulation regularly caused motor responses in the small intestine and usually delayed responses in proximal parts of the colon and sometimes even in the distal parts. However in these studies the continuity of the intestinal tract appeared to have been left intact implying that a vagally induced motility increase in the proximal intestinal part might have been propagated to the colon along the intrinsic wall plexa

The sympathetic neuro-hormonal influence appears not to have been taken into account in any of the above experiments It is clear from studies by e g Celander (1959) Kock (1959) and Lewenter (1965) that sympathoadrenal influences may markedly affect intestinal motor responses induced by vagal stimulation even to the extent that they can be completely suppressed However only in two recent studies of colonic motility (Fülgraff and Schmidt 1963a, Stavnov *et al* 1963) one of these factors appears to have been considered insofar as the splanchnic nerves had been cut. Vagal stimulation then produced excitatory responses in the proximal parts of the colon in dogs and cats and these responses were blocked by atropine.

2 *The pelvic nerve supply*

The distribution and functional significance of the sacral parasympathetic outflow to the colon (S II–S III the pelvic nerves) is also to some extent debatable even though there is general agreement that these nerves constitute the main excitatory control of distal colonic parts About two thirds of the medullated fibres in the pelvic nerves are efferent and fairly thin (M Fadden *et al* 1935) the remaining third being afferent and containing fibres up to 10 micron in diameter also noted by Langley in his extensive study of the pelvic visceral innervation in cats rabbits and dogs. These latter results, also based on experiments where weak tetanizing induction shocks were used and the motor responses were observed by naked eye suggested that the pelvic nerves produce contraction of the descending colon and rectum These responses were partly unaffected by atropine

Bayliss and Starling (1900) reinvestigated the effect of pelvic nerve stimulation recording colonic motility by means of balloons. They confirmed the results of Langley and Andersson (1895) and further claimed that all parts of the colon are simultaneously affected by pelvic nerve stimulation although this effect appeared to be most pronounced in the distal parts. Preceding the contraction, they often noted transient inhibitory responses which were ascribed to a descending aboral inhibition analogous to the effects of vagal stimulation on the small intestine Furthermore they observed that upon continued stimulation the pelvic nerves appeared to be rapidly fatigued

Garry (1933) studying the nervous control of the caudal region of the large bowel in the cat recorded a drastic fall in tone and some decrease in the rate of rhythmic activity after sectioning the pelvic nerves, indicating a considerable resting "tone in these nerves. This finding could however not be confirmed by M'Fadden *et al* (1935) in a radiological study on cats. With a balloon enterograph and electrical nerve stimulation, Wells *et al* (1942) obtained results in dogs and monkeys suggesting that the pelvic nerve influence was limited to the distal colon only Gray *et al* (1955) on the other hand, concluded that the pelvic nerves affect the motility of the entire colon confirming also Schmidt s dissection studies (1933) Their results thus suggest a considerable anatomical or functional overlap of the vagal and pelvic parasym

pathetics. Wells *et al* (19[illegible]) concluded that the pelvic nerves to the colonic smooth muscles are cholinergic, although they were able to block the responses completely with atropine in only half of the experiments. They also noted that acetylcholine produced a greater circular but a lesser longitudinal response of the colon musculature than that produced by pelvic nerve stimulation and tried to explain this finding by an unequal distribution of the pelvic nerve fibres to the two muscle layers." Garry and Gillespie (1935) showed in a study *in vitro* that the motility response to pelvic nerve stimulation could be abolished by atropine (see also Gillespie 1968) while Fülgraff and Schmidt (1964) concluded that the response was reduced in magnitude but not abolished by atropine. In another series of experiments, these investigators perfused the colonic vessels with Tyrode solution and under these circumstances the motor responses to pelvic nerve stimulation were easily abolished by atropine (Fülgraff and Schmidt 1963 b). After restoration of normal blood flow the same atropine-resistant contractions were again observed. They assumed that the cause of the atropine-resistant contractions was a humoral factor dependent of the blood plasma, but they could not find any evidence for a bradykinin mechanism similar to that found in the salivary glands which here may explain the atropine-resistant vasodilatation (Hilton and Lewis 1955, 1956).

Motor responses in the colon, evoked reflexly by mechanical stimulation of the intestinal wall, have been studied in anaesthetized, decerebrated or decapitated cats by Garry (1933). This extensive investigation suggested that the lumbar sympathetic outflow to the colon is inhibitory in function, that both the afferent and efferent links in the colonic excitatory reflexes are contained in the pelvic nerves and that specific mechano-receptors are located in the mucosa or adjacent parts of the wall of the colon and rectum.

3 *The thoracic sympathetic supply*

The concept th[illegible] splanchnic nerve fibres should be distributed to proximal parts of the colon [illegible] to have little or no experimental support. The only functional [illegible]udies [illegi]al [illegible] this question were performed by Bayliss and Starling (1900), Klee (191[illegible]) [illegible]r (1922). However, they did not observe any effect on colonic motility wh[illegible] splanchnic nerves were stimulated or cut.

The influ[illegible] of these nerves on the motility of the small intestine is, however, well documented (see e.g. Newton 1965). In this study concerning the sympathetic and vagal control of the small intestine it was concluded that distal parts of the small intestine are exposed to a more powerful inhibitory sympathetic control of a "tonic" nature than are the proximal parts. Furthermore, the sympathetic inhibitory fibres appear to exert their intramural effect mainly or perhaps only at the ganglionic level rather than directly on the intestinal smooth muscles. These functional results are in general agreement with the histochemical studies of Norberg (1964, 1965) which suggest that the great majority of adrenergic nerve terminals in the colonic

and gastric walls make contacts with the intramural ganglionic cells. However no clearcut information is so far available concerning the effect of the splanchnic sympathetic outflow on colonic motility and blood supply

4 *The lumbar sympathetic supply*

The lumbar sympathetic outflow the postganglionic fibres of which are named the *lumbar colonic nerves* are known to be mainly inhibitory in their action on colonic motility This is indicated by the effects obtained when these nerves are blocked (Lehmann 1913 Learmonth and Markowitz 1930 Rankin and Learmonth 1930 Garry 1933) or when they are electrically stimulated (Langley *et al* 1895 Bayliss and Starling 1900 Garry and Gillespie 1955 Wright *et al* 1939 Fülgraff and Schmidt 1963 a)

Carlsson (1930) observed on the other hand that stimulation of these nerves could lead to powerful contractions if the colon was relatively atonic, while inhibition resulted if colonic tone was initially pronounced Kuré *et al* (1931) claimed that spinal parasympathetic motor fibres are conveyed to the intestinal tract in the dorsal roots, and these fibres should be cholinergic and run together with the sympathetic inhibitory fibres in the lumbar colonic nerves according to Semba (1956) In fact in recent studies cholinergic fibres have been found to occur so frequently in sympathetic nerves that they may be considered as typical rather than exceptional. The detection of such fibres has been greatly facilitated by the use of reserpine or guanethidine which effectively block adrenergic inhibitory fibres and hence unmask the presence of cholinergic fibres. Thus, Day and Rand (1961) Gillespie and Mackenna (1961) and Boyd *et al* (1962) noted that stimulation of the sympathetic supply to the isolated colon in guanethidine- or reserpine-treated animals sometimes produced contraction instead of inhibition. The origin of these motor fibres could however not be determined but the optimum frequency of stimulation was similar to that of the parasympathetic nerves. It has not been possible to differentiate between the two fibre sets by means of histological analyses. According to M'Fadden *et al* (1935) the postganglionic lumbar colonic and hypogastric nerves contain a small proportion of medullated fibres with a diameter of 2–10 microns. However these might as well represent conventional sympathetic preganglionic fibres which make their synaptic contacts more peripherally

The hypogastric nerves take no obvious part in regulation of colonic motility Learmonth (1931) Garry (1933) but seem to be mainly involved in the control of the anal sphincters, Bishop *et al.* (1956)

C. Extrinsic nervous control of colonic blood flow

1 *The vagal supply*

Besides their gastrointestinal motor control the vagus nerves were previously assumed to contain specific vasodilator fibres. However Kewenter (1965) found no evidence of

such fibres to the vessels of the small intestine in the cat in accordance with earlier observations by Colander and Folkow (1951) Martinson (1965) observed that the high threshold group of efferent vagal fibres produces mucosal vasodilatation concomitantly with gastric secretion and corpus fundus relaxation. This mucosal vasodilatation could however as well be due to the increased production of metabolites in connection with the secretory response or of specific vasodilator agents, such as kinins or histamine It is not known whether the colonic vessels are affected by the vagal nerves and as mentioned above considerable controversy still exists concerning the vagal influence on colonic motility

2 *The pelvic nerve supply*

Langley *et al* (1905) observed flushing of the mucosa in the distal colon upon stimulating the pelvic nerves In an extensive investigation Wright *et al* (1938) studied the effects of pelvic nerve stimulation on the mucosa of the distal colon exposed through a perspex window in decerebrated cats. Stimulation caused a longitudinal colonic contraction a secretory response amounting to about 5 cc/hour and a mucosal vasodilatation Afferent pelvic nerve stimulation produced reflex secretion, which remained after sectioning the spinal cord in the thoracolumbar region. Pilocarpine and acetylcholine after eserine produced similar effects which were blocked by atropine Histological mucosal changes after pelvic nerve stimulation were characterized by increased vascularity around the crypts and a flattening of both goblet and chief cells with a widening of the crypts.

On the whole knowledge concerning colonic blood flow and especially its quantitative distribution to the different wall compartments is scant. The only studies which present quantitative figures of overall colonic blood flow are those of Geber (1960) Delaney and Custer (1965) and Bacaner (1966) while information concerning the capacity for autoregulation of colonic blood flow is presented by Hansson and Johnson (1967) Geber estimated the blood flow of the dog colon to be about 70 ml/min 100 g and Bacaner (1966) presented similar figures in man. Delaney and Custer working on dogs obtained a mean value of 82 ml/min × 100 g employing the radiorubidium distribution method Nothing appears to be known of the normal range of colonic blood flow from intense neurogenic vasoconstriction up to maximal functional hyperaemia

3 *The sympathetic supply*

Langley and Anderssen (1895) noted that stimulation of the lumbar colonic nerves produced blanching of the colon. This was later confirmed and extended by Drury *et al* (1929) Barcroft and Florey (1929) and Wright *et al* (1938) There appears to be no studies concerning the possible effects of stimulation of the splanchnic nerves on the colonic vessels. The vasoconstrictor fibre influence on the stomach and small intestine has on the other hand been studied (see e.g Jansson *et al* 1966 Wallentin

1966) It is well known that the vasoconstrictor fibres in the splanchnic nerves are tonically active, but the gastrointestinal vascular responses to vasoconstrictor fibre activity differ considerably from those in skeletal muscle or skin insofar as e.g the intestinal resistance vessels exhibit an "autoregulatory escape from the vasoconstrictor fibre influence At least partly this escape phenomenon implies a redistribution of mucosal blood flow to submucosal layers (see Wallentin 1966)

III SUMMARY OF EARLIER FINDINGS

Summarizing the results of earlier studies it may be concluded that—analogous to the situation in the small intestine—colonic motility is the result of myogenic activity as modulated and enhanced by the intrinsic ganglionic plexa which is, in turn modulated in both directions by the different types of extrinsic autonomic fibres (Texter 1963 and Kewenter 1965) The considerable degree of autonomy possessed by the large bowel is evident from the fact that even complete decentralization causes only temporary disturbance in motility (Garry 1933) On the other hand the most caudal parts of the large bowel which are directly involved in defaecation appears to be normally controlled by the central nervous system in a similar way as seems to be the case with the reservoir at the other end of the gastrointestinal tract the stomach (e.g Jansson 1969)

Opinions concerning the extrinsic nervous control vary considerably in several respects, e.g concerning the extent and significance of the vagal control of proximal colonic parts, whereas most authors agree that the pelvic nerves affect almost the entire colon. It is therefore possible that proximal parts of the colon might have a double excitatory innervation The significance of this seems obscure.

The lumbar sympathetic outflow exerts an inhibitory influence on colonic motility mainly affecting the distal parts. However this outflow also contains excitatory cholinergic fibres of unknown functional significance There appears to be no experimental evidence of a thoracic sympathetic supply to the proximal colonic parts although this has sometimes been assumed.

Besides their excitatory influence on colonic motility the pelvic nerves induce vasodilatation as well. The mechanism involved is however unknown, as is the extent of the response and its presence in the different wall layers. Whether the vagal colonic innervation also affects the colonic vessels is not known.

Vasoconstrictor fibres in the lumbar sympathetic outflow are on the other hand known to produce mucosal blanching, at least in distal colonic parts but little is known about the vasoconstrictor fibre control in proximal parts or whether the splanchnic outflow is involved here

IV THE AIM OF THE PRESENT STUDY

The anatomical and functional arrangement of the extrinsic innervation of the large bowel and its influence on motility and especially on blood flow is thus in many re

spects poorly understood partly because earlier results are to a considerable extent controversial. The divergent opinions met in the literature may often be explained by different types of interferences between the various sets of parasympathetic and sympathetic nervous supplies. For example a tonic activity in one of the fibre sets may suppress the impact of a nerve fibre blockade or of an electrical activation This is especially true of certain nerve trunks which contain both excitatory and inhibitory fibres.

The aim of the present study is therefore to explore systematically and when possible with quantitative methods the functional organization of the reciprocal nervous control of colonic motility and blood flow which may be unequally balanced in different parts of the colon. Therefore the following aspects of this control were studied

I The extent to which the vagal and pelvic nerves influence motility and blood flow in various parts of the colon.

II The arrangement of the sympathetic nerve supply and its influence on colonic motility and blood flow as compared with that induced by the vagal and pelvic nerves.

III The site of action of the nerve fibres producing colonic vasodilatation and vasoconstriction, both with respect to the different wall layers and the different consecutive vascular sections.

IV The involvement of the various nerve fibre sets affecting colonic motility and vasodilatation in some of the main reflex patterns known to influence function of the large bowel.

It was thought possible that the results might shed further light on the classical concept that the large bowel—apart from its distal sphincteric section—is comprised by two main functionally differentiated compartments. This opinion has so far been mainly based on theoretical and embryological grounds and on some observations of colonic behaviour in the intact organism. However the organization of the involved control mechanisms that may establish such a differentiated function is still little understood in several important respects.

CHAPTER II

EXTRINSIC NERVOUS CONTROL OF COLONIC MOTILITY

LEIF HULTÉN and MATS JODAL

I. INTRODUCTION

Although the nervous control of motility secretion and blood flow in the gastrointestinal tract has been much studied, the very complexity of the system has caused considerable controversy and many important problems remain unsolved. Recently however the efferent vagal control of motility in the stomach (Martinson 1965) and small intestine (Kewenter 1965) has been explored. Thus, gastric motility seems to be controlled by two vagal fibres; first a low threshold group eliciting the well known tonic effect, secondly a high threshold group which induces corpus-fundus relaxation, secretion and mucosal vasodilatation (Martinson 1965). This latter group is involved in "receptive relaxation of the stomach (Jansson 1967). The relaxation thus elicited does not, however necessarily imply any specific vagal fibres. It may be secondary to the secretory response, as a result of the production of tissue metabolites or/and from a local production of vasodilator agents such as bradykinin or histamine. Furthermore while vagal fibres no doubt increase jejunoileal motility there is no evidence of vagal motor fibres to the more distal parts of the gastrointestinal tract.

With respect to the sympathetic inhibitory control of gastrointestinal motility it appears from physiological studies in the cat as if the splanchnic fibres exert their main possibly even their only direct effect at the ileocaecal region (Jansson and Martinson 1966 Jansson 1969). Presumably they also affect the small intestine (Kewenter 1965) These physiological findings are in agreement with recent histo-chemical studies by Norberg (1964), Jodal (1965) and Jodal (1968)

With regard to the colon, it appears from more recent studies, as mentioned in chapter I that vagal fibres may reach proximal parts of the colon via splanchnic sympathetic fibres while the main pathway

from the pelvic nerves. Several physiological studies suggest that there is a vagal excitatory supply to the proximal colon of rabbits cats and dogs, (Langley 1903 Rentz 1938 Starney 1963 and Fülgraff 1963 a) but other investigators (Bayliss and Starling 1900 Carlson 1930 Wells *et al* 1942) could not provide evidence of such an innervation. Lehmann (1913) suggested that the motility response to vagal stimulation might be secondary to concomitant changes in blood flow Studies on this subject have been reviewed by Lannon and Weller (1947) Alvarez (1948) and Truelove (1966)

The functional relations between the suggested vagal supply to the proximal colon and that derived from the pelvic nerves are not fully understood neither are those between this excitatory supply and the sympathetic inhibitory influence, although Norberg s histo-chemical studies (1964 1965) suggest a ganglionic site for the sympathetic influence also in the colon. The functional significance of the excitatory fibres in the sympathetic colonic supply (see chapter I) remains unknown.

Moreover little is known whether the arrangement of the nervous control of the colonic vascular bed differs in the proximal and distal parts. However as earlier reported (Hultén *et al*, 1968) and described in more detail in chapter III the colonic vasoconstrictor fibres seem to be derived from two sources, those to the proximal third being conveyed in the splanchnic nerves and those to the distal two thirds in the lumbar colonic nerves. This finding might be taken as support of the classical concept that the large bowel is differentiated into two main sections. However with respect to involved regulatory mechanisms, this concept is largely unproven. Therefore the present series of experiments was undertaken to investigate whether the extrinsic nervous control of colonic motility is also so organized as to suggest the presence of two functionally different parts.

II METHODS

A. Operative procedures

Experiments were conducted on 115 cats of both sexes, many of which were also utilized for other purposes. Forty animals were utilized for simultaneous recording of colonic blood flow but the results of these will be described in chapter III The animals fasted for 4–48 hours were anaesthetized with chloralose (50 mg/kg) after induction with ether Body temperature was kept constant at 38°C by means of a thermostatically regulated heating pad under the animal. A tracheal cannula was inserted to allow a free airway A plastic tube was introduced via the mouth into the stomach to permit drainage of secretion and swallowed air and another catheter drained the bladder A femoral artery was connected to a mercury manometer for recording of arterial blood pressure. The animals were usually heparinized (3 5 mg/kg).

The abdomen was opened in the midline and the small intestine was extirpated from the duodeno-jejunal flexure to the ileocecal valve except in some animals where the motility of the small intestine was compared with that of the colon In these experiments the proximal 10–15 cm of the jejunum was left *in situ*, separated from the duodenum,

but otherwise left intact. The colonic and jejunal lumina were rinsed from contents for subsequent recordings of motility

B Recording of motility

The jejunal segment and the proximal third of the colon were each connected to a glass tube, which was connected by rubber tubing to an adaptable pressure reservoir coupled to a piston recorder The system was filled with warm Tyrode solution at body temperature. The proximal colonic segment (approximately one third of the total length of the colon) was isolated from the distal one by a loose ligature, so applied that it did not destroy either extra or intramural nervous or vascular connections or the wall continuity The glass tube to the proximal colonic segment was usually introduced from its distal but sometimes from its proximal end through a small longitudinal incision in the antimesenteric wall. By this arrangement the motility of the distal part of the colon could be separately recorded by means of a similar recording system introduced via the anal canal. The nervous or myogenic influences could therefore be freely transmitted along the largely intact wall or along the intact vascular and nervous connections in the mesentery

C. Nervous stimulations

The *splanchnic nerves* on both sides were cut just beneath the diaphragm nd the peripheral ends were mounted on ring silver electrodes. In most experiments the splanchnic nerves of both sides were stimulated simultaneously Supramaximal square wa o pulses (5 t 8 V 3–5 msec) were delivered from a Grass stimulator model 84 E. Generally frequencies between 4 and 8 imp/sec were used, which corresponds to the upper range of the physiological discharge rates. The *lumbar colonic nerves* were dissected free from the inferior mesenteric artery cut and their distal ends were placed on silver ring electrodes. Since these nerve fibres are postganglionic, a stimulation strength of 10–15 V was used. The *hypogastric nerves* were also cut and in some experiments stimulated in efferent direction. The *pelvic nerves* on both sides were dissected free divided as they emerged from the sacral roots, and their peripheral ends were mounted on electrodes as mentioned above. The stimulation threshold of these fibres was first determined by varying the pulse duration while keeping voltage and stimulation frequency constant. The relationship between voltage and pulse duration was then kept high, enough so as to ensure activation of all the nerve fibres. For determination f frequency response characteristics the nerves were stimulated at supramaximal strength (5–8 V 3–5 msec) The *vagal nerves* were usually dissected free in the neck or in some experiments subdiaphragmatically They were cut and their distal ends mounted on ring electrodes and stimulated with supramaximal square wave impulses (5–8 V 5 msec) and at frequencies between 4–16 imp/sec.

In several of the experiments the nerves were cut after the recording of intestinal motility had started. In some experiments a mesenteric nerve pedicle from the extirpated small intestine was prepared for afferent stimulation to induce intestino-intestinal inhibitory reflexes.

The electrodes were insulated from the surrounding tissues with silicone grease

The catecholamine secretion from the adrenal medullae, known to be potent in producing intestinal inhibition, was eliminated by isolating both adrenals from the circulation by encircling ligatures. Hydrocortisone (10 mg/kg) was given intramuscularly to substitute for the loss of cortisol secretion.

Acetylcholine and l-adrenaline hydrochloride could be infused intraarterially usually via a thin polyethylene catheter introduced in a small mesenteric arterial branch of the superior mesenteric artery or in the inferior mesenteric artery

Other drugs were administered i.v.: atropine (Atropine sulphate, Merck) in a dose of 1 mg/kg b.w., ktorsondamon (Ecolid® Ciba) 2 mg/kg b.w., guanethidine (Ismelin® Ciba) 3–5 mg/kg b.w., phenoxibenzamine (Dibenzyline® Smith, Kline & French) 2–5 mg/kg b.w. and alprenolol (Aptin® Hässle) 1 mg/kg b.w.

III RESULTS

A. Patterns of spontaneous colonic motility

1 *The motility in the non-denervated colonic preparation*

Despite the fact that the animals were starved for 24–48 hours, surgical exposure of the colon revealed that it still contained faeces in most cases. In the distal part they were regularly hard and expanded the lumen, whereas in the proximal part they were mostly soft or semisolid. No clearcut motor activity was seen in either part of the colon at this early stage after laparotomy. After gentle rinsing of the lumen the entire colon was as a rule still largely atonic; at the most faint circular contractions were infrequently seen in the proximal part.

2 *Effects of sympathetic nerve section*

Splanchnic nerve section sometimes caused a slight increase of motility but then in the proximal colon only. In contrast, section of the lumbar colonic nerves resulted in a considerable motility increase in the entire colon, although certain differences could be observed between the proximal and the distal parts. Thus, within less than 30 seconds the distal half or two thirds of the colon slowly contracted and shortened lengthwise, as if it was pulled down in the pelvis. The proximal part of the colon also took part in this mainly longitudinal shortening but only to a slight extent. The main effect in the proximal colon was the occurrence of frequent circular contractions, which swept downward along the proximal third. Subsequently these circular contractions often fused into a vigorous and more sustained circular contraction which again only engaged the proximal part of the colon.

After several minutes the colonic contraction gradually subsided whereby the *distal* part increased in length again although it seemed to retain a slightly higher level of tone compared with that before the sympathetic denervation. Infrequent, slight movements appeared in the wall, indicating a feeble resting motility. Also the motor activity in the proximal part subsided gradually although moderate circular contractions moved to and fro over this section for a longer period of time. This sequence of events upon sympathetic denervation occurred regularly and the characteristically different motility pattern of the proximal part never extended to the distal part of the colon. It should further be stressed that these effects of sympa-

thetic nerve section were largely the same whether the vagal and pelvic nerves had been previously sectioned or not Hypogastric nerve section had no obvious effect on colonic motility

3 *Effects of parasympathetic nerve section*

In another series of experiments the effects of vagal and pelvic nerve section were studied in a similar way However these procedures had no significant effects on prevailing motor activity in either part of the colon whether the sympathetic nerves had been previously sectioned or not Thus, neither rhythmic activity nor "basal tone was appreciably decreased by vagal or pelvic nerve section indicating that these nerve fibres were not significantly tonically active in the present experimental situation.

4 *Volume recordings of spontaneous colonic motility in the denervated proximal and distal parts*

When the pressure on the colonic wall was kept at 10–15 cm H_2O a considerable spontaneous motility was usually present in the acutely denervated preparations Although the pattern of colonic motility varied somewhat between animals, it was regularly very different from that in the small intestine as reflected by the volume changes. While the jejunal activity exhibited frequent rhythmic contractions of small amplitude proximal colonic motility was characterized by relatively slow but powerful volume reductions lasting 10–40 sec On the other hand the pattern of "spontaneous activity in the distal colonic part often differed markedly from that in the proximal one with very slow contractions, occurring far less frequently

Both the jejunal and colonic rhythmic activity seemed to occur at fairly constant levels of "basal tone However this basal tone level was in general not so pronounced in the colon, as judged from the relatively smaller increases of colonic volume that could be induced by intra-arterially injected adrenaline As mentioned above neither the rhythmic activity nor the "basal tone was appreciably decreased by vagal or pelvic nerve section, indicating a very low resting" tonic activity in these nerves in the present experimental situation.

B Effects of graded direct stimulation of the parasympathetic supply

1 *The vagal nerves*

As is shown in Fig 1 vagal stimulation at supramaximal strength produced a characteristic motor response in the proximal colon evident both by direct inspection and by the volume recording Superimposed motility waves of increased amplitude and frequency were seen on a slightly elevated tone. This effect was immediately eliminated upon cessation of stimulation. Even intense vagal stimulation had no effects on

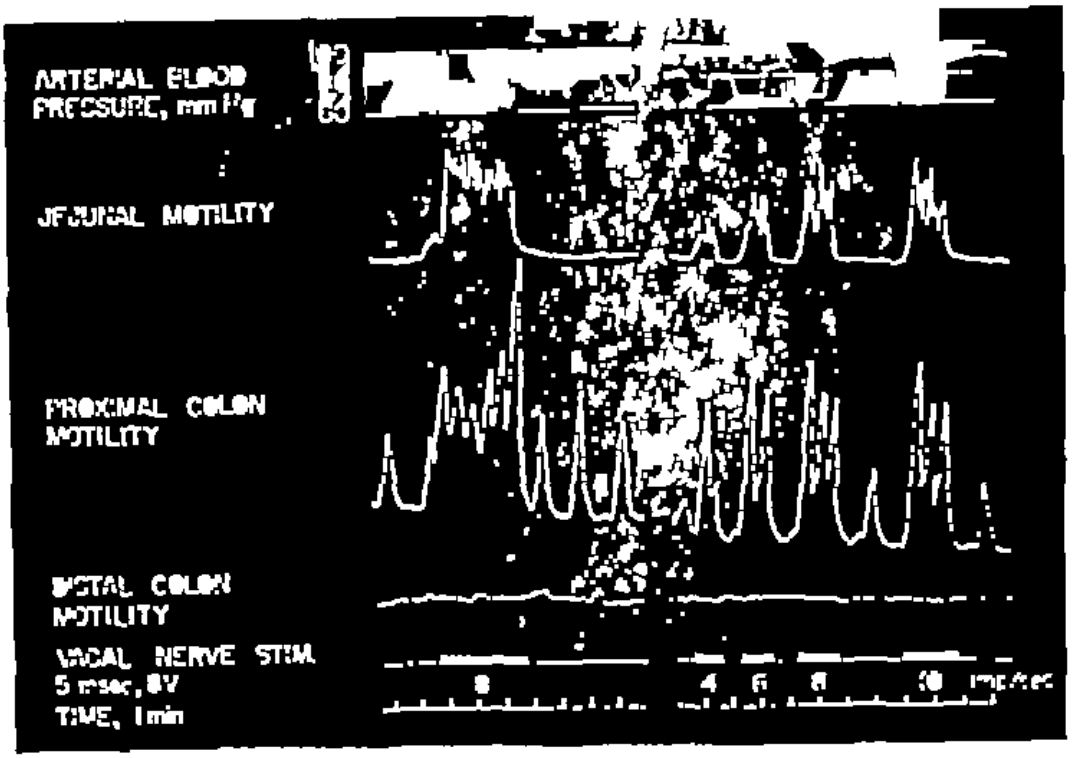

Fig. 1 Cat 3.5 kg Chloralose (Left panel) Effects of efferent cervical vagal stimulation upon proximal and distal colonic motility compared with that of jejunal motility Note the motility waves of increased amplitude and frequency superimposed on the elevated a erage tone. (Right panel) The frequency response relationship for the vagal effect on proximal colon compared with that of the jejunum. The verage volume decreases shown in the figure imply only moderate decreases of the jejunal and colonic lumina.

the distal colon despite the continuity of wall connections. Thus, as is the case with the small intestine vagal stimulation largely intensified the pattern of "spontaneous" rhythmic activity present in the proximal colon, without changing its general characteristics appreciably The same type of motor response was achieved when the vagus nerve (*right dorsal branch*) was *stimulated at the subdiaphragmal level.*

By varying the rate of stimulation, while pulse duration and voltage were kept constant the frequency response relationship for the vagal effect on the proximal colon was found to be similar to that in the small intestine The response increased from low frequencies (1–2 imp/sec) to reach a maximum at 10–16 imp/sec (Fig 1 right panel) Further increases in frequency usually resulted in decreased motor responses but the maximal response was regained once the pulse rate was again lowered to 10–16 imp sec In order to ascertain the stimulation threshold of the vagal excitatory fibres to the colon the pulse duration was varied over a wide range while voltage and frequency were kept constant at 5 volts and 4 imp/sec. A clear colonic response was recorded first when the duration reached 0.8–1 msec. indicating if anything a slightly higher stimulation threshold for these fibres compared to those to th small intestine (see also Kewenter 1965) On further increases of

pulse duration the motor response increased gradually to reach its maximal level for the given frequency at about 3 msec Intravenous administration of atropine (1 mg/kg) blocked the vagal motor response completely There was no evidence of inhibitory vagal fibres to the colon.

2. *The pelvic nerves*

To judge from direct inspection of the colon in situ the characteristics of the motor response to high frequency *pelvic nerve stimulation was very similar to but more* intense than that following section of the lumbar colonic nerves (see page 24) Thus, immediately upon supramaximal pelvic nerve stimulation, there was a sustained contraction of the distal part of the colon which especially shortened in length giving the impression that this part of the colon was forcibly pulled down into the pelvis. Circular contractions here were less prominent The proximal part of the colon also shortened somewhat but the most prominent effect here was a series of circular contractions which rapidly fused into a pronounced and sustained circular contraction limited to this part At the height of this response to high frequency pelvic nerve stimulation the proximal half of colon was transformed into a hard "rod with a largely obliterated lumen and a blanched serosal surface Thus pelvic nerve stimulation evoked an intense and essentially *tonic* contraction of the *entire* colon, provided that the loose ligature separating the proximal and distal parts had not destroyed the continuity of the bowel wall. If, however this ligature was tightened or the wall continuity was broken by cautery the motor response was restricted to the distal segment only even if extramural vascular nervous connections and the colonic mesentery remained intact (Fig 2 right panel)

When colonic motility was studied by means of the volume recorder the motor response to pelvic nerve stimulation occurred within a few seconds in the distal colon segment and in the proximal within another 1–2 seconds. With this type of recording the colonic response to pelvic nerve stimulation was especially characterized by a sustained and powerful reduction of the lumen of both parts, with little sign of rhythmic action, except initially in the proximal part (Fig 2) This response should be contrasted to the vagal response which was characterized by a rhythmicity with only a slightly reduced average volume Furthermore the response to pelvic nerve excitation often declined slowly over several minutes after cessation of the stimulation, again in contrast to the response to vagal stimulation (compare Figs. 1 and 2)

Estimation of the stimulation threshold revealed a motor response to pelvic nerve stimulation with stimuli of 0 08–0 1 msec duration. Frequency and voltage were kept constant at the same levels as during vagal stimulation, i e 4 imp/sec and 5 volt respectively Increasing the pulse duration over a wide range did not provide evidence of any involvement of high threshold inhibitory fibres in the pelvic nerve supply The frequency response characteristics of the pelvic fibres were also

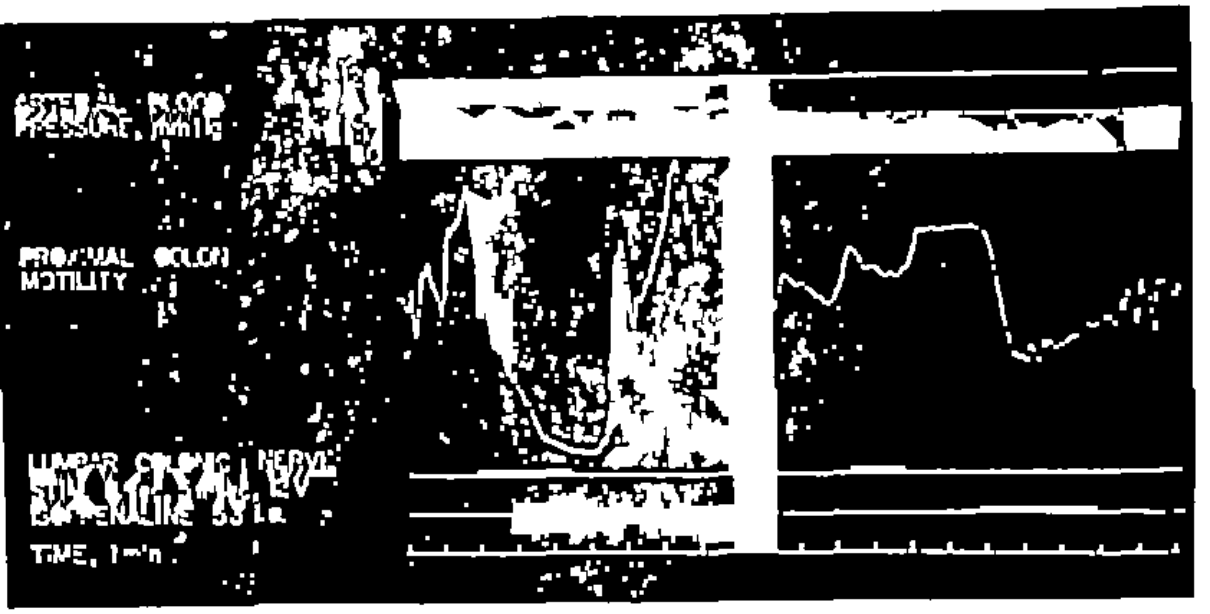

Fig 5 Chloralose Effects of lumbar colonic nerve stimulation upon spontaneous motility in the acutely denervated proximal colon in two different experiments. Left panel shows the prompt inhibitory effect on pronounced spontaneous activity In right panel where "spontaneous activity appeared to be *low* lumbar colonic nerve stimulation had only slight inhibitory effects, whereas intraarterial infusion of isoprenaline relaxed the colonic musculature profoundly

2 *The lumbar colonic nerves*

When spontaneous motility of the proximal and distal colon was weak, stimulation of the lumbar colonic nerves exerted no inhibitory effect until high frequencies were used Then a somewhat delayed inhibition occurred. On the other hand in experiments where spontaneous motility was pronounced indicating a high level of intramural ganglionic activity even low frequency stimulation induced prompt inhibition (Fig 5) Similarly vagally induced motor activity in the proximal colon and the more sustained motor response of the entire colon to pelvic nerve stimulation were both dramatically and promptly inhibited—perhaps less strongly so in the distal colon—by stimulation of the lumbar colonic nerves (Fig 6) This was the case even when low frequencies were used. In contrast colonic motor responses of similar size produced by intraarterially infused acetylcholine were not influenced by stimulation of the lumbar colonic nerves (Fig 7) The inhibitory effect of sympathetic stimulation on the pelvic nerve response was the same before and after atropine administration.

Lumbar colonic nerve stimulation after administration of guanethidine often induced powerful but usually transient contraction of both colonic parts, an effect that was readily blocked by atropine Such effects were never obtained upon splanchnic nerve stimulation after guanethidine

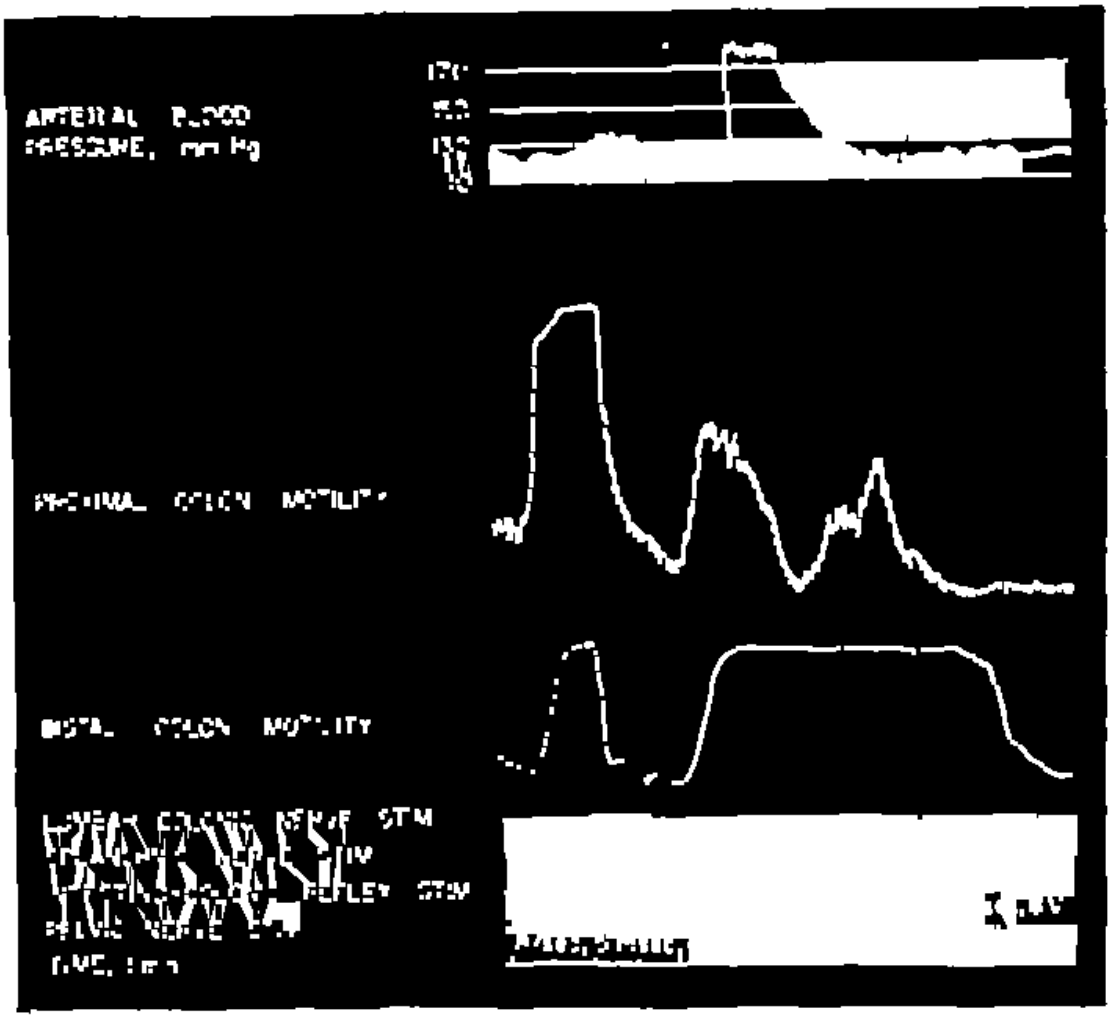

Fig 6. Cat 3.8 kg Chloralose. Effects of lumbar colonic nerve and splanchnic nerve stimulations upon colonic motility induced by pelvic nerve stimulation. Note the sustained contraction of both proximal and distal colonic parts upon pelvic nerve stimulation. The motility is similarly and promptly inhibited in both parts of the colon by lumbar colonic nerve stimulation. In contrast, splanchnic nerve stimulation inhibits only proximal colonic motility N t also that intestino-colonic reflex inhibition occurs readily in the proximal colonic part whereas no effect whatsoever can be traced in the distal part of the colon.

3 *The hypogastric nerves*

Stimulation of the hypogastric nerves in the distal direction had no inhibitory effect on the spontaneous or parasympathetically induced motility of the colon, despite the rate and strength was varied over a wide range Excitatory effects similar to those obtained on lumbar colonic nerve stimulation after administration of guanethidine were never observed

IV COMMENTS

The present results of efferent vagal and pelvic nerve stimulation on the acutely denervated colon of the cat suggest that the vagal nerves affect the *proximal* part of

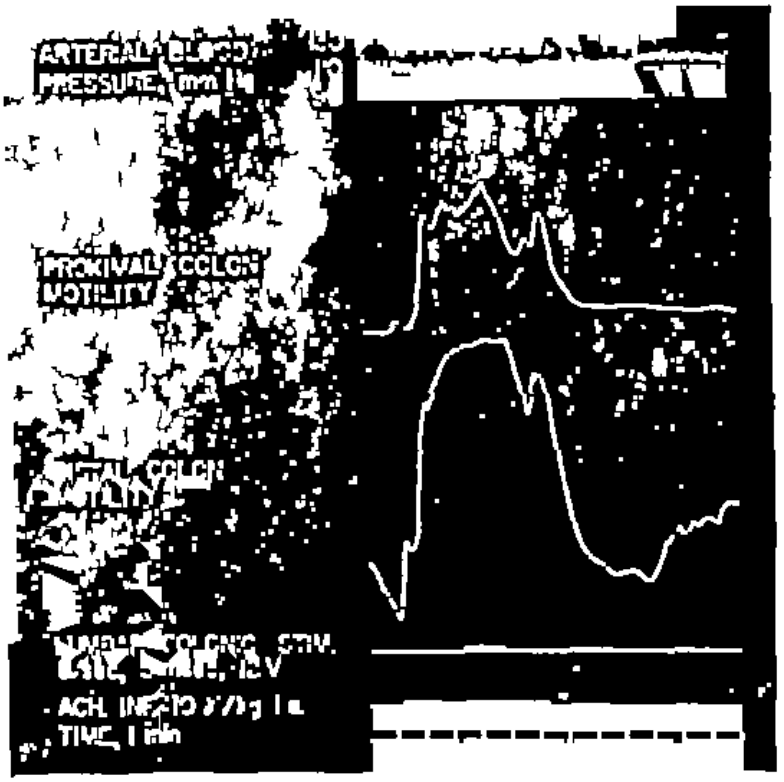

Fig 7 Cat 3.1 kg. Chloralose Effects of lumbar colonic nerve stimulation upon colonic motility induced by intrarterial infusion of acetylcholine N inhibitory effects whatsoever can be seen either in the proximal or in the distal part.

the colon only while the pelvic nerves affect almost the entire colon. This is in accordance with the morphological results of Schmidt (1933) who after vagal section traced degenerated nerve fibres only to the proximal colonic parts whereas this was found largely in the entire colon after division of the pelvic nerves. The opinions as regards a vagal supply to the colon are as mentioned, contradictory Whereas many investigators (Rentz 1938 Stavney *et al* 1963 Fülgraff and Schmidt 1963 a) have reported excitatory responses in proximal colonic parts in rabbits cats or dogs others (Bayliss and Starling 1900 Carlsson 1930 Wells *et al* 1942) denied the existence of an excitatory vagal influence on the colon

The divergent results of these earlier studies might be due to differences in the influence of sympathetic activity whether nervous or hormonal. No doubt sympatho-adrenal activity may markedly even completely suppress motor responses to parasympathetic stimulation in the gastrointestinal tract This is illustrated both in the present experiments and in those of e.g Celander (1959) Kock (1959) and Kewenter (1960) The fact that Fülgraff and Schmidt (1963 a) and Stavney *et al* (1963) did observe vagal motor responses in proximal colonic parts may be due to their experimental condition as they had cut the splanchnic nerves in order to allow for their direct stimulation An alternative explanation may also be that the spinal medulla in one of these experimental series was destroyed This procedure will block the

sympathetic intestino-intestinal reflex inhibition which is spinally mediated (e.g Johansson and Langston 1964) The powerful suppressing effects of a tonically active sympathetic supply upon cholinergic activity in the colon is also clear from the present experiments. This is illustrated by both the drastic release effects of sympathetic section and by the effects of graded stimulations of the cut sympathetic nerves.

The exact morphological distribution of vagal fibres to the colon cannot be determined by stimulation experiments alone However the functional extension of their impact can be shown since extrinsic excitation of only part of the intramural ganglionic plexuses appears to trigger a spread of activity along the entire colonic wall provided that its continuity is not broken. In the present experiments the colonic lumen was separated into a proximal and a distal part without disruption in the continuity of either the wall or the mesentery

According to Wright *et al* (1938) the fibres of pelvic nerves run within the colonic wall This could be confirmed in the present study since the proximal colonic segment no longer responded to pelvic nerve stimulation when the colonic wall was crushed although extramural vascular and mesenteric connections were intact Thus the preparation was shown to allow for free transmission of nervous or myogenic influences along the entire colon Nevertheless, excitatory responses to vagal stimulation were always restricted to about the proximal third of the colon No effects were ever observed in the distal colon. It therefore seems justified to conclude that the vagal supply is restricted to about the proximal third of the colon and that their influence here does not spread along the intrinsic plexuses or by myogenic propagation to distal parts.

The vagal excitatory effect on the proximal colon characteristically enhanced the extent and rate of spontaneous rhythmic activity in a fashion which would greatly improve mixing and stirring of the contents rather than causing any gross expulsion. The average reductions of the colonic lumen were usually small Furthermore these vagal effects were completely blocked by atropine indicating a cholinergic transmission. In contrast the motor response to pelvic nerve stimulation was characterized by a more steady *overall* contraction—although the proximal and distal parts were involved in somewhat different ways as described in Results—a type of activation that would favour expulsion rather than mixing The pelvic nerve response was not significantly reduced by atropine, but became somewhat delayed and occasionally it was preceded by slight motility decline

It is of interest that the different motility responses in the proximal and distal colonic parts to pelvic nerve activation (described in detail in Results) are not necessarily the result of a different mode of action of these nerve fibres in the two parts, although such a difference may well exist Thus even in colonic preparations where all extrinsic nerves had been cut the same difference can be traced in the far less powerful spontaneous motility patterns of the two parts Rhythmicity is a more prominent feature in the proximal part while the distal part exhibits more sustained and generalized contractions. Whether these regional differences in spontaneous motility are

inherent in the functional characteristics of the intrinsic plexuses or in the myogenic activity or both is not known.

It should however also be stressed with respect to the proximal colon that the vagal effect mainly enhances the rate and extent of the inherent rhythmicity while the regional pelvic nerve effect is particularly characterized by a powerful and an ultimately sustained contraction of the circular wall layer which causes almost complete emptying These differences in nerve effects on the same effector suggest that the two types of parasympathetic nerves affect the intramural ganglionic plexuses in different ways This is also suggested by the striking differences in atropine sensitivity between the vagal and pelvic nerve effects. These findings agree with observations in man by Fink and Friedman (1960) who reported a clear difference in the motility response of the proximal and distal colonic parts upon intravenous administration of mecholyl and neostigmine This was taken to support the view that the human colon may be composed of two functionally different segments with the line of division in the transverse part of the colon. The above investigators also suggested that a different concentration of cholinesterase in the two parts of the colon might be a possible explanation for the different effects of drugs on the proximal and distal colonic parts.

The resistance of the pelvic nerve effect to atropine was noted by Langley and Anderssen (1895) and more recently by Fülgraff and Schmidt (1963 b 1964) Garry and Gillespie (1955) however studied an isolated cat colon preparation in an organ bath and showed that the pelvic nerve effect could in such a preparation be completely abolished by atropine. It is possible that both a cholinergic and a non-cholinergic link might be involved in the colonic motor response to pelvic nerve stimulation and that only the cholinergic link can be traced in preparations in vitro In fact the motor response can evidently be abolished by atropine also in preparations in vivo if the colonic vascular bed is perfused with Tyrode solution instead of with blood (Fülgraff and Schmidt 1963 b) On the basis of such experiments Fülgraff claimed that a plasma component might be responsible for the atropine-resistant contraction. Although the extent of the pelvic nerve response was not significantly reduced after atropine in the present experiments it became obviously delayed in onset This might suggest the presence of some indirect excitatory link, resistant to atropine which becomes fully efficient only after a period of stimulation.

Similar findings indicating the release of excitatory factors other than acetylcholine at some parasympathetic neuro-effector junctions have been made concerning the bladder contraction to pelvic nerve stimulation (Eckert 1962 Edwardsen 1967) Furthermore the vasodilatation occurring in salivary glands upon parasympathetic stimulation is at least in part due to such mechanisms (Hilton and Lewis 1956) Lastly the gastric relaxation induced by the vagal high threshold fibres is also uninfluenced by both atropine and guanethidine (Martinson 1965) It is possible that in most perhaps all of these situations a release of plasma kinins might be involved in a similar way as bradykinin (or rather kallidin) release is involved in the

neurogenic vasodilatation in the salivary glands (Hilton and Lewis 1955 1956) Both in the stomach and in the colon (see chapter IV) the secretory responses to parasympathetic stimulation are closely connected to profound and atropine-resistant mucosal vasodilatations as well as to atropine resistant motility changes—relaxation in the stomach and contraction in the colon. As mentioned above the atropine-resistant motility response of the colon might be dependent on the presence of normal blood plasma If this is also the case with respect to the vagally induced gastric relaxations is not known

The inhibitory action of the splanchnic nerves on colonic motility is restricted to the proximal third where it strongly suppresses the excitatory influence of both the vagal and pelvic nerves. The sympathetic lumbar colonic nerves on the other hand suppress both vagal and pelvic nerve effects in the entire colon. It should be noted that the lumbar colonic nerves affect the colonic vascular bed only in the distal parts of the colon (Hultén *et al* 1968) This implies a distinct difference in the distribution of the sympathetic fibres to colonic blood vessels and to the colonic wall proper

Furthermore, the sympathetic inhibitory influence on intestinal motility—whether mediated by splanchnic or lumbar colonic nerve fibres—seems to be predominantly and perhaps only conveyed via an action on the intramural plexuses rather than on the smooth muscles directly Thus even low frequency stimulation of the sympathetic supply profoundly suppresses parasympathetically induced effects throughout the colon, or an inherent activity of the intramural ganglionic plexuses. On the other hand, sympathetic stimulation at "physiological rates has virtually no effect on such motility presumably of myogenic nature which is induced by mild distension. Similarly it has no effect on the motility induced by acetylcholine infusion which causes a muscarine-like activation of the intestinal smooth muscles directly Such a combination of observations appears to be consonant only with the view that the *major* perhaps sole sympathetic effect is exerted at the intramural ganglionic level. This is also suggested by histo-chemical studies (Norberg 1964 Jacobowitz 1965 Schofield 1968)

Inhibition of spontaneous jejunal activity by splanchnic nerve stimulation is according to Celander (1959) essentially due to overflow of the vasoconstrictor transmitter since these inhibitory effects were seen only when "supraphysiological frequencies were used In contrast to this intra-arterial injections of even small amounts of catecholamines brought about immediate and prompt jejunal inhibition. It is likely that in Celander s experiments the jejunal motility studied was largely of a myogenic nature with only little influence from intramural nerve plexa In fact in his preparations these plexa may have been reflexly suppressed via adrenergic connections other than those conveyed in the splanchnic nerves. It is now known that such extra-splanchnic sympathetic connections are present and that they readily convey intestino-intestinal inhibitory reflexes which are indeed often continuously active in experimental preparations of this type (cf. Johansson and Langston 1965) In any

case Celander's results do not support the view that the jejunal smooth muscles should be directly influenced by sympathetic inhibitory fibres to any *significant extent*. The results of Kock (1959) obtained with a similar technique indicate that centrally and reflexly induced inhibition of intestinal myogenic activity is mainly or solely dependent on the *hormonal* component of the sympatho-adrenal system are also consonant with such a view.

However when the intramural plexuses of the colon are active, whether "spontaneously" or due to a superimposed parasympathetic activity such a neurogenic excitatory influence is strongly counteracted by even low frequency activation of the sympathetic fibres. This suggests that there is an adrenergic influence mainly or perhaps only confined to the *ganglionic* level at least in the cat (Norberg 1965 Kewenter 1965 Jansson and Martinson 1966 Jansson 1969). The present results are in full agreement with such a view with respect to the sympathetic control of the colon.

In most of the present experiments where the adrenals were excluded and the splanchnic as well as the lumbar colonic nerves were divided vagal motor responses were nevertheless often difficult to produce until the animal had been left undisturbed for about an hour after the abdominal operation. This suggests that the remaining peritoneal intestinal reflex inhibitions via "aberrant" sympathetic fibre connections to the proximal colon might interfere with the vagal motor response (see chapter VI) as is also the case with the small intestine (Johansson and Langston 1964).

Excitatory apparently cholinergic fibres distributed to largely the entire colon within the lumbar colonic nerves were revealed first after guanethidine administration. This is in accordance with the reports given by Day and Rand (1961) and Boyd *et al.* (1962). The functional significance of these fibres are obscure. Their possible involvement in the reflex control of colonic motility are briefly explored in chapter VI.

Thus there seems to be a clearcut difference not only in distribution, but also partly in function as well between the splanchnic and lumbar colonic nerves as to their suppressing effects on the proximal and distal parts of the colon. The proximal part has in this respect a dual innervation, where the splanchnic supply seems to be involved in "long" intestino-intestinal reflexes while the lumbar colonic supply mediates a tonic possibly centrogenic inhibitory influence (see also chapter VI). Only the latter type of influence effects the distal colon. This again may lend further support to the view that the two colonic parts—despite a considerable overlap—are specialized for different functions as reflected here by this difference in sympathetic inhibitory control. It should also be stressed that the sympathetic vasoconstrictor fibre supply is derived from two sources but then with a fairly distinct borderline between them (see chapter III).

Furthermore the motor response patterns are also different with respect to the vagal influence. Enhanced rhythmic activity is produced in the *proximal* part in a way which would considerably enhance stirring and mixing. On the other hand the

pelvic nerve influence produces strong and sustained contractions favouring expulsion, affecting the proximal and distal segments somewhat differently These observations fit nicely with the classical concept of a differentiated function of proximal and distal colonic parts and indicate by which means this differentiation is achieved

In general the present findings help to explain the establishment of the colonic motility patterns observed in intact organisms, first studied by means of X ray in awake cats by Cannon (1902) and confirmed by M'Fadden *et al* (1935) Their observations suggest that movements characterized as "rhythmic antiperistaltic waves" withhold the contents in the proximal colon until sufficiently dried by absorption. The "ring of contractions of the proximal colon regularly occurring after meals ultimately propelled the contents further down into the descending part of the colon At the same time the liquid contents of the ileum were once again delivered to the caecal part of the colon However this pattern of colonic motility evidently favouring absorption, differed markedly from that during defaecation when extensive contractions pulled almost the entire colon towards the pelvis by a shortening predominantly of the descending colonic part.

The present experiments indicate that the vagi may be concerned with the above mentioned *rhythmic* motility the proximal colonic parts apparently being of importance for the absorption of water and salts by its stirring and mixing effect The pelvic nerves on the other hand are called into action to produce a powerful generalized and sustained colonic contraction specifically designed for expulsion. However the difference in motility patterns between the proximal and distal colonic parts can also be due to their *inherent* wall activities. This of course does not deny that the various parasympathetic nerves in different ways affect the intrinsic plexuses to achieve the mentioned differences of function and extrinsic control in the two colonic parts

Thus, in the cat colon these two functions appear to be controlled by separate sets of reciprocally acting parasympathetic and sympathetic fibres, but they are also dependent on the wall elements themselves. However the two functions obviously overlap somewhat morphologically which is also indicated by the fact that the distribution of the different nerve fibre sets overlaps somewhat in the proximal and distal parts. Thus the lumbar colonic nerves—both their inhibitory and excitatory fibres—as well as the pelvic nerves extend their effects on colonic motility to largely the entire colon, while the splanchnic and vagal nerves are in this respect confined only to the *proximal* third. The vasomotor control is more distinctly separated in the two colonic parts, both with respect to the sympathetic and pelvic nerve influence (see chapter III) It is possible that the spatial overlap of function and motility control is less prominent in man.

Lastly it is interesting to compare the dual vagal control of the stomach with the dual parasympathetic control of the colon, both being reservoir organs but one specialized for rapid reception, the other for rapid evacuation. The stirring and mixing functions appear in both organs to be directed by vagal excitatory fibres, while the

adjustments of the reservoir *per se* are effected by a specific set of nerves in both organs Here the vagal relaxatory fibres (Martinson 1965 Jansson 1969) accomodate the corpus-fundus regions of the stomach for reception, and in a similar fashion the pelvic nerves, by their powerful contractile influence, command the emptying of the reservoir placed at the other end of the gastrointestinal system

CHAPTER III

EXTRINSIC NERVOUS CONTROL OF COLONIC BLOOD FLOW

L. HULTÉN, M. JODAL and O. LUNDGREN

I. INTRODUCTION

There are, as mentioned in chapters I and II, reasons to believe that the colon may be comprised by two functionally different parts, a view that seems to be in agreement also with its embryological development. Thus, according to the classical concept the proximal part would be preferentially involved in water and salt absorption while the distal part would be essentially concerned with storage and subsequent expulsion. Several reports indicate that also the extrinsic nervous control of the colon may be so organized as to suggest such a functional differentiation and some of the findings reported in chapter II concerning the motility control are in agreement with this.

However, despite much effort during earlier years to clarify these problems experimentally, the great technical difficulties involved have in several important respects led to conflicting results and opinions. This is also true with respect to the exact distribution and mode of action of the vagal, pelvic and sympathetic innervation as regards blood flow.

The present chapter deals with the effects on colonic blood flow induced by the efferent sets of extrinsic nerves with particular respect to the localization and gross extent of their vascular actions. Since it is known that electrical stimulation of the lumbar colonic nerves causes blanching of the mucosa in distal parts of the colon (e.g. Langley and Anderssson 1895, Wright *et al.* 1938), it is, for example, tempting to suppose that corresponding vascular effects may be induced in proximal parts by splanchnic nerve fibres, though no such studies appear to be available. It is furthermore known that the pelvic nerves contain fibres which on stimulation induce flushing of the mucosa in distal parts of the cat colon (Langley and Anderssson 1895, Wright *et al.* 1938). On the other hand, it is not known as to what an extent similar

effects are also induced in proximal parts of the colon or whether the vagal supply may here exert such effects. Should such a regional differentiation exist with respect to the nerve fibres, affecting not only motility but also blood flow in the corresponding region this would lend further support to the concept that the colon is functionally comprised by two different parts It is, however evident that the morphological borderlines between the mentioned differentiated functions i e absorption and storage expulsion, can hardly be expected to be distinct a considerable overlap seems likely

II METHODS

A. Operative procedures

Observations were carried out on 73 cats, fasted for 24 hours. After induction with ether they were anaesthetized intravenously with chloralose (50 mg/kg) A tracheal cannula was inserted The abdomen was then opened in the midline and the entire small intestine was extirpated together with the greater omentum and the spleen. The animals were heparinized (3–5 mg/kg b.w) and a femoral artery was connected to a mercury manometer for recording of arterial blood pressure The animals were kept on a heating pad which was thermostatically regulated so that the body temperature was kept around 37–38 C A plastic tube was introduced via the mouth into the stomach to permit drainage of secretion and swallowed air and another catheter drained the bladder

In some experiments (18 cats) the colon was cautiously split with thermo-cautery along its antimesenteric border from the caecum down to the peritoneal deflection border The cut edges were fixed with pins on a cork plate thus exposing the mucosa for direct inspection during stimulation of the different sets of nerve fibres. Great care was taken to keep the exposed colon at body temperature by means of steady superfusion with warm Tyrode solution and with a heating lamp under temperature control.

B Determination of blood flow and blood volume

To establish the magnitude of the overall colonic blood supply the total venous outflow was recorded, either simultaneously with the visual inspection of the mucosa or with an intact mesentery For this purpose a wide-bore polyethylene tube was inserted into the superior mesenteric vein, distally to its confluence with the splenic vein *Since a minor portion of the blood supply to the distal part of the colon is probably* drained by small veins close to the anal region, these small venous connections were ligated so that the venous drainage occurred via the superior mesenteric vein exclusively The venous outflow from the colon was then diverted to a closed perspex drop chamber filled with paraffin oil and returned to the animal via the right external jugular vein An optical drop counter operated an ordinate writer which recorded the flow rate on smoked kymograph paper The height of the ordinates are largely inversely proportional to the rate of the blood flow and by means of a calibration curve the height of the ordinates could be directly converted into flow in ml min. In experiments where the colonic arterial blood flow was simultaneously recorded the left carotid artery was cannulated and connected via a drop recording unit with the superior mesenteric artery By using siliconized tubes of wide lumenmens and keeping them as short as possible the flow resistance of the

recording system was minimized. Peripheral resistance units (PRU_{ss}) were calculated as the ratio of mean arterial blood pressure to blood flow (ml/min × 100 g tissue).

The blood volume contained within the acutely denervated colonic preparation and its mesentery in the steady state was estimated at the end of a number of experiments. A sample of venous blood from the colon was drawn while at the same time the colonic vessels were suddenly clamped. The tissue blood content was washed out with a known amount of dextrane Tyrode solution and the haematocrit and/or haemoglobin content of this sample, as well as the venous sample, were determined. The blood volume could be deduced from the extent of dilution caused by the known amount of dextrane Tyrode solution. A slight underestimation of the blood volume can be expected with this technique as the haematocrit in the small vessels should be somewhat lower than in venous blood.

C. Nervous stimulations

The extrinsic nerves to the colon were in all experiments prepared for subsequent stimulation in the following manner:

The *splanchnic nerves* on both sides were cut just beneath the diaphragm and the peripheral ends were mounted in ringformed silver electrodes. In most experiments the splanchnic nerves of both sides were stimulated simultaneously. Supramaximal square wave pulses (5 to 8 V, 2–5 msec) were delivered from a Grass stimulator, model S4 E. Generally between 4 and 8 imp/sec were used, which corresponds to the upper range of the physiological discharge rates. In some experiments the sympathetic nerves were dissected periarterially for subsequent postganglionic stimulation. The stimulation strength was in these cases raised to 10–12 V.

The *lumbar colonic nerves* were dissected free from the inferior mesenteric artery, cut and their distal ends were placed on silver ring electrodes. Since these nerve fibres are postganglionic, a stimulation strength of 10–12 V was used. This was also the case when *the hypogastric nerve* were stimulated in a few experiments.

The *pelvic nerves* on both sides were dissected free, divided as they emerged from the sacral roots, and their peripheral ends were mounted on electrodes as mentioned above. The stimulation threshold of these fibres was first determined by varying the pulse duration while keeping voltage and stimulation frequency constant. The relationship between voltage and pulse duration was then kept high enough so as to ensure activation of all the nerve fibres. For determination of frequency-response characteristics the nerves were stimulated at supramaximal strength (5 V, 5 msec).

The *vagus nerves* were dissected free in the neck or in some experiments subdiaphragmatically. They were cut and mounted on ring electrodes and stimulated with supramaximal square wave impulses (5–8 V, 5 msec) and at frequencies between 4–16 imp/sec.

In order to prevent the secretion from the adrenal medullae from interfering with the direct nervous effects on the colonic vessels, both adrenals were excluded from the circulation by encircling ligatures. 10 mg hydrocortison was given intramuscularly for substitution.

In 18 cats the respective weights of the proximal and distal colonic segments blanched by splanchnic and lumbar colonic nerve stimulation were determined when the experiments were finished.

Acetylcholine and isopropyl-noradrenaline (INA) could be infused intraarterially to the respective intestinal segments, usually via a thin polyethylene catheter introduced into a small mesenteric arterial branch.

Other drugs were administered i v atropine (Atropin sulphate Merck) in a dose of 1 mg/kg b.w., hexamethonium (Ecolid© Ciba) 2 mg/kg b w., guanethidin (Ismelin© Ciba) 3–5 mg/kg b w., phenoxibenzamine (Dibenzyline© Smith Kline & French) 3–5 mg/kg b w., and alprenol 1 (Aptin© Hässle) 1 mg/kg b w

III. RESULTS

A. Effects of graded direct stimulation of the sympathetic supply

Fig 1 (upper panel) shows typical vascular responses in the colonic mucosa upon splanchnic and lumbar colonic nerve stimulation, respectively Stimulation of the *lumbar colonic nerves* (Fig 1 A) at a high physiological frequency (8 imp/sec) produced a drastic blanching of the mucosa in the *distal* 1/3–3/4 of the colon with a relatively distinct borderline towards the proximal segment which did not show any significant change The mucosa remained blanched throughout the period of stimulation followed by a transient reddening upon cessation of the stimulation.

A similar drastic and sustained mucosal blanching occurred in the *proximal* part of the colon upon stimulation of the *splanchnic nerves* (Fig 1 B) the response showed a borderline zone of overlap towards the caudal 2/3–3/4 of the colon. The distal sections were quite uninfluenced by the splanchnic stimulation. Cessation of the stimulation was also followed here by a transient period of mucosal flushing Simultaneous stimulation of the two vasoconstrictor fibre sets led to a uniform blanching of the entire colonic mucosa (Fig 1 C) No change in colour was observed in the exposed part of the colonic mucosa, when the hypogastric nerves were stimulated in the distal direction, however The proximal colonic portion controlled by the splanchnic nerves and the distal portion controlled by the lumbar colonic nerves comprised some 30 and 70 per cent respectively of the total colonic weight.

The lower panel of Fig 1 illustrates the shifts in venous outflow from the colon induced by stimulation of the different sets of vasoconstrictor fibres. Resting" blood flow of the colon was in most experiments approximately 15–25 ml/min × 100 g tissue As with the case with the small intestine (Folkow *et al* 1964*a*) the neurogenic constriction of the colonic resistance vessels exhibited two phases. First a transient but intense flow reduction was seen reaching its maximum within 30–40 sec and corresponding in time of onset with the mucosal blanching This initial flow reduction subsided within 2–3 minutes and was followed by a second phase of sustained but less intense flow reduction, whereas the intense mucosal blanching was kept virtually unchanged throughout the stimulation period A profound reactive hyperaemia occurred at cessation of the stimulation. Analogous to the situation in the small intestine the decline of the overall neurogenic flow reduction may be called an autoregulatory escape from the constrictor fibre influence A small, almost negligible, increase in resistance occurred in some experiments when the hypogastric nerves were stimulated in the distal direction at high frequencies

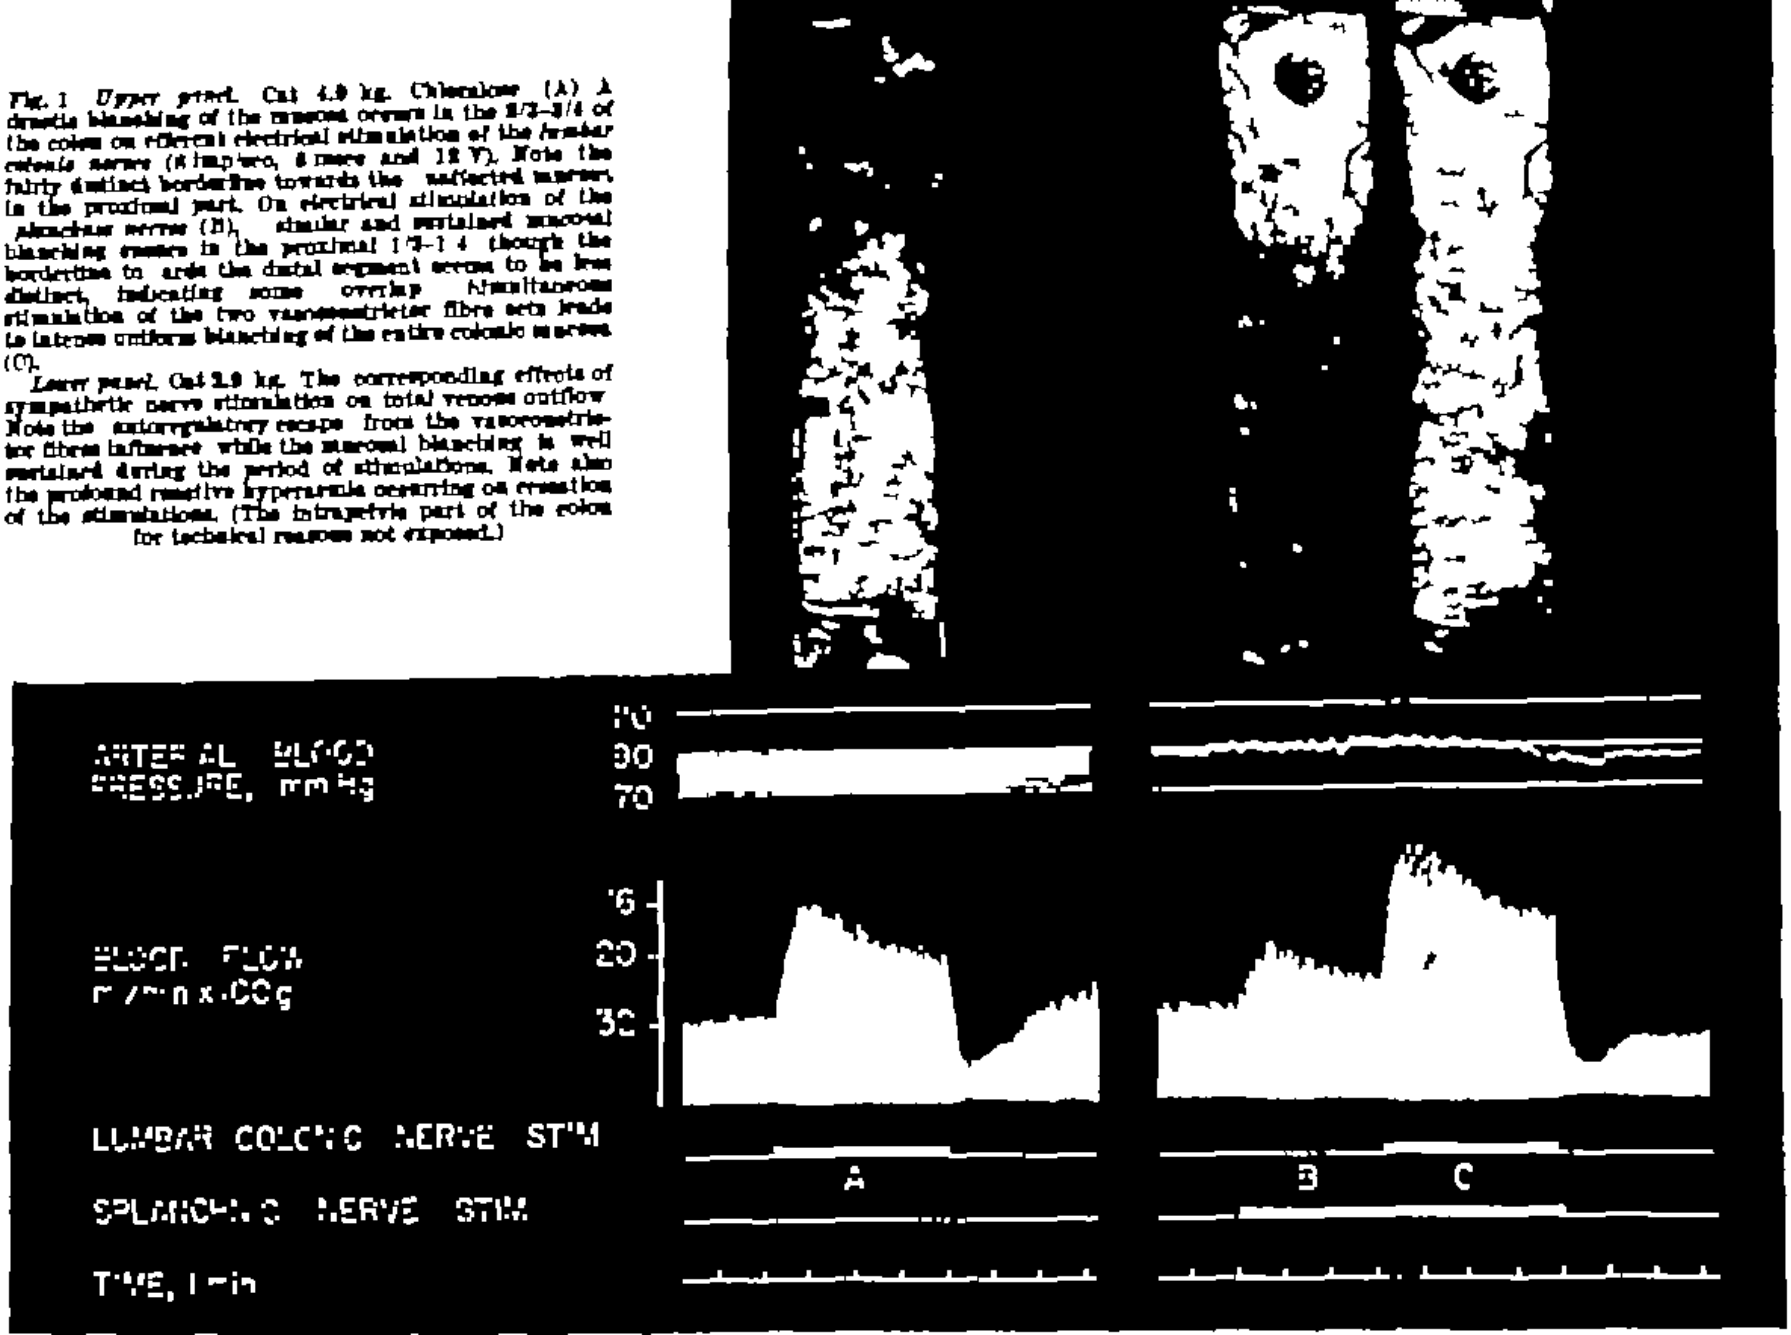

Fig. 1. Upper panel. Cat 4.0 kg. Chloralose (A) A drastic blanching of the mucosa occurs in the 2/3–3/4 of the colon on efferent electrical stimulation of the *lumbar colonic nerves* (6 imp/sec, 6 msec and 12 V). Note the fairly distinct borderline towards the unaffected mucosa in the proximal part. On electrical stimulation of the *splanchnic nerves* (B), similar and sustained mucosal blanching occurs in the proximal 1/3–1/4 though the borderline to ards the distal segment seems to be less distinct, indicating some overlap. Simultaneous stimulation of the two vasoconstrictor fibre sets leads to intense uniform blanching of the entire colonic mucosa (C).

Lower panel. Cat 2.9 kg. The corresponding effects of sympathetic nerve stimulation on total venous outflow. Note the autoregulatory escape from the vasoconstrictor fibres influence while the mucosal blanching is well sustained during the period of stimulations. Note also the profound reactive hyperaemia occurring on cessation of the stimulations. (The intrapelvic part of the colon for technical reasons not exposed.)

In experiments where guanethidine had been administered in doses that entirely block adrenergic transmission, stimulation of the sympathetic nerves had no effect on vascular resistance. Thus no vasodilator effects could be observed on activation of the cholinergic fibres which are suggested to be distributed in the lumbar colonic nerves (see chapter II).

Following activation of either or both splanchnic nerves there was a considerable (20–60 mm Hg) increase in systemic blood pressure evidently due to vasoconstriction and blood expulsion in other abdominal viscera i.e. in the stomach, liver and kidneys. Thus no significant pressure increase resulted upon stimulation of the lumbar colonic nerves or by periarterial stimulation of postganglionic splanchnic fibres running along the superior mesenteric artery and its branches to the colon. However independent of the site of vasoconstrictor fibre stimulation the vascular reactions in the appropriate parts of the colon were essentially the same.

B. Effects of graded direct stimulation of the parasympathetic supply

1 *The vagus nerves*

No obvious change in colour of the colonic mucosa could be traced upon activation of the vagal nerves, whether when stimulated at the cervical or subdiaphragmatic levels. Vagal stimulation did not produce any decrease in colonic blood flow resistance that could be ascribed to any direct dilator action of these fibres. Thus upon vagal stimulation in the neck venous outflow from the colon was somewhat reduced which is explained by a fall in the pressure head. No changes in colonic blood flow were seen when the vagal fibres were activated at the subdiaphragmatic level.

2 *The pelvic nerves*

Bilateral stimulation of the pelvic nerves produced a marked flushing of the colonic mucosa (Fig. upper panel) which seemed to spread in the proximal direction until it engaged some 2/3–3/4 of the colon or largely the portion of the colon that was blanched by stimulation of the lumbar colonic nerves. The remaining proximal part of the colonic mucosa showed no significant change in colour although there was no distinct separating borderline. The colour was first bright red but after about one minute of sustained stimulation the bright mucosal redness in the mucosa seemed to change into a flush tinged colour. Concomitant with the flush a contraction of the colon occurred and a transparent mucoid secretion was obvious, at least in the distal part.

Fig. 2 (lower panel) illustrates the change in total colonic blood flow that occurred simultaneously with the above mentioned mucosal flushing upon pelvic nerve stimulation. Within 5–10 sec after commencement of the pelvic nerve stimulation blood flow increased rapidly to reach maximum in 20–30 sec. However this initial flow increase was transient beginning to vanish after 30–40 sec. and only occasionally

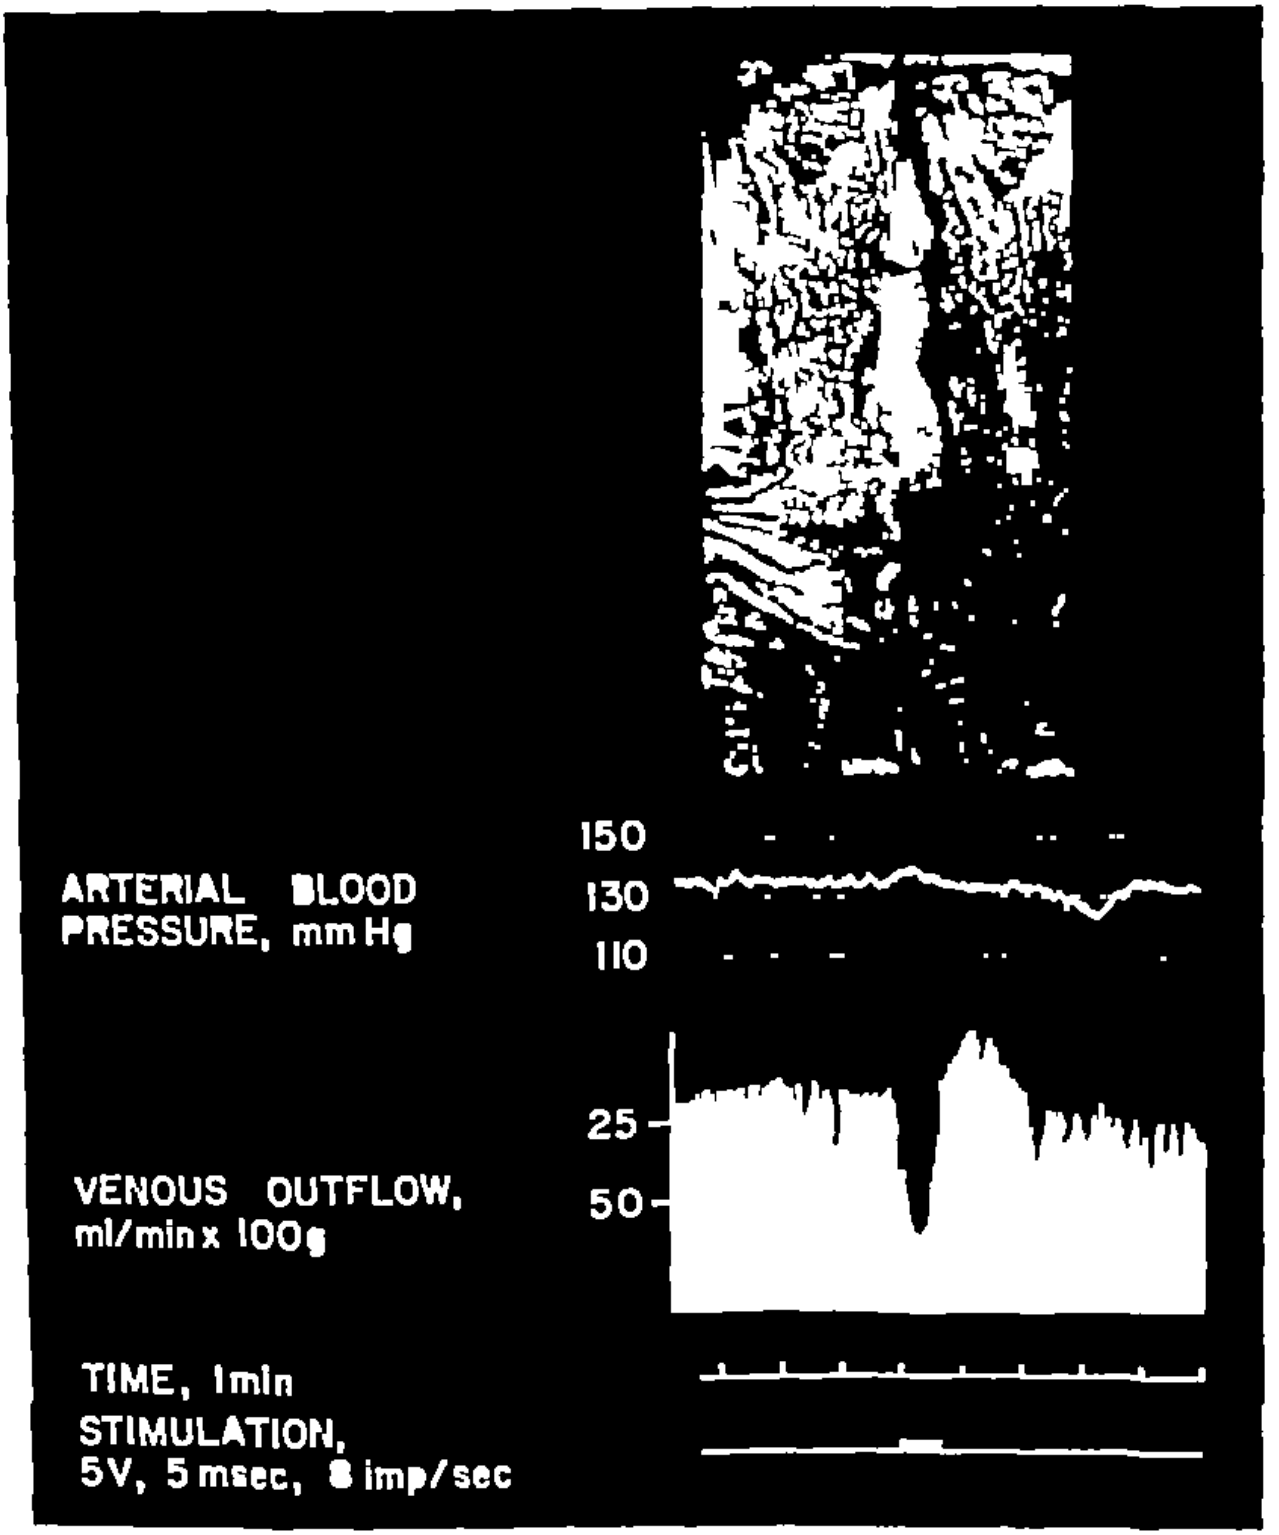

Fig 2. *Upper panel.* Cat 4.0 kg Chloralose A marked mucosal flushing occurs upon efferent pelvic nerve stimulation. This redness is exhibited at least in the distal 2/3–3/4 of the colon while the proximal part seems to be unaffected. Note the motor contraction, especially marked in the distal colonic part.

A corresponding transient blood flow increase is shown in *lower panel* Cat. 4.2 kg Note the phasic reduction of blood flow

lasting more than 1½ min This return towards the resting" blood flow level despite continued stimulation corresponded in time to the change in colour of the hyperaemic mucosa from bright red to bluish.

A blood flow increase was evident already upon stimulation at rates as low as 0.5 imp/sec Maximal values were reached at 8–10 imp/sec when flow values as high as 150–200 ml/min × 100 g tissue could be reached. This corresponded to a nearly maximal dilatation of the colonic vessels, as tested by intraarterial injections of supramaximal amounts of isopropyl noradrenaline

In order to ascertain that the pronounced but transient increase of venous outflow produced by pelvic nerve stimulation, was not to a great extent simply an effect of mechanical squeezing of the intramural capacitance vessels produced by the concomitant motility increase both the arterial inflow and the venous outflow were simultaneously recorded in some experiments. It was then clear that pelvic nerve stimulation evoked an increase of arterial inflow of the same magnitude as the increase of venous outflow (see Fig 3) showing that the venous outflow increase reflected a powerful vasodilatation. In such experiments it was also shown that even during high blood flow levels occlusion of the inferior mesenteric artery did not significantly change venous blood flow as long as the arterial connections to the superior mesenteric artery were intact

In some experiments the continuity of the bowel wall was broken by means of a ligature so applied that the extramural vascular and nervous connections and the colonic mesentery remained intact (see also chapter II) While exclusion of the caecum and the proximal 1/3–1/4 of the colon did not affect the vasodilator response indicating that vasodilation is probably not brought about in this part it was successively diminished in magnitude when the ligature was applied at lower levels and was abolished completely when the continuity of the bowel wall was broken at the peritoneal deflection. As the ligatures did not interfere with the colonic blood supply and drainage this indicates that the fibres mediating vasodilation are distributed intramurally as is also the case with the motor fibres in the pelvic nerves (see chapter II)

In order to ascertain the stimulation threshold of the pelvic nerve fibres, which produce colonic vasodilatation, the pulse duration was varied while voltage and stimulation frequency were kept constant at 5 V and 8 imp/sec A slight vasodilatation occurred at 0 03–0.1 msec, but as a rule a clearcut increase in blood flow was not recorded until durations of 0.8–1 msec were reached As a comparison threshold activation of the preganglionic sympathetic vasoconstrictor fibres was obtained at pulse durations of 0 03–0 1 msec when the same voltage and frequency were applied The dimensions of the nerve trunks stimulated were about the same. Furthermore the stimulation threshold of the motor fibres to the colon was tested in the same way and could not be separated from those producing colonic vasodilatation (see chapter II) However the motor fibres to the bladder which were stimulated in the same way in a few experiments during recordings of bladder volume seem to have a somewhat lower stimulation threshold.

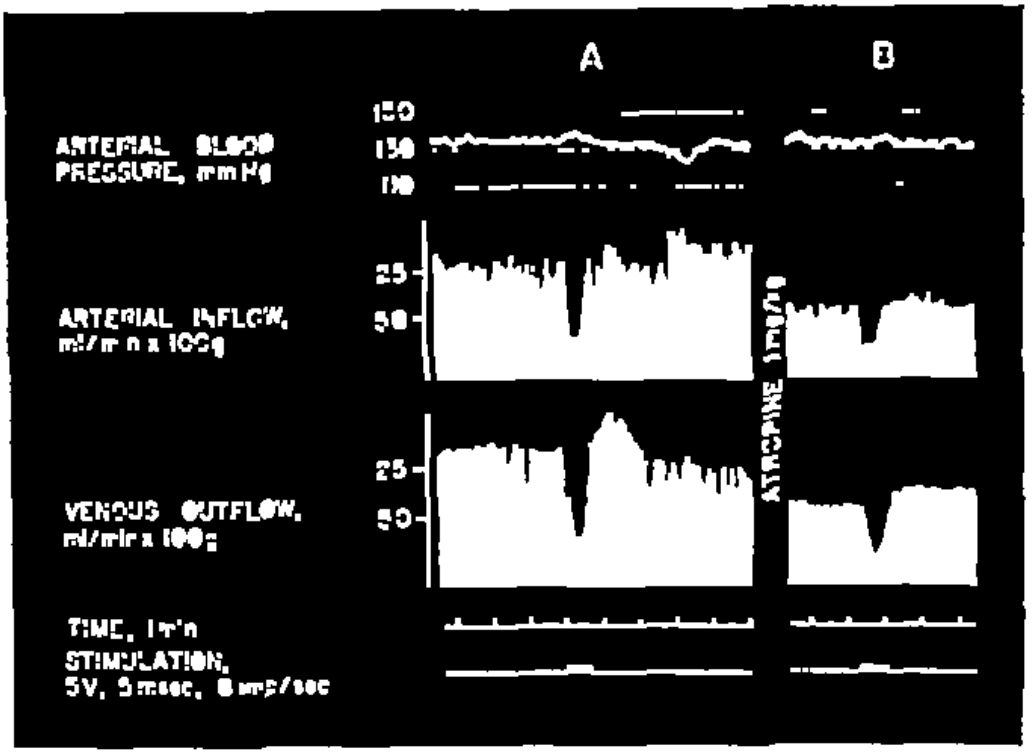

Fig 3. Cat 3 6 kg Chloralose. Effects of pelvic nerve stimulation (8 imp/s, 5 msec 5 V) on simultaneous recording of colonic arterial inflow and venous outflow before (left panel) and after (right panel) atropine administration (1 mg/kg).

In some experiments atropine was given in order to check if the vasodilatation upon pelvic nerve stimulation was mediated by a cholinergic mechanism However as shown in Fig 3 intravenous administration of atropine sulphate in a dose of 1 mg/kg did not interfere with the vasodilator response. Whereas administration of α and β-blocking agents or guanethidine did not affect the response it was completely abolished by a ganglion blocking agent (Ecolid® 2 mg/kg) indicating that a ganglionic synapse is present in the neurogenic pathway

3 *Blood volume determinations*

The regional blood volume of the colon and its mesentery was estimated in five experiments. It amounted to 8–10 ml/100 g tissue

IV COMMENTS

The present findings indicate that the vasoconstrictor fibres to the vascular bed of the colon are supplied from two sources. The thoracic sympathetic outflow innervates the proximal third via the splanchnic nerves while the lumbar sympathetic outflow via the lumbar colonic nerves controls the vessels in the remaining part of

th colon sometimes with a moderate overlap in distribution Both fibre sets produce an intense and uniform blanching of the respective sections of the colonic mucosa The effect produced by the lumbar colonic nerves was observed in the distal colon by Langley and Anderssom (1894) and confirmed by Wright *et al* (1938) However there seem to be no earlier reports concerning the effect of pelvic nerve stimulation Accordingly Hunter (1958) and Hulten (1961) embryologically the distal part of the colon is developed from the hindgut while the proximal part is derived from the midgut which may explain the differences in vasomotor fibre distribution

As in the case with the small intestine (Folkow *et al* 1961a) the neurogenic constriction of the colonic resistance vessels is characterized by a biphasic with an initial peak response followed by a decline to a new steady state of moderately increased resistance despite continued stimulation This autoregulatory escape from the vasomotor fibre influence will be further dealt with in chapter IV However the sustained and dramatic mucosal blanching suggests that the autoregulatory escape with return of the overall blood flow toward control level takes place in deeper wall layers This implies a neurogenic redistribution of blood flow from the mucosa toward submucosal structures also in the colon

Besides their motor influence on the gastrointestinal tract the vagal nerves were earlier assumed to exert widespread vascular effects via specific vasodilator fibres Martinson (1960) showed that vagal stimulation to the stomach produced vasodilatation associated with gastric secretion and corpus fundus relaxation It was further demonstrated by Swan and Jacobson (1960) that stimulation of vagal fibres increased blood flow in the stomach mucosa However this mucosal vasodilatation may well have been metabolic secondary to the increased secretion rather than due to specific vasodilator fibres Brewster (1956) found no evidence of vagal vasodilator fibres in the small intestine In the present study no sign of increased colonic blood flow whether as a mucosal flushing or as a reduced blood flow resistance was observed even upon maximal activation of the vagal nerves It is therefore unlikely that the vagal nerves convey any vasodilator fibres to the colon and this may also be true for the gastrointestinal tract as a whole to judge from the studies quoted also

In agreement with the results of Langley and Anderssom (1894) and Wright *et al* (1938) pelvic nerve stimulation led to an intense flushing of the colonic mucosa It appeared first of this mucosal vasodilatation (see chapter V) spread gradually in the proximal direction It did not however involve at all the most proximal 50 per cent of the colonic mucosa and the borderline zone toward the markedly vasodilated distal parts was indistinct The mucosal vasodilatation was in other words largely restricted to that part of the colon which is also controlled by the sympathetic lumbar colonic nerves perhaps being slightly larger However pelvic nerve stimulation regularly produced increased secretion and a concomitant motor response where the increased motility involved the entire colon (see chapter II)

Thus the vascular response was never obtained alone and the fibres mediating vascular and motor response could not be separated by means of differences in their electrophysiological properties.

The colonic vascular response produced by pelvic nerve stimulation showed a characteristic response pattern when explored by concomitant recording of the venous outflow and of the mucosal flushing. A rather shortlasting but nearly maximal blood flow increase occurred in close parallel with the mucosal flushing. Soon however flow returned towards control, while the mucosa remained hyperaemic but changed in colour from red to bluish. The explanation for the short duration of the initial blood flow increase is not known (cf. chapter IV).

Since pelvic nerve stimulations produced a transient increase of arterial inflow of the same order of magnitude as that concomitantly observed in the venous outflow it is excluded that the phasic venous outflow increase was mainly due to a "squeezing" effect on the venous content of blood due to the motor contraction. It is no doubt a true vasodilator response which the mucosal flush also clearly indicates. Furthermore the regional blood content in the colon during "resting" condition was calculated to be 8–10 ml/100 g tissue and a mere venous squeezing could not possibly be responsible for an increase of venous outflow amounting to more than 100 ml/min × 100 g tissue.

It is thus clear that the pelvic nerves can produce a nearly maximal vasodilatation in the colon probably mainly involving the mucosal vessels (see chapter V). Even though a cholinergic link may be involved it is hardly likely that the vascular smooth muscles are directly affected by cholinergic nerve endings. Even large doses of atropine failed to affect the dilator response while the effect of infused acetylcholine was completely abolished. In this respect the colonic vasodilatation closely resembles the vasodilatation causing penile erection as produced by the pelvic nerves (Dorr and Brody 1967), the vagally induced vasodilatation in the stomach (Martinson 1966) and the salivary gland vasodilatation obtained on stimulation of the chorda tympani (Hilton and Lewis 1955, 1956).

As discussed in the introduction the large bowel may be looked upon as an organ especially designed for mixing the contents delivered by the small intestine and to allow for a final absorption of mainly salt and water. These functions may be dependent mainly upon the proximal colonic parts. On the other hand, storage of the contents and their subsequent expulsion may constitute the main function of distal colonic parts. To facilitate the passage of the often firm faeces lubrication is required calling for a mucus secretion in connection with emptying of the distal colon. The secretory response to pelvic nerve stimulation seems to be mainly limited to the distal part of the colon and is accompanied by a mucosal blood flow increase presumably to supply the glands with raw material for the secretion of mucus. Such a view might explain why the vasodilator and probably also the secretory response to pelvic nerve stimulation are largely restricted to the distal parts of the colon and why the corresponding motility response although involving the entire colon is

different in it characteristics in the proximal (mainly circular contraction) and distal (mainly longitudinal contraction) part (see chapter II)

While the vasodilator effect produced by the pelvic nerves emerges the distal /3–3/4 of the colon the vagal nerve supply to the proximal part of the colon has no influence on the corresponding blood vessel The two sets of colonic vasomotor fibre supply essentially the corresponding part of the colon These result with respect to the differences in vasomotor fibre control may lend further support to the view that the colon is functionally differentiated into two main parts as was also the case with several aspect of the motor innervation to the colonic musculature as described in chapter II

CHAPTER IV

LOCAL AND NERVOUS CONTROL OF THE CONSECUTIVE VASCULAR SECTIONS OF THE COLON

L. Hultén, M. Jodal and O. Lundgren

I. INTRODUCTION

The control of the various systemic vascular circuits have been studied in detail, and considerable differences exist between their functionally specialized series-coupled sections (for a recent review see Mellander and Johansson 1968). Studies of such consecutive vascular sections have been made possible by means of continuous measurements of tissue weight or volume (e.g. the plethysmographic technique) as combined with direct and continuous blood flow recording. This approach originally designed by Pappenheimer and co-workers for their studies of capillary function (see Pappenheimer 1953) was developed for the analysis of the nervous control of the skeletal muscle vascular bed (Mellander 1960) and later applied to the small intestine (Folkow *et al.* 1963). The present study describes the application of this method for the analysis of the consecutive vascular sections of the colon in the cat.

As in the small intestine secretion and absorption are important features in colonic function, both processes being energy consuming and requiring a considerable blood supply. Furthermore the colonic vascular bed is also under the control of a potentially powerful neurogenic control. It was therefore considered of interest to study blood flow during resting conditions and during vasodilatation induced by a drug as well as the range of control exercised by the sympathetic vasoconstrictor fibres and by the vasodilator action of the parasympathetic pelvic nerves.

II. METHODS

A. Operative procedures

Observations were carried out on a total of 46 cats fasted for 24 hours. The operative procedures, the registration of blood flow and the nervous stimulations were with minor modifications (see below) identical to those described in chapter III (see page 40)

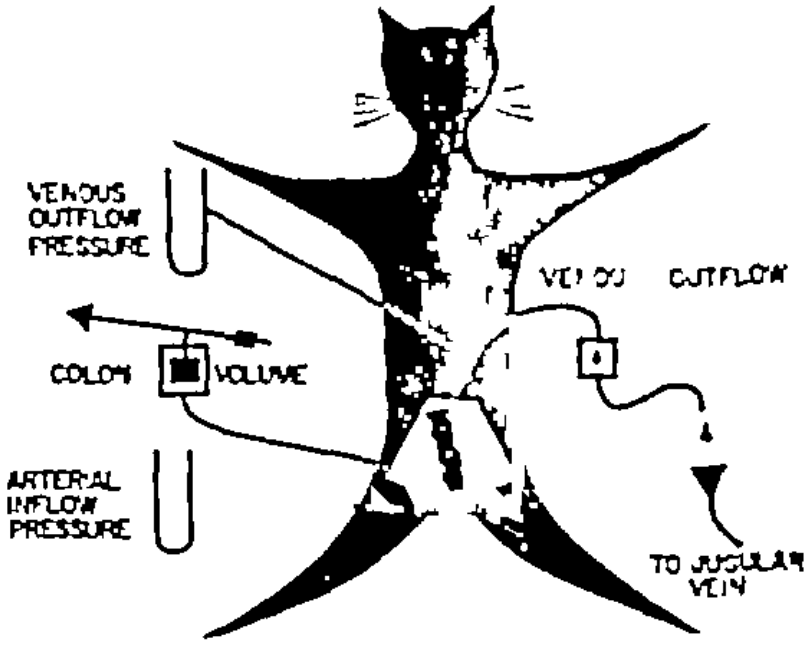

Fig 1 Schematic illustration of the technique used for isolating the rectum with the connected proximal section of the large bowel.

To induce graded vasodilatation close intraarterial infusions of norepinephrine-noradrenaline (NA) were performed by means of a thin polyethylene catheter inserted into a small branch of the superior mesenteric artery Atropin sulphat and l-a lrenaline were administered i v and i.a. respectively

B Plethysmographic technique

To allow a continuous recording of changes in tissue volume the colon was enclosed in a perspex plethysmograph For this purpose the colon was dissected distally in the pelvis beneath the entrance of the pelvic nerves and separated from the bladder Furthermore the colonic mesentery had to be cut up to the superior mesenteric root thereby sacrificing the inferior mesenteric artery In the experiments described in chapter III where the arterial inflow was recorded simultaneously with the total venous outflow it was known that even during maximal flow levels occlusion of the inferior mesenteric artery in the preparation used did not significantly change venous blood flow as long as the arterial connections to the superior mesenteric artery were intact

The colon, with ring electrodes mounted on the planchnic the lumbar colonic and the pelvic nerve was then placed in the plethysmograph in such a manner that the superior mesenteric artery and the cannulated vein passed through a closely fitting opening which was further sealed with plast base (Squibb) or Vaseline grease (see Fig 1). To make the enclosement of the colon easier most of the lymph nodes in the mesentery were often resected The widebore venous cannula was always introduced far enough distally as to be well inside the sealed opening thereby avoiding venous collapse by undue lateral pressure The exact value of the venous outflow pressure was in most experi-

ments recorded by means of a water manometer coupled to the connection between the superior mesenteric vein and the drop recorder The colon was thus enclosed in a perfectly air and watertight way without interference with either arterial inflow or venous outflow and colonic motility and colour could be directly inspected. The plethysmograph was filled with Tyrode solution kept at 38°C and controlled by a thermocouple, leaving only a small air volume in the upper outlet which was connected to a sensitive volume piston recorder

C. Determination of the capillary filtration coefficient (CFC)

After enclosing the colon in the plethysmograph it was, in most experiments, possible to adjust the venous pressure so that an isovolumetric state was attained implying that the net transcapillary movement of fluid was zero This isovolumetric equilibrium could then be deliberately disturbed by temporarily increasing venous outflow pressure by a known amount, usually 7 mm Hg (= 10 cm H O) This procedure evoked a characteristic volume increase in two phases which showed completely different slopes (see e.g. Fig 2) As earlier demonstrated (Mellander 1960 Kjellmer 1965) the first rapid change in volume is caused by vascular distension, mainly of the thin walled veins while the continuous and slower increase of the volume curve the filtration slope reflects the outward filtration caused by the raised capillary hydrostatic pressure The capillary filtration coefficient (CFC) expressed in ml of fluid filtered across the capillary wall per min in 100 g tissue and per mm Hg pressure difference, was calculated assuming a mean hydrostatic capillary pressure of 15 mm Hg at a venous outflow pressure close to zero (cf Folkow *et al.* 1963 Wallentin 1966).

III RESULTS

A Infusion of isopropyl noradrenaline

1 *Resistance vessels*

Intraarterial infusions of supramaximal amounts of isopropyl noradrenaline (INA) increased colonic blood flow from a resting level of about 15–25 ml to approximately 200 ml/mn × 100 g tissue. This corresponded to a maximal vasodilatation. Expressed in terms of *peripheral resistance units per 100 g tissue* (PRU_{100}) the *flow resistance* at rest 4-9 PRU_{100} was reduced to about 0 4–0.5 PRU_{100} during maximal vasodilatation.

2. *Capacitance vessels*

Corresponding in time to the blood flow increase induced by INA, the colonic tissue volume also increased maximally some 3 per cent reflecting a widening predominantly of the capacitance vessels. Since the blood volume of the acutely denervated colon, including the mesenteric vessels was 8–10 ml/100 g of tissue (see chapter III) this change in tissue volume corresponds to a 30–40 per cent increase of blood content.

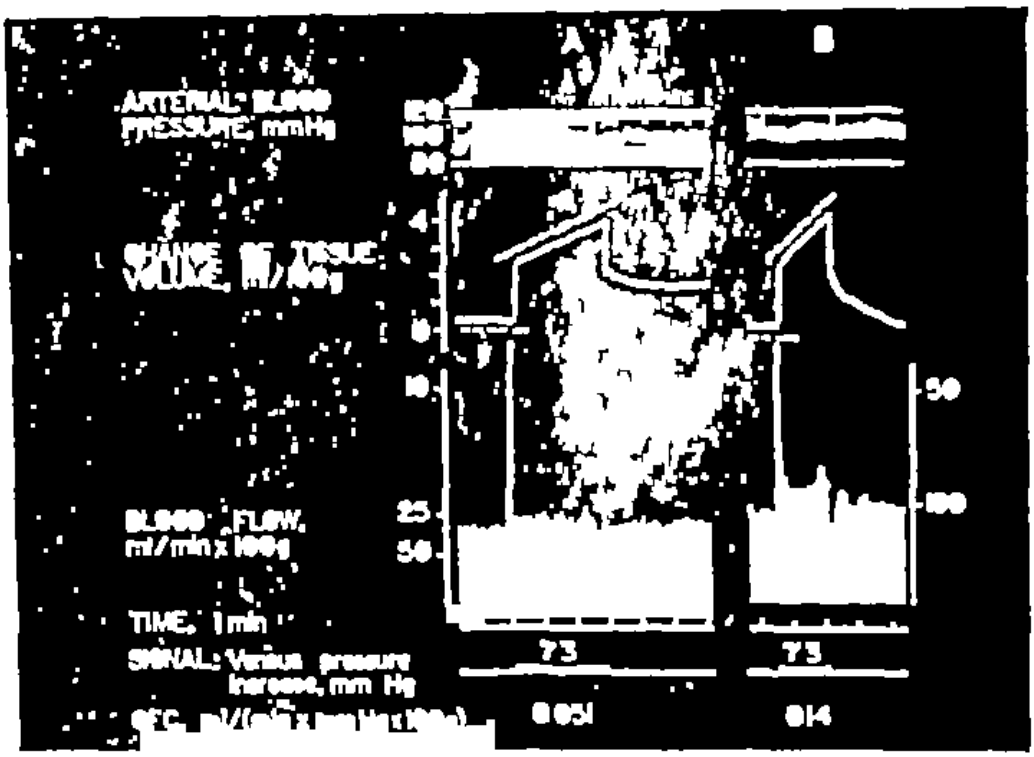

Fig. C t ..8 kg The effect of sudden venous pressure increase (7.3 mm Hg = 10 m H_2O) on colonic tissue volume and blood flow before (A) and during an infusion of norepinephrine (B) The capillary filtration coefficient (CFC) was calculated from the low continuous filtration slope indicated by dotted lines. Note that the blood flow calibration differs in the two panels.

3 *Exchange vessels*

The intestinal capillary filtration coefficient (CFC) reflecting the capillary surface area available for transcapillary exchange and hence varying with precapillary sphincter tone was determined at different levels of vascular tone

Fig illustrates the effects of a sudden rise in venous pressure on tissue volume and blood flow A rapid increase in tissue volume is obtained due to dilatation of the capacitance vessels which corresponds in time with a transient reduction of venous outflow This phase is followed by a second far slower but fairly continuous volume increase reflecting an outward capillary filtration (see Method) At resting colonic blood flow levels CFC was approximately 0.03 ml min 100 g tissue x mm Hg and increased to about 0.15 at maximal vasodilatation when blood flow was approximately 80 ml min 100 g tissue The accumulated data in Fig 3 show the correlation between colonic blood flow and CFC at different levels of vascular tone

B Effects of graded direct stimulation of the sympathetic supply

1 *Resistance vessels*

The neurogenic increase of colonic flow resistance consisted of two phases as was briefly discussed in chapter III After an initial peak flow resistance declined again

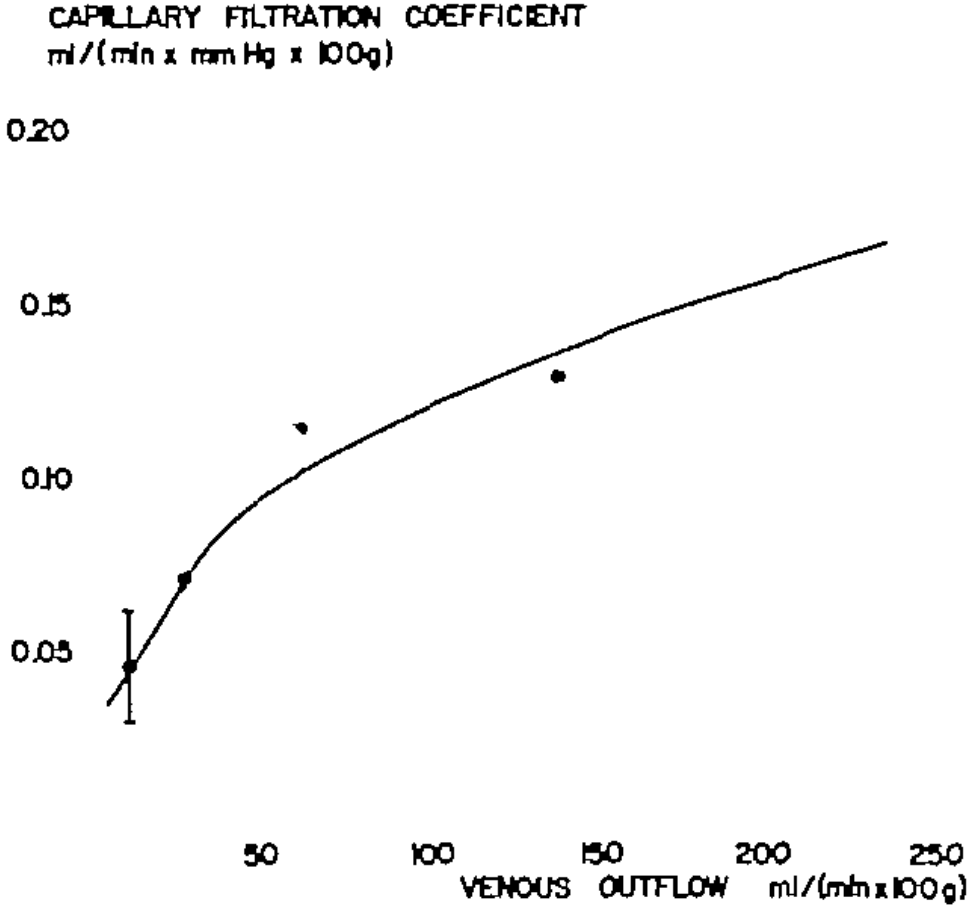

Fig 3. Cumulated data (n = 93) on the correlation between total colonic blood flow and CFC at different levels of vascular tone Vertical lines indicate ± one standard deviation. Curve drawn by inspection. Graded vasodilatations were induced by i.a. infusions of isopropyl-noradrenaline.

within 2 to 3 min, a phenomenon which in the small intestine is denoted "autoregulatory escape from the vasoconstrictor fibre influence (see Fig 4) The peak response increased markedly with increasing rates of stimulation from a "resting value of 4–9 PRU_{100} it reached about 30 PRU_{100} when all vasoconstrictor fibres were simultaneously activated at 8 imp/sec Activation of the lumbar colonic nerves alone increased peak flow resistance to some 15 PRU_{100} but involved as mentioned in chapter III, only about the distal 2/3–3/4 of the colon

The autoregulatory escape was pronounced at high rates of stimulation, but the steady state neurogenic response nevertheless showed an augmentation with increasing stimulation frequencies (Fig 5) The steady state resistance response at high frequencies only exceptionally exceeded control resistance by 100 per cent, cessation of the stimulation led to a reactive hyperaemia (see Fig 6)

2. *Capacitance vessels*

Fig. 4 (panels A, B and C) illustrates the effect of regional vasoconstrictor fibre stimulation on blood flow and tissue volume reflecting changes in blood content and

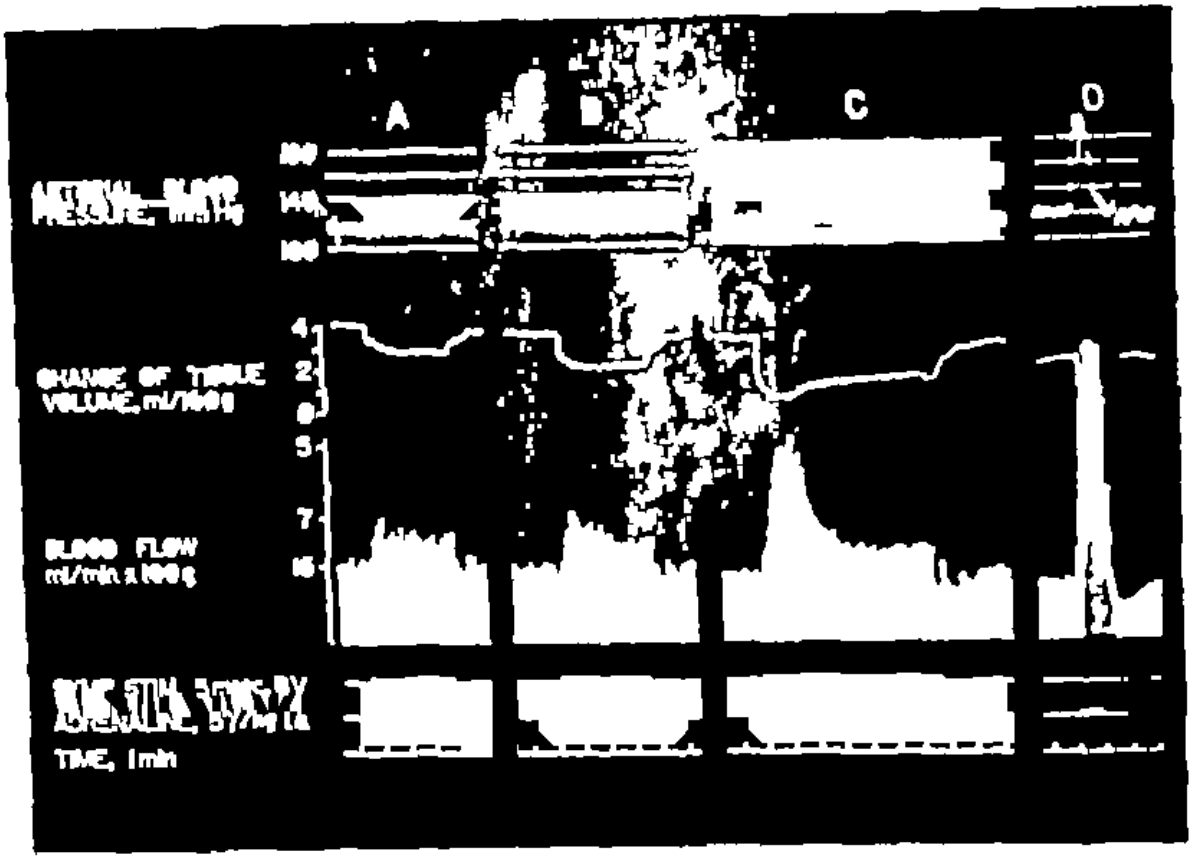

Fig. 4. Cat 3.8 kg. The effect of graded stimulation of the sacral vasoconstrictor fibres on arterial blood pressure, blood flow and tissue volume of the large bowel at normal venous outflow pressure (15 cm H_2O) (panels A, B and C). As a comparison the effect of an i.v. injection of large dose adrenaline is illustrated in panel D.

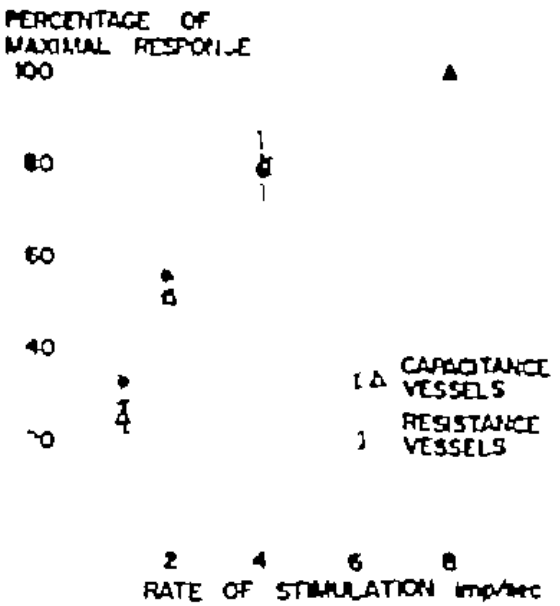

Fig. 5. Frequency response curves derived for the colonic resistance and capacitance vessels. The effects of graded vasoconstrictor activation are expressed in per cent of maximal response obtained in the two vascular sections. The steady state response of the resistance vessels was used in the calculations. The experiments were performed at venous outflow pressure of approximately 15 cm H_2O. Vertical lines indicate ± one standard error of the mean.

tissue fluid Corresponding in time with the drastic resistance increase there is a rapid decrease in volume which was kept far more constant during the stimulation period than the resistance response where the "autoregulatory escape was often pronounced. However when venous outflow pressure was kept low there was often an initial but transient decrease in volume in phase with the peak resistance response This evidently reflects a mere passive-elastic recoil and partial collapse of the venous capacitance compartment in turn due to a transient increase in the pre to post capillary resistance ratio which implies an initially reduced transmural pressure in capillary and venous sections. The largely passive nature of this initial decrease in volume was obvious from the fact that it was largely absent when venous outflow pressure was kept high enough to keep the capacitance vessels distended. This is evident from the experiment in Fig 4 performed at a venous outflow pressure of 15 cm H_2O The volume increase following cessation of stimulation equalled the decrease at the onset of stimulation suggesting that the active capacitance response was well sustained "Resting" colonic blood content estimated separately in five experiments (see chapter III) was related to the volume decrease caused by graded vasoconstrictor fibre stimulation. It was calculated that approximately 20 per cent of the blood content was expelled at a discharge rate as low as 2 imp/sec the maximum of some 30–50 per cent being reached at 8 imp/sec A marked flow reduction caused by adrenaline was accompanied by a capacitance response of a similar magnitude (panel D)

Fig. 5 illustrates the frequency response curve for the capacitance vessels as compared to that of the resistance vessels during the *steady state* phase The response of the resistance and capacitance vessels are expressed in per cent of the maximal values obtained. The figure is based on experiments performed at a venous outflow pressure of 15 cm H_2O It can be seen that the frequency response curves of the two vascular sections are almost identical when in this way the *locally* modulated resistance response to nerve stimulation is used The same result was obtained also when venous pressure was kept low If, on the other hand the *peak* resistance responses were plotted in the same way as in Fig 5 the curve was placed to the right of the capacitance curve

Finally during the steady state of the vasoconstrictor response the volume recording was isovolumetric indicating that the pre-to postcapillary resistance ratio remains largely the same as during the control state i.e. mean hydrostatic capillary pressure was unchanged

3 *Exchange vessels*

Vasoconstrictor fibre stimulation reduced colonic CFC, the approximate maximal effect being reached at 8–10 imp/sec Fig 6 illustrates a representative experiment in which CFC was reduced from 0 065 to 0 045 ml/min × 100 g × mm Hg during a stimulation of 4 imp/sec. As was the case with the capacitance response the CFC reduction was well sustained during the entire stimulation period.

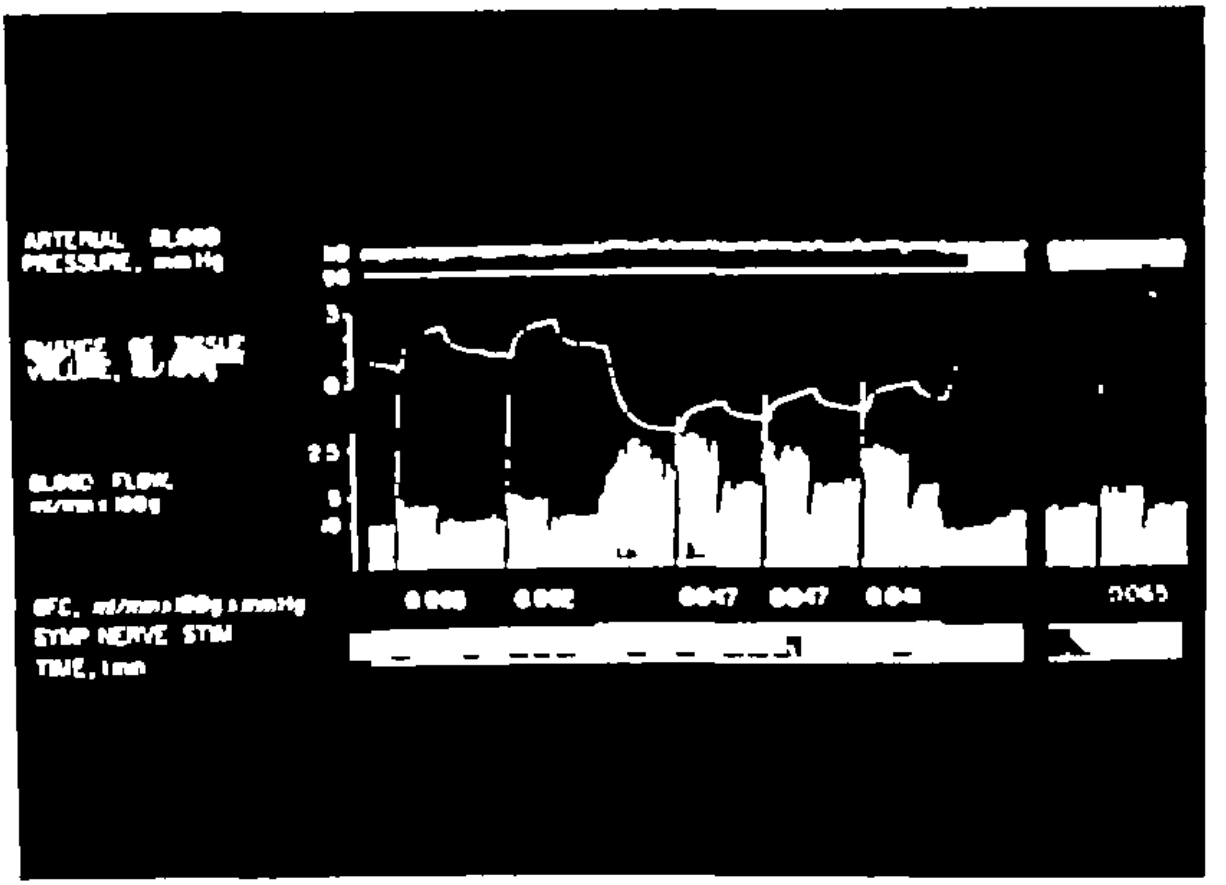

Fig. 4. C. 3.6 kg. The effect of ... vasoconstrictor fibre stimulation at 4 imp/sec on blood pressure, blood flow, tissue volume and capillary filtration coefficient (CFC) of the large intestine. (For details, see text.)

C. Effects of graded direct stimulation of the parasympathetic supply (the pelvic nerves)

1. *Resistance vessels*

Within 5–10 sec after commencement of pelvic nerve stimulation blood flow increased to reach maximal levels in 20–30 sec. This flow increase, in the following referred to as *initial*, usually began to vanish within 30–40 sec, only exceptionally lasting more than $1\frac{1}{2}$ min, despite continued stimulation. In general, the *duration* of the vasodilatation varied inversely with the rate of stimulation, fairly long-lasting flow increases occurring at low frequencies, whereas the magnitude of the blood flow increase was directly graded to the stimulation rate (see Fig. 7).

An initial blood flow increase was evident already at 0.5 imp/sec and maximal values, 150–200 ml/min/100 g tissue, were obtained at 8 imp/sec, with about 80 per cent of the maximum reached at 2–4 imp/sec (Fig. 7). The magnitude of the flow

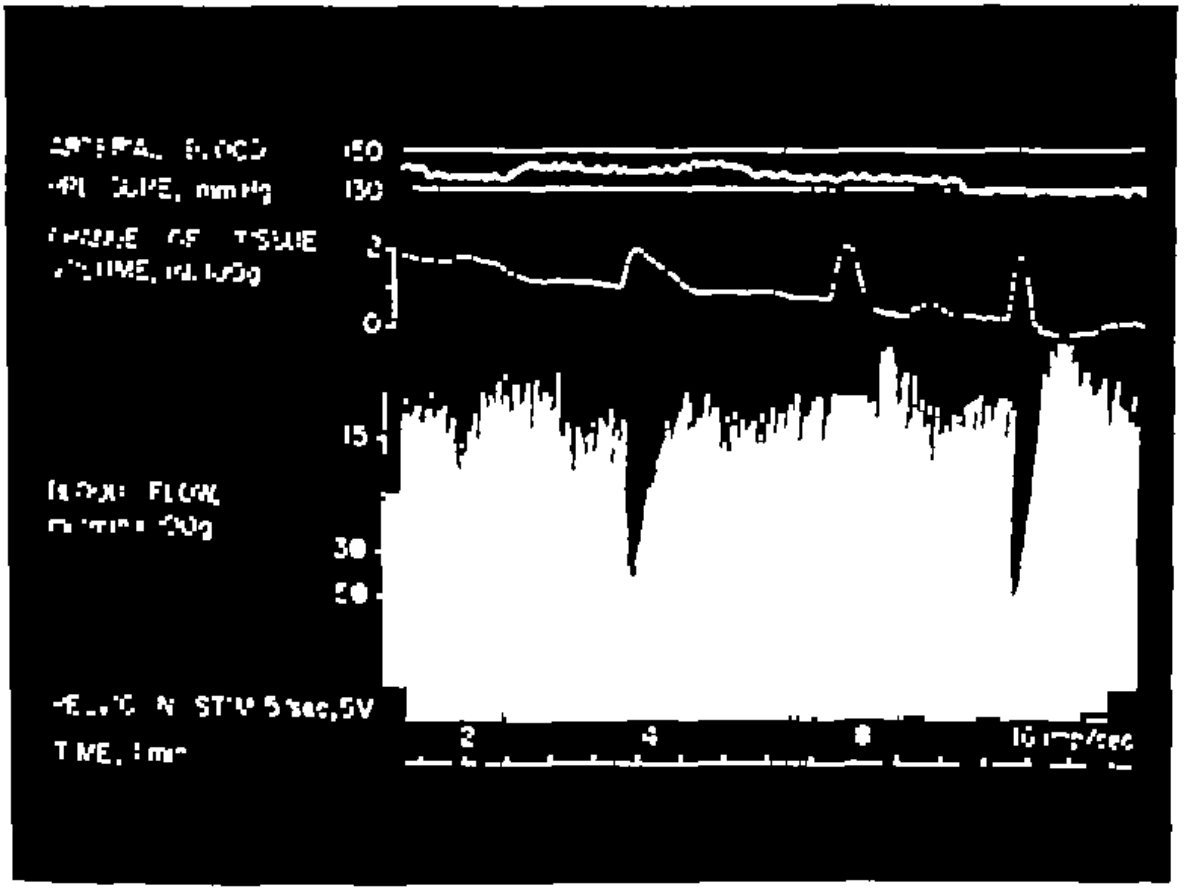

Fig. 7 Cat ~1 kg. The effect of graded stimulation of the pelvic nerves on blood pressure blood flow and tissue volume of the colon. The animal was tropinised (1 mg/kg b.w.) Note the small and transient volume decrease corresponding t the phasic reduction of blood flow

increase was roughly the same whether one or both pelvic nerves were activated indicating extensive overlap in innervation. Expressed as PRU_{100}, flow resistance fell from resting levels of 4–8 to 0.4–0.6 PRU_{100}. Supramaximal amounts of ACh could only exceptionally reduce flow resistance further (see page 53)

Once induced a fully developed initial vasodilator response occurred within 5–10 sec despite interruption of the stimulation. On the other hand this vasodilator response vanished despite continuation of the stimulation and was followed by a phasic blood flow reduction proportional to the stimulation rate and consequently to the magnitude of the vasodilatation. During this transient flow reduction vascular resistance could increase some 50–70 per cent above control at maximal rates of stimulation. In chapter III it was pointed out that this phasic reduction of blood flow corresponded to a bluish colour shift in the hyperaemic mucosa. However as illustrated in fig. 7 (left panel) during *prolonged* pelvic nerve stimulations this resistance increase in the most experiments followed by series of shortlasting blood flow increases until it returned to the resting level upon cessation of stimulation. These oscillations in the following referred to as *recurring* were, however always smaller than the initial blood flow increase, on the average reaching about 40–60 per cent of the

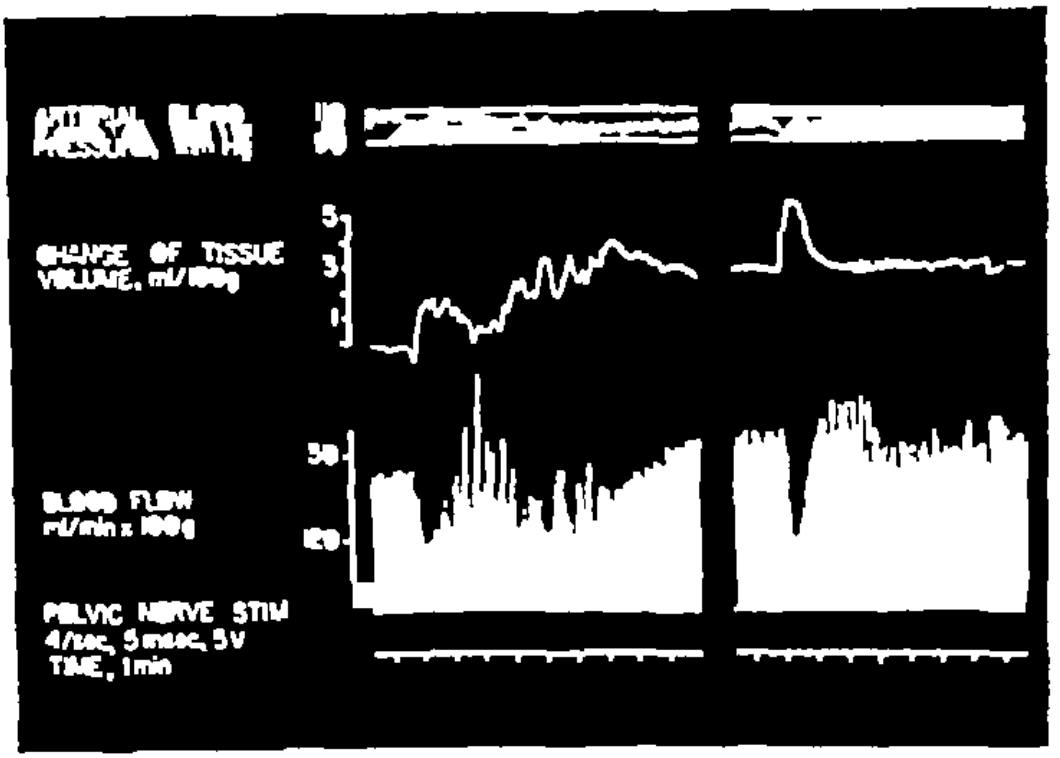

Fig 8 Cat 3.. kg The effect of bilateral pel ic nerv stimulation t 4 imp sec on blood pressure blood flow and tissue volume f the colon bef ee (left panel) and after (right panel) admin tration of atropine (1 mg/kg b w) Note the *initial* and *recurring* blood flow increases, the latter abol shed by troj ne admi istrat n.

The administration of atropine in doses that blocked the vagal effects on heart rate did not reduce the *initial* blood flow increase on pelvic nerve stimulation but aboll hed the recurring blood flow increases seen during prolonged nervous activa tion (Fig 8 right panel)

The pelvic nerves seemed to be more or less fatigued when exposed to repeated stimulations at high rates and the largest initial vasodilatory responses were m stly seen upon th first few stimulations \ high frequency stimulation following one of low frequency often resulted in a smaller initial vasodilator response if a sufficient rest period wa not allowed between the stimulation If one of the pelvic nerves was *stimulat d to fatigue stimulation of the other one resulted in an immediate* and marked vasodilatation despite the evidence mentioned above of a considerable overlap of innervation

° *Capacitance vessels*

Fig 7 taken from an experiment on an atropinized animal illustrates the effect of graded bilateral pelvic nerve stimulation with the characteristic shortlasting initial vascular responses corresponding in time with a rapid increase of tissue volume which is follow l by a somewhat slower volume decline towards control The magni

tude of the volume change followed closely the resistance response increasing with increasing rates of pelvic nerve stimulation At most, volume increased 2 0–2.5 ml/100 g tissue at 8 imp/sec i.e an approximately 25 per cent increase of blood content, with 80 per cent of the maximum being reached at 4 imp/sec Increasing venous outflow pressure from 5 to 15 cm H_2O reduced the capacitance response on pelvic nerve stimulation by some 30–40 per cent. The relation between capacitance and resistance responses was also close with respect to their time courses. Thus as the duration of the resistance response was shortened with increasing rates of stimulation so was the shift of colonic tissue volume Corresponding to the phasic reduction of blood flow a small and transient volume decrease was sometimes observed (Fig 7)

The changes in tissue volume during prolonged pelvic nerve stimulation before and after administration of atropine is illustrated in Fig 8 The response pattern in the atropinized cat (right panel) was similar to that described above (cf. Fig 7) The experiment illustrated in Fig 8 (left panel) shows that before atropine an initial abrupt increase of tissue volume is followed by a comparatively slow irregular volume increase. *Furthermore, upon cessation of stimulation tissue volume never returns to* pre-stimulation control level. For such reasons it seems reasonable to assume that the slow volume increase is to a great extent caused by secretion If this is true the slow phase may reflect a secretion amounting to 0 1 ml/min or 0.5 ml/min × 100 g tissue

3 *Exchange vessels*

Since the initial vasodilator response induced by pelvic nerve stimulation is fairly brief (Fig 7 and 8) lasting at most 1½ min, and accompanied by a transient increase of tissue volume *determination of CFC during that period was not possible. It was* also impossible to determine CFC during prolonged activation of the pelvic nerves in animals not atropinized (see Fig 8 left panel) Determinations made during prolonged pelvic nerve stimulations in atropinized animals and immediately after cessation of pelvic nerve activation gave no conclusive evidence for any change of CFC although in some experiments a slight increase was observed.

IV COMMENTS

A plethysmographic technique which is modified from that developed by Mellander (1960) and also applied to studies of the vessels of the small intestine (Folkow *et al* 1963) was used in the present study for an investigation of sympathetic and parasympathetic control of the colonic vasculature The reactions of the consecutive vascular sections i.e. pre- and postcapillary resistance vessels precapillary "sphincters and capacitance vessels with their secondary effects on capillary exchange, were thus studied at rest" during vasodilatation and at different levels of nervous activity

To facilitate the interpretation of the complex responses within the different vascu

lar sections the effects of sympathetic vasoconstrictor fibre stimulation will be dealt with first. The present results indicate that the colonic vascular responses with few exceptions correspond to those occurring in the small intestine (Folkow *et al.* 1961*a*, *b*). This contrary to the conditions in resting skeletal muscle where the neurogenic increase of flow resistance is fairly well sustained and the precapillary sphincters exhibit a considerable escape as judged from CFC measurement in the colon the resistance response exhibits "escape" while CFC is kept reduced throughout the period of constrictor fibre stimulation. However the escape of the colonic resistance vessels as well as the reduction of CFC was less pronounced than in the small intestine. This perhaps implies that the extent of blood flow redistribution from the outer mucosa to deeper wall layers is not as extensive in the colon as in the small intestine (Folkow *et al.* 1961*a*, *b*). But mucosal low resistance channels allowing for a physiological shunting (but *not* a true low pass of exchange vessels) seem to be involved in this blood flow redistribution (Drost *et al.* 1960). Shunt like vessels have been described both in the stomach and in the small intestine on the basis of morphological studies (Spanner 1953; Thamm 1960; Walker 1961; Wiedman 1963) while such vessels appear to be less numerous in the colon and rectum (Boulter and Parks 1960). It is possible that this difference in the arrangement of the vascular bed in the mucosal-submucosal compartment might explain a less pronounced redistribution of blood flow in the colon when the vasoconstrictor fibres are stimulated. However the sustained mucosal blanching despite the autoregulatory escape of overall flow resistance strongly suggests that flow redistribution does occur in the colon too favouring flow in deeper parts of the mucosa and/or the submucosa.

The type and magnitude of the capacitance response to vasoconstrictor fibre stimulation closely resembled that seen in the small intestine (Folkow *et al.* 1964*a*). Thus the active component of blood expulsion from the venous side was well sustained. However it could be more or less masked by passive recoil effects as venous outflow pressure was kept so low as to allow for partial venous collapse in connection with the peak response of the precapillary resistance vessels. Maximal capacitance responses corresponding to some 40 per cent blood expulsion were obtained at 8 imp/sec. The resistance vessels during the steady state phase exhibited a frequency response curve similar to that of the capacitance vessels. This observation is apparently contrary to the one reported by Mellander (1960) for the skeletal muscle vascular bed where the frequency response curve of the capacitance vessels is placed well to the left of that of the resistance vessels. The observed discrepancy may be explained by the fact that a redistribution of blood flow from superficial to deeper mucosa-submucosal layers occurs in the colon during the autoregulatory escape and this locally induced adjustment is often especially pronounced at high frequency stimulation. The resistance response of the vessels in superficial parts of the mucosa is probably quite similar to that in skeletal muscles being sustained during the period of stimulation. This suggestion is strengthened by the observation that the frequency response curve of the *peak* responses of the resistance increases in the colonic vascular bed was

similar to that of skeletal muscles and placed well to the right of the capacitance curve.

The resting" colonic blood flow after acute vascular denervation largely corresponding to a situation of reflexly inhibited sympathetic activity in the intact organism, ranged between 15 and 25 ml/min × 100 g tissue This is about the same as in the stomach (Martinson 1965) but only about half that of the small intestine when studied under similar experimental conditions (Folkow *et al* 1963 Lundgren 1967) With maximal vasodilatation in the colon induced by infusion of INA the blood flow increased to approximately 200 ml/min × 100 g tissue which corresponds to about 75 per cent of the maximal flow capacity observed in the small intestine (Folkow *et al* 1963) The range of control of the colonic vascular bed as exercised by locally produced vasodilator factors and by the centrally controlled constrictor fibres therefore coincides well with that of the small intestine although the small intestine seems to be in general terms better vascularized

The capillary filtration coefficient (CFC) of the colonic vascular bed amounted to 0 05–0.07 ml/min × 100 g × mm Hg during resting conditions (Fig 2 and 3) and could be increased to approximately 0 15 ml/min × 100 g × mm Hg during maximal vasodilatation induced by isopropyl-noradrenaline (INA) These values are only 1/5–1/3 of the values reported for the small intestine of the cat (Folkow *et al* 1963) This difference is probably explained mainly by a larger capillary surface area in the small intestine reflecting the dominating absorptive function of this part of the gastrointestinal tract

Whereas the vasodilator action of the pelvic nerves upon the colonic vasculature was observed by Langley and Anderssen (1895) no investigations seem to have specifically dealt with the distribution and quantitative effects of these nerves. The results of the present study indicate that the initial dilatation of the resistance vessels observed during pelvic nerve stimulation was accompanied by a widening of the capacitance vessels corresponding to an increase of regional blood volume of about 25 per cent at maximum This value represents in all probability an underestimation since it is calculated on the total weight of the colonic preparation, not taking into account that the vasodilatation occurs mainly in the distal 2/3–3/4 of the colon (see chapter III and V) From the present experiments it cannot be settled whether this widening of the capacitance vessels is only due to a secondary venous distension as a result of precapillary vascular relaxation or if the nerve action causes relaxation of the venous smooth muscles as well Furthermore it was demonstrated that stimulation of the pelvic nerves increased colonic secretion (cf chapter III) with *recurring* increases of total colonic blood flow (Fig 8) The administration of atropine abolished the recurring increases of blood flow and probably the colonic secretion (Fig. 8) while the *initial* marked blood flow augmentation and the motor response were largely unaffected This observation suggests that two vasodilator mechanisms may be involved, one atropine-resistant and one abolished by atropine possibly induced by unspecific metabolites produced during secretion.

The present result indicate that the fibres which mediate the initial marked vasodilatation are distributed with considerable overlap since almost identical responses are induced whether one or both pelvic nerves were activated. The vasodilator effect was easily fatigued but when repeated stimulation of one pelvic nerve had led to elimination of the response an undiminished effect was obtained if the other nerve was stimulated. This finding suggests that the site of overlap is central to the site of "fatigue". The initial vasodilatation which was eliminated by a ganglion blocking drug was not significantly reduced by administration of even large doses of atropine (1 mg/kg) which suggests that a purely cholinergic transmission can hardly be involved (see chapter III). In these respect the mechanism by which colonic vasodilatation is produced closely resembles that involved in parasympathetic vasodilatation in salivary glands (Hilton and Lewis 1955, 1956) or in penile erection (Kerr and Brody 1967).

The general characteristics of pelvic nerve stimulation on colonic function are quite similar to those observed in the stomach during vagal stimulation. Thus there are in both organs three functionally different responses i.e. motility, secretion and vasodilatation which seem to be inseparable. This was the case also when the respective nerve sets were stimulated using different pulse duration or voltages in an attempt to differentiate between fibres with possibly different stimulation threshold. Secretion is accompanied by vasodilatation in both the stomach and the colon while the parasympathetic stimulation produces a widening of the corpus-fundus reservoir sections in the stomach and a contraction of the colon. It seem therefore possible that all these effects in the two organs are induced by one and the same set of nerve fibres.

CHAPTER V

NERVOUS CONTROL OF BLOOD FLOW IN THE PARALLEL-COUPLED VASCULAR SECTIONS OF THE COLON

L. Hultén M. Jodal and O. Lundgren

I INTRODUCTION

It was demonstrated in preceding chapters (III and IV) that efferent stimulation of the pelvic nerves induced a transient increase of total colonic blood flow a nervous effect which persisted after administration of atropine. Concomitantly a marked flushing of the colonic mucosa was observed on visual inspection. Furthermore activation of regional sympathetic vasoconstrictor fibres induced, at moderate and high rates of stimulation a characteristic response pattern, an initial pronounced vasoconstriction followed by increased blood flow in spite of prolonged nervous stimulation to a new steady state flow level. Resistance was then increased moderately as compared to control. Simultaneously a marked blanching of the mucosa was noted which remained unchanged throughout the stimulation period.

In order to investigate in more detail these nervous effects on the different *parallel-coupled* sections of the colonic vascular bed a study was undertaken in which the blood flow in the mucosa-submucosa and in the muscularis layers was studied by means of local injections of minute volumes of radioactive inert gases. The results of these experiments are reported below.

II METHODS

A. Theoretical considerations

The theoretical considerations utilized below are largely based on Kety's approach to tissue-blood exchange of inert gases and the reader is referred to his reviews for more detailed discussions (Kety 1951, 1960).

The elimination of an inert gas from a constantly and uniformely perfused tissue can be

described by the following equation provided that the arterial concentration of the gas is zero or negligibly low during the washout period

$$C_t = C_0 \cdot e^{-kt} \quad (1)$$

where C_t and C_0 denote the tissue concentrations of the gas at times t and 0, respectively, and k denotes the clearance constant. The constant k, which is directly related to blood flow (see below), can be determined from the mathematically derived equation

$$k = \frac{l}{t_{1/2}} \quad (2)$$

where $t_{1/2}$ denotes the half time of disappearance in min. $t_{1/2}$ can be calculated from the straight line obtained when plotting equation (1) on semilogarithmic paper.

If it can be assumed that the equilibration of the tracer between blood and tissue is extremely rapid (i.e. negligible concentration gradients exist in the tissue), blood flow (f) in a tissue can be calculated in ml/min × 100 g tissue from the formula

$$f = k \cdot \lambda \cdot 100 \quad (3)$$

Here k denotes the "clearance" constant (see equation (1)) and λ denotes the tissue/blood partition coefficient of the tracer (divided by the specific weight of the tissue). Experimental data validating the assumption of the blood flow limited washout of inert gases, have been presented for the myocardium (Aukland, Bower and Berliner 1964), the white matter of the brain (Kety 1965), the adipose tissue (Larsen, Larsen and Quaade 1966) and the small intestine (Kampp and Lundgren 1968).

In the present study it was assumed that the washout of the injected inert gases was blood flow limited. This seems to be reasonable since the injected volumes were minute (see below) and a transcapillary diffusion equilibrium for inert gases was demonstrated in the small intestine (Kampp and Lundgren 1968). This conclusion is furthermore supported by the results obtained at experiments carrying an atraumatic labelling technique described below.

B Operative procedures

The experiments were performed on 5 cats anesthetized i.v. with chloralose (50 mg/kg) after induction with ether. The cats had been deprived of food for at least 4 hours.

The operative procedures were similar to those used in previous chapters (III and IV) and were described in detail in chapter III (page 40). Thus, total venous outflow of the colon was registered by an optical drop recorder operating an ordinate writer. Mean arterial blood pressure was recorded from the left femoral artery by means of a mercury manometer. In those experiments where local injections (see below) were made into the mucosa-submucosa, the colon was cut open by thermocautery along the antimesenteric border. It was then mounted with needles on a cork plate to assure constant geometry during the radioactive registrations. The sympathetic and parasympathetic nervous outflow to the colon was prepared and stimulated electrically as described in chapter III (see page 41).

In 18 experiments the muscularis was dissected free from the mucosa-submucosa at the end. From these measurements it was possible to calculate the relative weights of these wall layers. To abolish secretion atropine (Atropine sulphat. Merck) was administered i.v. in a dose of 1 mg/kg b.w. (cf. chapter IV).

C. Local injections

Local injections of a saline solution containing ^{85}Kr or ^{133}Xe (purchased from Radiochemical centre Amersham, England and AB Atomenergi Studsvik, Sweden respectively) were made using a microburette ("Agla micrometer syringe Burroughs Wellcome and Co., England) with a fine-bore glass needle (outer diameter 50–200 μm). 10–20 μl of the solution, coloured with Evan s blue, was injected during 10–30 sec into the intestinal wall, either from the serosal side into the muscularis or from the luminal side into the mucosa submucosa. After the injections the needle was withdrawn and the surface of the colon was flushed with large amounts of bodywarm saline to remove the radioactivity possibly adhering to the colonic surface. The colonic wall at the site of the injections was then covered by Mylar® (1 μm thick; Du Pont) to prevent diffusion of the tracer from tissue to air. The rest of the large bowel was covered by gauze soaked in bodywarm saline.

The disappearance of ^{85}Kr from ~4 local tissue depots was simultaneously recorded by a Geiger Müller end window counting tube (Philips No. 18504, diameter of window 9 mm) completely enclosed in lead (5 mm thick) except for the window. In order to ensure that radioactivity from only the large bowel was recorded, the whole abdomen except the large bowel was covered by a lead plate 5 mm thick. The injections of ^{85}Kr were made from the mucosal side. The window of the G-M tube was placed 2–5 mm from the colonic surface and connected to a linear ratemeter (Packard series 200 A or Philips AW 4242) coupled to an ink recorder (Rika Denki, Kogyo Model 34 B). The time constant of the ratemeter was usually set at 3 or 10 sec. When counts exceeded 5000/min correction was made for coincidence loss, using a value of 100 μsec for dead time of the G-M tube.

The disappearance of ^{133}Xe from 2–4 local tissue depots, usually located in the muscularis, was registered by a scintillation detector with a thallium-activated NaI-crystal (size 1¾ × 2") placed approximately 5 cm from the intestine with the front surface of the crystal parallel to the cork support of the colon. The abdomen was covered by a lead plate as described above. The scintillation detector was coupled to a spectrometer (Packard, Auto-Gamma, Series 410 A) and a linear ratemeter (Packard Model 385) operating an ink writer (Rika Denki or Servogor 60 R Re 511). The time constant of the ratemeter was usually set at 3 or 10 sec. Pulses corresponding to γ-energies between 60 and 200 Kev were recorded.

Background was subtracted from the recorded wash-out curves and the counts per min were plotted *versus* time on semilogarithmic paper. The curves were analysed manually and blood flow was calculated utilising equations (2) and (3).

In order to be able to estimate blood flow from the wash-out curves, the tissue-blood partition coefficient (λ) of the tracer used must be known (see equation (3) above). A tissue-blood partition coefficient for ^{85}Kr of 1, at a haematocrit of 50 per cent, was assumed (cf. Kampp and Lundgren 1968). For ^{133}Xe a partition coefficient of 0.70 at a haematocrit of 30 per cent was assumed (Tönnesen and Sejrsen 1967). The haematocrit of the blood from the mesenteric vein was repeatedly determined in each experiment. The differences in haematocrit were corrected for by utilising the formula of Lassen and Munck (1955) for ^{85}Kr and that of Tönnesen and Sejrsen (1967) for ^{133}Xe.

D. Atraumatic labelling

In a few experiments the tissue was atraumatically labelled using a technique originally described by Sejrsen and Tönnesen (1968). The mucosal or serosal surface of the colon was covered by a Mylar® sheath and the radioactive solution was injected as a gas between the sheath and the tissue. The tracer was allowed to diffuse into the tissue for 30 sec

after which the Mylar was removed and the colonic surface was flushed with large amount of Lyrom saline. The surface was then again covered by Mylar and registration of the elimination of radioactivity was identical to that described here (see section III).

III RESULTS

It was demonstrated in control experiments that the wash-out of radioactive tracer from the minute local injections formed a straight line when plotted versus time on semilogarithmic paper (cf. Fig. 2 and 4). Even in experiments where the registration was continued until a radioactivity level around 5 per cent of the initial one was reached. These control recordings of the tracer wash-out from the mucosa-submucosa and from the muscularis were performed when total colonic blood flow was constant as registered by the venous drop counter. Similar results were obtained in experiments with the atraumatic labelling technique (see Meth. I).

A Resting blood flow of the mucosa-submucosa and muscularis

The regional blood flow of the mucosa-submucosa of the denervated colon amounted to 30–40 ml/min × 100 g tissue (Fig. 3) while the blood flow of the colonic muscularis was calculated to be ~ 14 ml/min × 100 g tissue.

B Effects of direct stimulation of the pelvic nerves

Fig. 1 illustrates the effects of pelvic nerve stimulation in an atropinized animal on total colonic blood flow and on the rate of elimination of ^{85}Kr from a small depot injected *superficially* in the mucosa-submucosa of the distal part of the colon. The nerve stimulation causes a moderate transient increase in total colonic blood flow and a marked augmentation of the wash-out rate of ^{85}Kr reflecting a regional blood flow increase from 35 to 100 ml/min × 100 g tissue during the peak of the vasodilatation. As total blood flow returns to control level despite continued stimulation, there is a simultaneous decrease in the rate of ^{85}Kr elimination and within 2–3 min after the start of the stimulation both recordings have regained the prestimulatory level. Upon cessation of the stimulation no significant changes of the recorded parameters are observed. In a few experiments the wash-out of ^{133}Xe from the mucosa-submucosa was followed during prolonged activation of the pelvic nerves in not atropinized animals. The initial as well as the *recurrent* increases of total colonic blood flow (cf. chapter IV) were accompanied by augmentation in the rate of wash-out of ^{133}Xe.

The response pattern illustrated in Fig. 1 is representative for the effects of pelvic nerve stimulation on the elimination rate from depots of ^{85}Kr injected in *superficial* parts of the mucosa-submucosa of the distal two thirds of the colon. However in some experiments the local injections of the tracer were made into the *deeper* layers

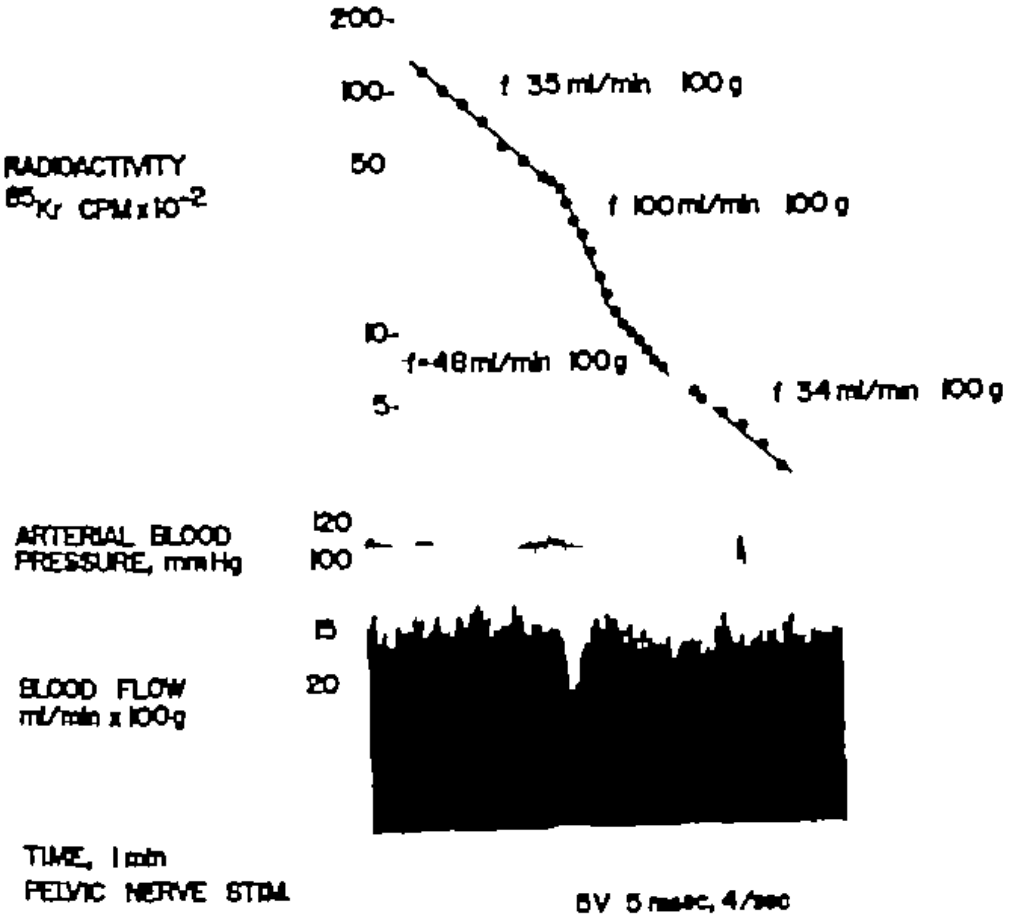

Fig. 1 Cat 2.3 kg The effect of pelvic nerve stimulation on arterial blood pressure total colonic blood flow and wash-out rate of ^{85}Kr from kept the superficial mucosa submucosa of the distal part of the large bowel. The animal was trapanized (1 mg/kg b w) N t the pronounced transient increase of wash-out rat on nerve stimulation kept only moderate increase in the total venous outflow

of the mucosa-submucosa. In these experiments, insignificant increases in the rate of elimination were observed during pelvic nerve stimulation even when marked increases of total colonic blood flow occurred

In a number of experiments two G M tubes were utilized to monitor simultaneously the rate of elimination of the ^{85}Kr from local injections in the mucosa-submucosa in both the *proximal* and the *distal* part of the colon a representative experiment is illustrated in Fig 2 The proximal injections were made in the upper third of the large bowel. As usual stimulation of the pelvic nerves causes a transient increase in regional blood flow of the mucosa submucosa of the distal colon (cf Fig 1) while no significant change occurs in the proximal colon

Fig 3 summarizes the results obtained in those experiments in which injections were made from the mucosal side The wash-out rate of radioactivity expressed in ml/min x 100 g is plotted on a logarithmic scale *versus* the simultaneously registered total colonic blood flow The pelvic nerve stimulations illustrated (filled circles) are

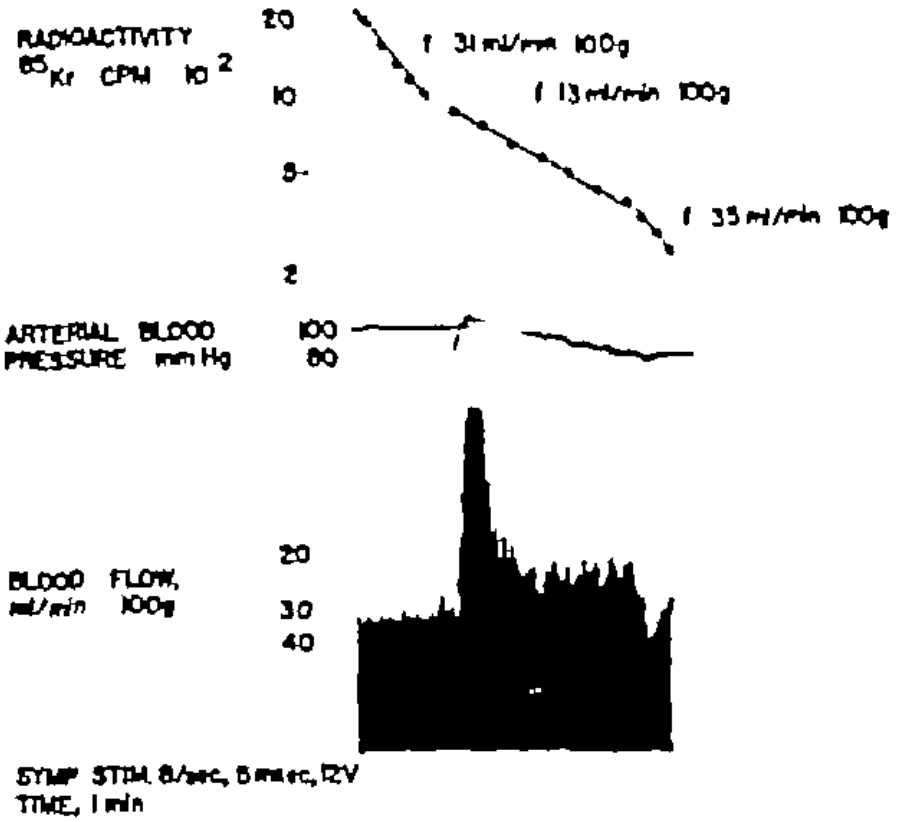

Fig. 5 (cat ~5 kg) The effect of stimulation of the sympathetic vasoconstrictor fibers to the colon (splanchnic and lumbar colonic nerves) on arterial blood pressure (—) colonic blood flow and rate of wash out (^{85}Kr) from a depot in the mucosa submucosa of the large bowel.

C. Effects of direct stimulation of the sympathetic nerves

Fig. 5 illustrates the effects of stimulation of the splanchnic and lumbar colonic nerves on total colonic blood flow and on the rate of elimination of ^{85}Kr from a minute local injection made into the mucosa submucosa of the large bowel. While sympathetic stimulation (splanchnic and lumbar colonic nerves) evokes the characteristic autoregulatory escape phenomenon described earlier (chapters III and IV) the ^{85}Kr wash-out rate remained decreased to approximately the same extent throughout the stimulation period. This corresponds to a blood mucosal flow decrease from 31 to 13 ml/min 100 g. Upon cessation of stimulation a transient hyperaemia occurs reflected both in total colonic blood flow and in the blood flow at the site of the injection. This response pattern is representative of the majority of the sympathetic stimulations but in 7 out of 11 stimulations a biphasic response was observed in the wash-out curve. In such experiments an initial reduction of mucosa submucosal blood flow was registered during the intense initial restriction of total colonic blood flow. As total blood flow increased (autoregulatory escape) regional blood flow also increased in these experiments but to a lesser extent. It cannot be settled

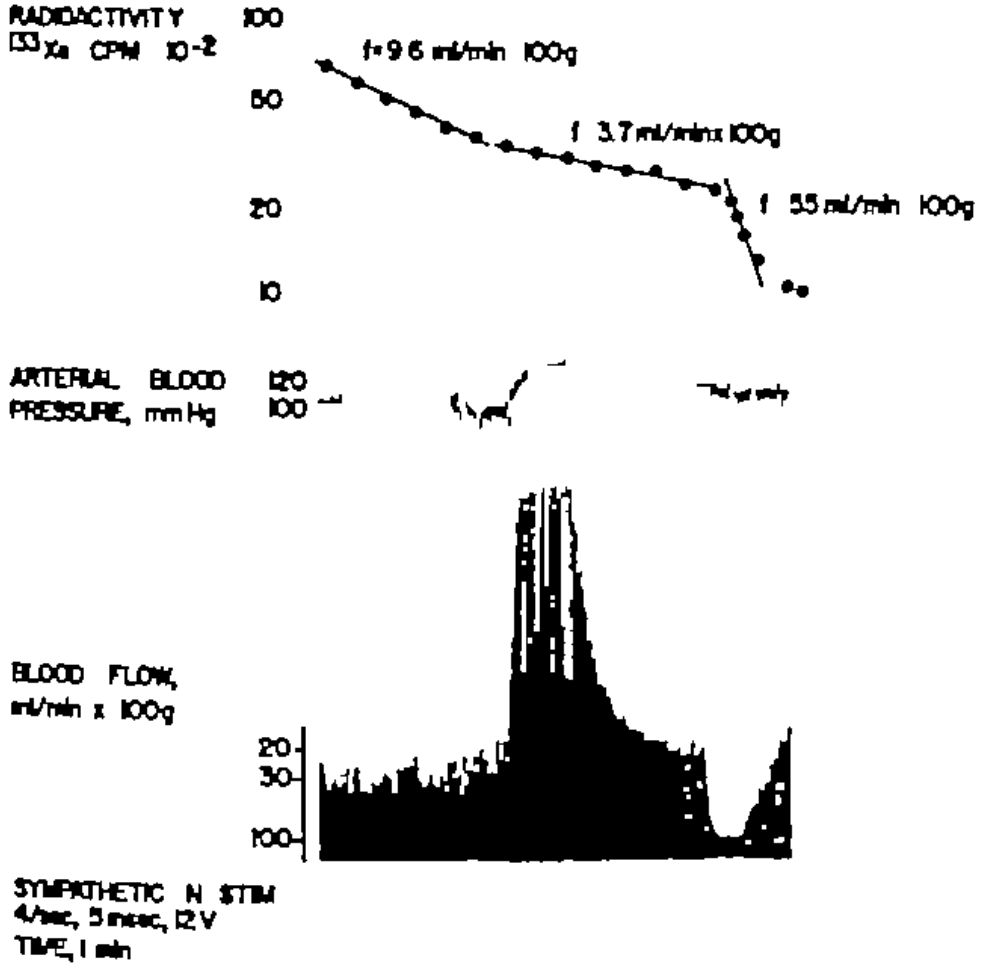

Fig. 6. Cat 2.5 kg. The effect of stimulation of the sympathetic vasoconstrictor fibres to the colon (splanchnic and lumbar colonic nerves) on arterial blood pressure, total colonic blood flow and rate of wash-out of ^{133}Xe from a depot in the colonic muscularis.

whether the tracer might have been more deeply deposed in this group of experiments, so as to reflect also blood flow in the deeper mucosa.

Fig. 3 (circles) summarizes the results obtained during sympathetic stimulation. The illustrated data were obtained in experiments in which the splanchnic and lumbar colonic nerves were simultaneously stimulated at rates of 2, 4 and 8 imp/sec and represent values recorded during the steady state phase of vasoconstriction. It can be seen that the rate of mucosal wash-out is in the lower range of, or below the control values observed at a similar total colonic blood flow.

The effect of sympathetic stimulation on the rate of elimination of ^{133}Xe from the muscularis was studied in a few experiments and is illustrated in Fig. 6. There is a reduction of rate of wash-out (upper panel) during the nerve stimulation, the decrease corresponding to a reduction in blood flow from 9.6 to 3.7 ml/min × 100 g at a stimulation rate of 4 imp per sec. Upon cessation of stimulation a marked transient increase of both total and muscularis blood flow is observed.

IV COMMENTS

The results of the present study strongly suggest that the increase in total colonic blood flow observed on pelvic nerve stimulation mainly reflects a vasodilatation in superficial parts of the mucosa submucosa restricted to the distal two-thirds of the colon at the most (Fig 1 2 and 3) These observations are in accordance with the results obtained on visual inspection reported in chapter III which also suggested that the blood flow increase predominantly occurs in the colonic mucosa Since pelvic nerve stimulation causes an increase in colonic secretion (cf chapter IV) one may assume that blood flow is augmented mainly in the secretory part of the mucosa when pelvic nerve activation is induced This conclusion also reached by Wright *et al* (1038) who provided histological evidence of an augmented vascularization around the colonic crypts and of increased secretory activity of the colonic epithelium during pelvic nerve stimulation

The present experiments also suggest that blood flow may sometimes become moderately increased in some part of the colonic muscularis during pelvic nerve activation. Thus, a transient small increase of muscularis blood flow was seen in 3 out of 17 measurements Possibly this increase is secondary to the marked activation of the colonic smooth muscles that always occurs upon pelvic nerve activation (cf. chapter II)

Quantitatively regional blood flow amounted to 7–14 ml/min × 100 g (Fig 4 and 6) in the colonic muscularis and to 30–40 ml/min × 100 g in the mucosa (Fig 1 2 and 3) in the resting" colon. These values are in good agreement with those reported for the resting small intestine of the cat (Lundgren 1067 Kampp and Lundgren 1068) The relative weights of the mucosa submucosa and of the muscularis in the colon were determined to be 60 and 40 per cent respectively (see Method) The total colonic blood flow can therefore be deduced from the regional flow figures being then approximately 30 ml/min × 100 g (Table I left panel) which is in close agreement with direct measurements of total colonic blood flow This indicates that blood flow of the mucosa submucosa of the denervated colon may be fairly homogenous (cf. Kampp and Lundgren 1068) It can furthermore be calculated that about 80 per cent of total colonic blood flow is distributed to the mucosa submucosa during rest the remaining 20 per cent being diverted to the muscularis (Table I)

During pelvic nerve activation blood flow in superficial mucosal portions is increased transiently from 20–40 up to 300 ml/min × 100 g (Fig 3) with a less pronounced augmentation of total colonic blood flow which in this series of experiments was increased only to about 60–70 ml/min × 100 g However in other experiments (see chapters III and IV) total colonic blood flow could at a maximum increase to 150–200 ml/min × 100 g Assuming that the regional blood flow increase during pelvic nerve stimulation is augmented proportionally to total colonic blood flow it can be calculated that the maximal blood flow in the superficial mucosa submucosa amounts to approximately 400 ml/min × 100 g tissue In this connection it should be pointed out however that the increase of total colonic blood flow in-

Table I

	Total blood flow at rest — ml/ml × 100 g		Moderate increase of total blood flow by pelvic nerve stimulation 60 ml/min × 100 g		
	Mucosa submucosa	Muscularis	Mucosa-submucosa Superficial	Deep	Muscularis
Regional blood flow	30	10	150	30	20
Relative weight (per cent of total)	60	40	68	32	40
Calculated blood flow distribution (per cent of total)	82	18	78	17	13

Calculated values are given in *italics*

duced by pelvic nerve stimulation represents an underestimation of the "true" blood flow increase since it is calculated on the total weight of the colonic preparation including regional lymph nodes, mesentery etc The results in chapter III and IV and those in the present series of experiments clearly indicate that the blood flow increase induced by pelvic nerve stimulation is restricted mainly to the distal 2/3–3/4 of the colon. Thus the maximal increase of blood flow in the superficial mucosa-submucosa may be even higher than calculated above

In Table I (right panel) the flow distribution has been estimated during pelvic nerve stimulation which increased total colonic blood flow to 60 ml/min × 100 g It is assumed that the muscularis blood flow is increased to 20 ml/min × 100 g and blood flow in the superficial mucosa-submucosa to 150 ml/min × 100 g (Fig 3) Blood flow in deeper parts of mucosa-submucosa is presumed to equal control. This agrees with the observations reported above. It can then be estimated that approximately 70 per cent of total colonic blood flow is diverted to the vasodilated part of the mucosa which constitutes only part of the mucosa-submucosa. Concomitantly a smaller proportion of total blood flow is distributed to the muscularis as compared to control. The calculated relative weights of the different blood flow compartments are also given in Table I

Stimulation of the regional sympathetic vasoconstrictor fibres induces an initial reduction of total colonic blood flow causing a decrease in regional blood flow in the mucosa-submucosa as well as in the muscularis (Fig 5 and 6) During prolonged stimulation total colonic blood flow again increases and reaches a new steady state level within 2–3 min. (cf chapter III and IV) while in most experiments there is no change or only small changes in regional blood flow of the mucosa or of the muscularis as registered with the techniques of the present study These findings suggest that a redistribution of blood flow occurs within the colon during the autoregulatory

escape This conclu ion is also supported l y the foll wing bservation *First* the mucosa remained blanched on vi ual in pection throughout the stimulati n period (chapter III) *Second* the reduction of regional blood flow in the mucosa and mucosa during the st ady state phase wa greater than could be explained by the concomi tant reduction of total c l mic l lood flow (Fig 3)

A similar blood flow red tribution during nervou vasoconstriction ha been described in the small intestine (Folkow *et al* 1961*b* Wallentin 1966) From the present experiments it i not possible to draw any conclu ion exactly where the blood flow increase occurs during the autoregulatory escape It i proposed however that blood flow is augmented around the base of the crypt and in a jacent parts of the submucosa since autoradiographic studies in the *small intestine* (Lundgren *unpublished* observation) suggest such a localization

CHAPTER VI

REFLEX CONTROL OF COLONIC MOTILITY AND BLOOD FLOW

LEIF HULTÉN

I INTRODUCTION

The reflex changes of colonic motility in man, elicited from mechanical stimulation of the rectal wall, are relatively well known from previous investigations summarized by Hurst (1910) Alvarez (1948) and recently by Mendeloff (1968) With respect to animal experiments, studies on cats (e g Cannon 1902 Garry 1933 Schmidt and Fülgraff 1963) show that the motility is increased in the entire colon during defaecation with peristaltic contractions occurring even in the caecum.

Most investigations indicate that this defaecation reflex" is dependent on the integrity of the pelvic nerves and with at least the main bulk of afferent as well as efferent fibres running in these nerves. The exact nature of the stimulus for this pelvo-pelvic reflex response is however still debated (Zimmerman 1909 Hertz 1911 Cannon 1902 Garry 1933) and it is also discussed whether other pathways and mechanisms may be involved Thus it has been suggested that vagal efferents may be involved in the reflex activation of proximal colonic parts in association with defaecation (Schmidt and Fülgraff 1963)

The expulsive motility in the descending colon and the rectum seems to be governed also by autonomic centres in the cerebral cortex and the brain stem (Davenport 1966) A medullary area close to the vomiting centre has thus been claimed to control defaecation (Hatcher and Weiss 1923 Koppanyi 1930 Langworthy and Rosenberg 1939) and inhibitory hypothalamic centres have also been suggested to exist (Wang *et al* 1940 Sheehan *et al.* 1941) The normal dominance of supraspinal excitatory influences may explain why transection of the cervical or thoracic cord in man acutely leads to suppression of colonic motility but later reflex hyperactivity develops (White *et al* 1940) presumably a result of sensitization after partial denervation of the spinal reflex arcs. In chronically spinal man it has further been observed that passage of faeces through the colon seems to augment its motility presumably as a result of pelvo-pelvic reflexes. Moreover stimulation of the skin

around the anus or activity of the bladder facilitates reflex defaecation in man (Denny Brown and Robertson 1933).

In anaesthetized cats rectal distension results in enhanced defaecatory responses but they become obvious first when the excitatory sacral reflex influence on the colon is released from the suppressing impact of the sympathetic lumbar colonic nerves (Garry 1933) an effect presumably exerted at the intramural ganglionic level. While the pelvo-pelvic autonomic reflex mechanism involved in defaecation thus seem to be relayed at the sacrospinal level the somatic" defaecation responses are dependent on centres cranially to the spinal cord itself for their full expression (Garry 1933).

Another important type of colonic response ultimately often leading to expulsion the clinically well known gastro-colic reflex was previously supposed to be mediated in vagal efferents and afferents (Hertz 1913 Lehmann 1913 Larsson and Bargen 1932). More recent investigations have however cast doubt upon such a nervous basis for this reflex" response (Logan 1967 Connell 1969 see also chapter I).

Whereas the general principles of reflex colonic activation in connection with defaecation are fairly well documented information concerning the corresponding effects on colonic blood flow is scant. Wright *et al.* (1938) described a marked mucosal vasodilatation occurring concomitantly with an increased secretion and motility as a result of afferent pelvic nerve stimulation in the cat while Cuber (1964) claims that defaecation is accompanied by a diminution of colonic blood flow. No systematic and quantitative studies concerning reflexly induced changes in colonic blood flow whether pelvo-pelvic or of other nature seem to have been performed apart from the apparently contradictory studies already mentioned.

As partly outlined in chapter II a sympathetically mediated spinal reflex—the so called intestino intestinal inhibitory reflex (Kuntz and Saccomanno 1944) studied in detail with respect to the small intestine by Johansson *et al.* (1964)—can strongly inhibit gastrointestinal motility exerting its effect mainly or perhaps only on the ganglionic level (see Norberg 1965 Kewenter 1965 Jansson 1969). To what an extent and in which situations, a corresponding type of reflex also affects colonic motility is unclear although the results of chapter II suggest that such a tonically active inhibitory reflex might be in part responsible for the suppression of vagal excitatory responses in proximal colonic parts.

As the so-called gastro-colic and defaecation reflexes are essential for bringing about appropriate colonic emptying it is the aim of the present investigation to explore further some of the major reflex effects on colon motility and blood flow to examine whether the reflex organization is different in proximal and distal colonic parts and explore to what extent sympathetically mediated intestino-intestinal reflex inhibition is involved in the colonic motility control. It was also considered of interest to explore if the excitatory apparently cholinergic fibers within the lumbar colonic nerves (cf. chapter II) were possibly involved in the reflex control of colonic motility.

II METHODS

A. Operative procedures

32 cats, fasted for 24 hours, were anaesthetized intravenously with chloralose (50 mg/kg) after induction with ether A tracheal cannula was inserted to allow a free airway T permit drainage of swallowed air and secretion a plastic tube was introduced orally into the stomach. Another catheter drained the bladder The arterial pressure was recorded from a femoral artery by means of a mercury manometer The animal was kept on a heating pad which was thermostatically regulated keeping the body temperature around 37–38°C. The abdomen was opened in the midline and the small intestine was extirpated from the duodenum to the ileo-caecal junction together with the greater omentum and the spleen In some experiments a small jejunal segment or a mesenteric nerve pedicle from the extirpated small intestine was isolated for subsequent intestino colonic reflex activation (see below) Great care was taken to avoid any interference with the vascular and nervous connections to the colon. The secretion from the adrenals was eliminated by isolating the glands from the circulation by means of encircling ligatures; hydrocortisone 10 mg/kg was given intramuscularly for substitution

B Recording of motility

The proximal half of the colon was used for recording of reflex changes in colonic motility while the distal part was utilized for activation of the appropriate receptor mechanisms. For this purpose the lumen of the proximal colon was connected to a glass tube as described in chapter II, and was by way of a rubber tube and an adaptable pressure reservoir connected to a piston recorder The proximal colonic segment was isolated from the distal one by a loose ligature, so applied that it did not destroy either extra or intramural nervous or vascular connections or the wall continuity to distal colonic parts. Motility of the distal part was sometimes separately recorded in a similar way via a tube inserted into the anal canal especially when pelvic afferents were stimulated electrically Thus nervous or myogenic influences, overbridging the artificially separated colonic parts could be freely transmitted along the largely intact intestinal wall. The recording systems were filled with Tyrode solution at body temperature The volume reservoir was arranged in such a way that the intracolonic pressure could be set and continuously adjusted to a level of 10–12 cm H_2O

C. Determination of blood flow

For quantitative recordings of colonic blood flow the total venous outflow was, after heparinization (3–5 mg/kg), diverted through a closed photoelectric drop recorder (see chapter III) and returned via the external jugular vein. The recorder operated an ordinate writer where the heights of the ordinates are inversely proportional to the flow rate, allowing conversion of the recording into ml of flow/min and 100 g tissue The peripheral resistance unit per 100 g of tissue (PRU_{100}) were calculated as the ratio of mean arterial blood pressure (mm Hg) to blood flow (ml/min × 100 g tissue)

D Nervous stimulations

Sympathetic *intestino-intestinal reflex* activation was induced either by graded distension of a small jejunal segment or by afferent electrical stimulation of a mesenteric pedicle.

In some of these experiments all sympathetic nerves connected to the colon were left intact; in others the existence of an inhibitory sympathetic connection was explored by section of the major sympathetic trunk. In other experiments the cut peripheral ends of the sympathetic nerves were placed on ring electrodes for frequent electrical stimulation described in Chapter II. The colon could also be investigated for its sympathetic inhibitory control pharmacologically by intravenous administration of guanethidine (3 mg/kg).

Reflex activation of the pelvic nerves was achieved by mechanical stimulation of the colonic mucosa either by a functional stimulus, namely by distension of balloons placed in the rectal lumen. In a few experiments electrical stimulation was applied to proximal colonic parts or small pieces of cotton attached to a silk thread was introduced through the anal canal and placed in the proximal part of the colon. By means of the thread the cotton could be dragged along the intestinal lumen in an attempt to initiate an adequate mechanical stimulation of the wall. Reflex activation of the pelvic nerves was also studied by means of graded electrical stimulation of afferent fibres in one of the pelvic nerves, the other one being left intact.

The presence of a *vagal reflex control* of the colon was examined by distension of a balloon within the stomach when the vagal fibres were left intact. In some experiments the ventral vagal trunk was dissected out at the subdiaphragmatic level with its central end mounted on a silver ring electrode for afferent stimulation. The pelvic nerves in these experiments were dissected free but otherwise left intact.

For *somatic afferent stimulation* the hamstring nerve was dissected free, cut and its central end mounted on a silver ring electrode.

The nerve stimulations were delivered from a Grass stimulator S4 L. For afferent stimulation the nerves were stimulated at 4–50 pulses/sec at a voltage of 15 and a pulse duration of 0.05–3 msec. In four experiments the spinal medulla was transected either initially or in the course of the experiment at the cervical or upper thoracic level (Th I–V).

The following drugs were administered i.v.: atropine (Atropine sulphate, Merck) in a dose of 1 mg/kg b.w., guanethidine (Ismelin® Ciba) 3–5 mg/kg b.w. In some experiments gallamine triethiodide (Flaxedil® May & Baker) was used to prevent disturbing somatomotor reflex movements. Artificial respiration was then maintained by a respirator pump.

III RESULTS

A. The intestino-colonic inhibitory reflex

Activation of this sympathetically mediated reflex either by distension of a small intestinal loop or by electrical stimulation of afferent mesenteric nerve fibres usually had no effect or only a weak inhibitory effect on the sparse colonic motility recorded in the parasympathetically denervated colon. Inhibition was first observed when high frequency afferent stimulation (above 10 imp/sec) was utilized; then a delayed and slight increase in the proximal colonic volume could be induced in such a preparation.

In contrast, a prompt and marked inhibition of the vagally induced motility in the proximal colon occurred, even upon slight intestinal distension (Fig. 1, upper panel) or upon low frequency stimulation of mesenteric afferents (Fig. 1, lower panel).

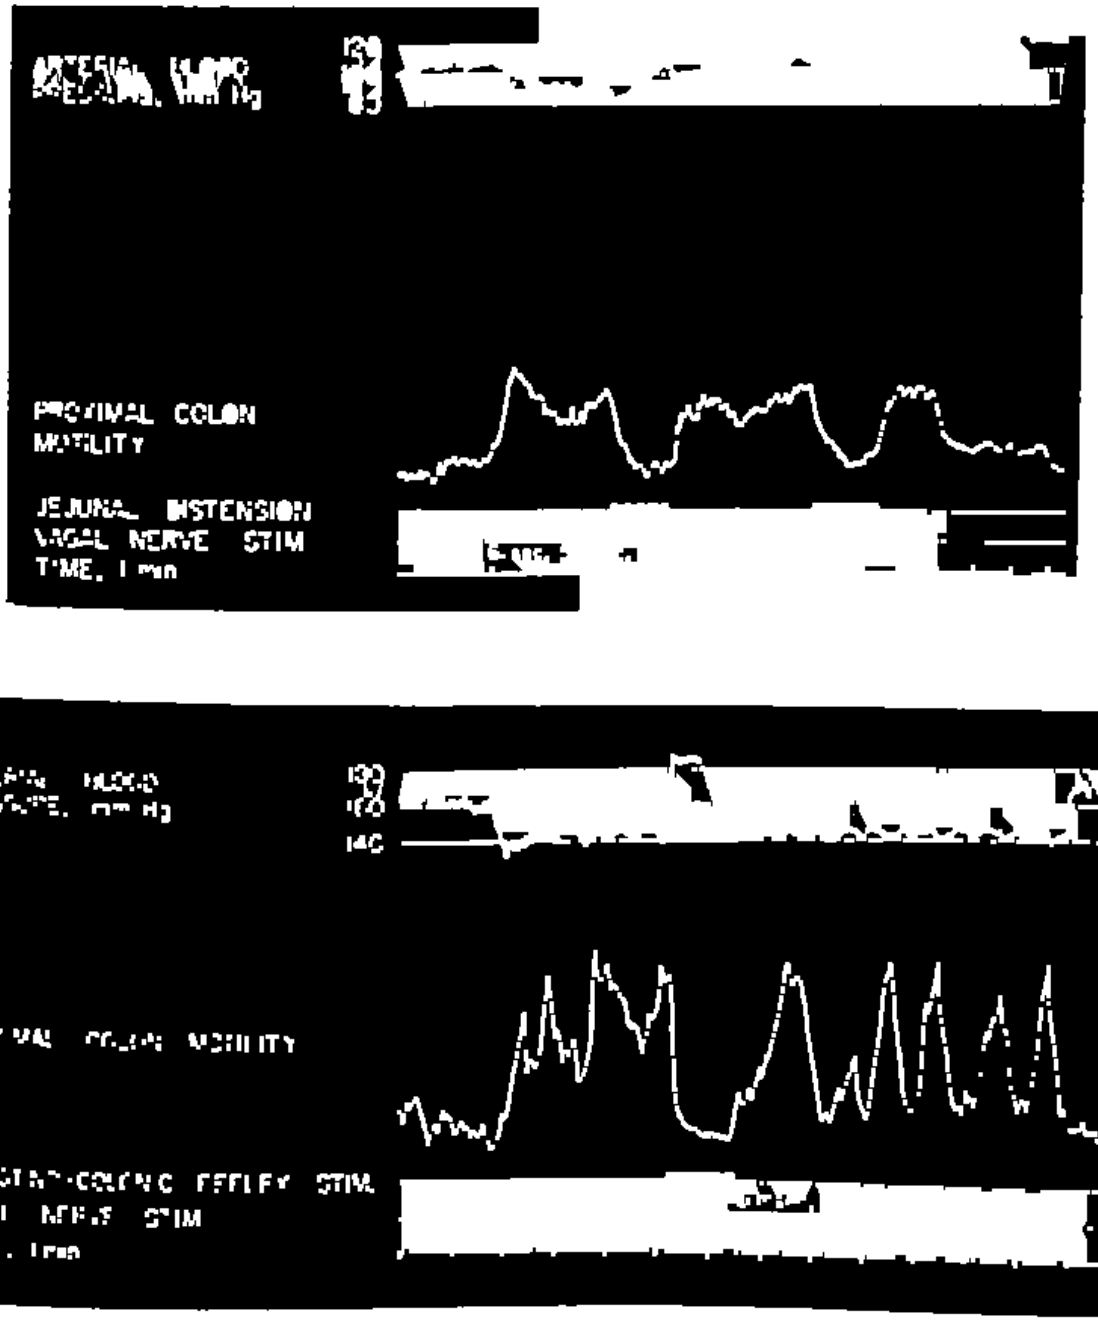

Fig. 1. *Upper panel.* Cat 2.8 kg. Chloralose. Intestino-colonic reflex inhibition of vagally induced proximal colon motility produced by jejunal distension (60 cm H_2O). *Lower panel.* Cat 2.1 kg. A similar and prompt reflex inhibition of vagally induced motility is achieved by stimulation of visceral afferents. Not the vagally induced rhythmic activity superimposed upon a moderate increase of tone.

Similarly a drastic inhibitory effect was exerted also when a motor response of the proximal colon was induced by pelvic nerve stimulation. In contrast the excitatory response to pelvic nerve stimulation in the distal part of the colon was largely unaffected even with afferent stimulation at high frequencies (10–16 imp/sec) (Fig. 2.)

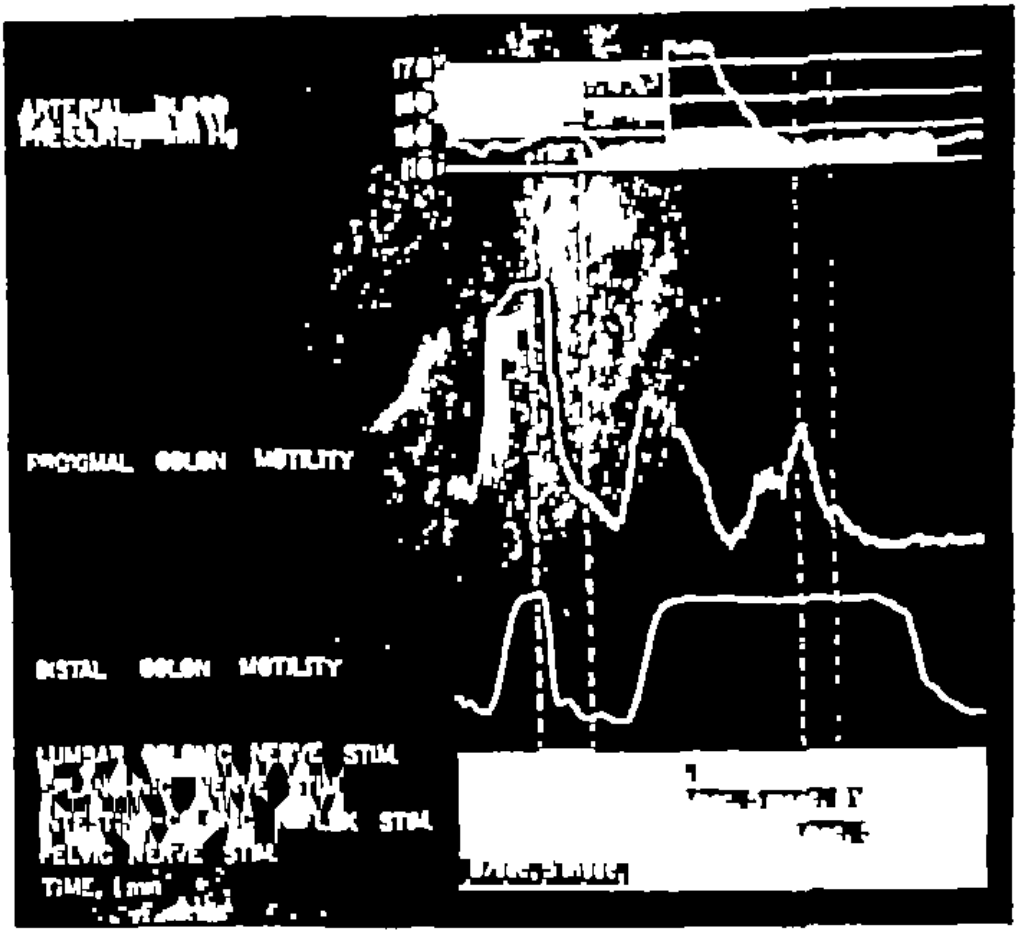

Fig. — Cat 3 kg Chloralose The effect of intermittent colonic reflex activation by high frequency stimulation of rectal efferent pelvic nerve induced colonic motility as compared with the inhibitory effect of efferent splanchnic nerve stimulation. Note the sustained contraction of both segments after pelvic nerve stimulation. Inhibition of motility of the proximal part of the colon is only achieved as a result of direct or reflex activation of the sympathetic nerves whereas the motility of the distal part is not affected whatsoever

B The pelvo-pelvic reflex

1 *Effect of mechanical stimulation of the rectal wall*

Since in these experiments reflex increases of colonic motility and blood flow were achieved either by a frictional stimulus applied to the rectal wall or by distending a balloon in the rectal lumen colonic motility was recorded only in the proximal part

As is shown in Fig 3 mechanical stimulation of the rectal wall led to a strong reflex motor response and a concomitant transitory increase in colonic blood flow The vasodilator response had qualitatively and quantitatively the same characteristics as that induced by longlasting electrical stimulation of the efferent pelvic nerve fibres, as described in chapter III and IV although the motor response sometimes seemed to be less sustained Cutting the vagus nerves in the neck did not affect the extent of the response

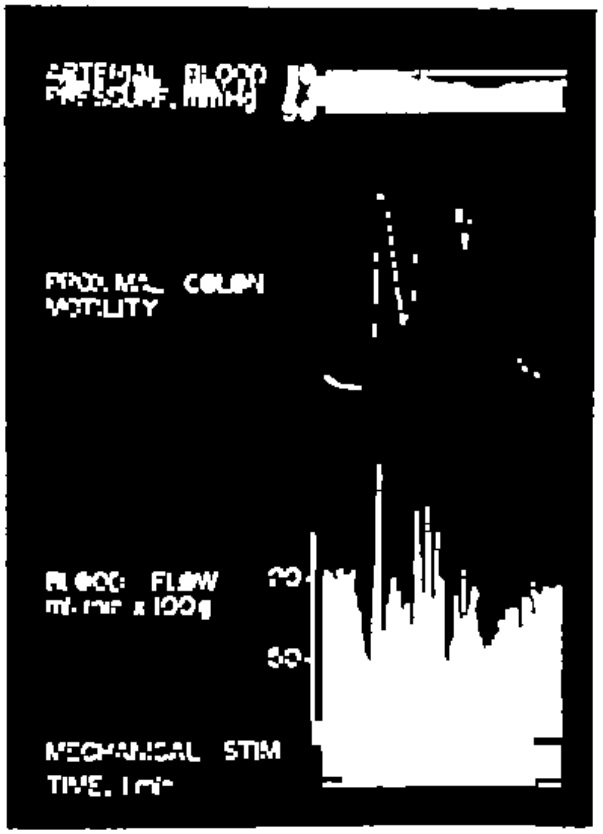

Fig. 3. Cat 3.1 kg Chloralose. Effects of frictional stimulation by means of to and fro movement in the rectum, on proximal colonic motility and total venous outflow. The sympathetic supply to the colon was cut in this experiment. Note the *initial* blood flow increase followed by *recurring* increases on prolonged stimulation.

Straining movements were seldom seen in association with this frictional stimulation, although such somatomotor reflex effects were sometimes noted when strong rectal distension was applied. When straining occurred the reflex vasodilator response was preceded by a brief decrease in blood flow and was consequently somewhat delayed. A small reflex decrease of arterial blood pressure was sometimes noted upon frictional stimulation of the rectum but it was far more pronounced when rectal distension was performed. Frictional stimuli or distension applied to the colon proximally to the rectal part had little or no influence on colonic motility or blood flow.

The reflex responses described, both with regard to motility and blood flow were often difficult to reveal until the sympathetic colonic nerve supply had been divided or the sympathetic influence blocked by guanethidine (3 mg/kg). This indicates the presence of considerable sympathetic tonic discharge which suppresses the parasympathetic reflex effects. This inhibitory sympathetic influence could also be demonstrated after sympathetic section by the fact that both the reflex motor and vasodilator responses in the colon could again be suppressed when either of the cut sympathetic supply (splanchnic and lumbar colonic nerves) were directly stimulated at low rates (see Fig. 4 A, B and C).

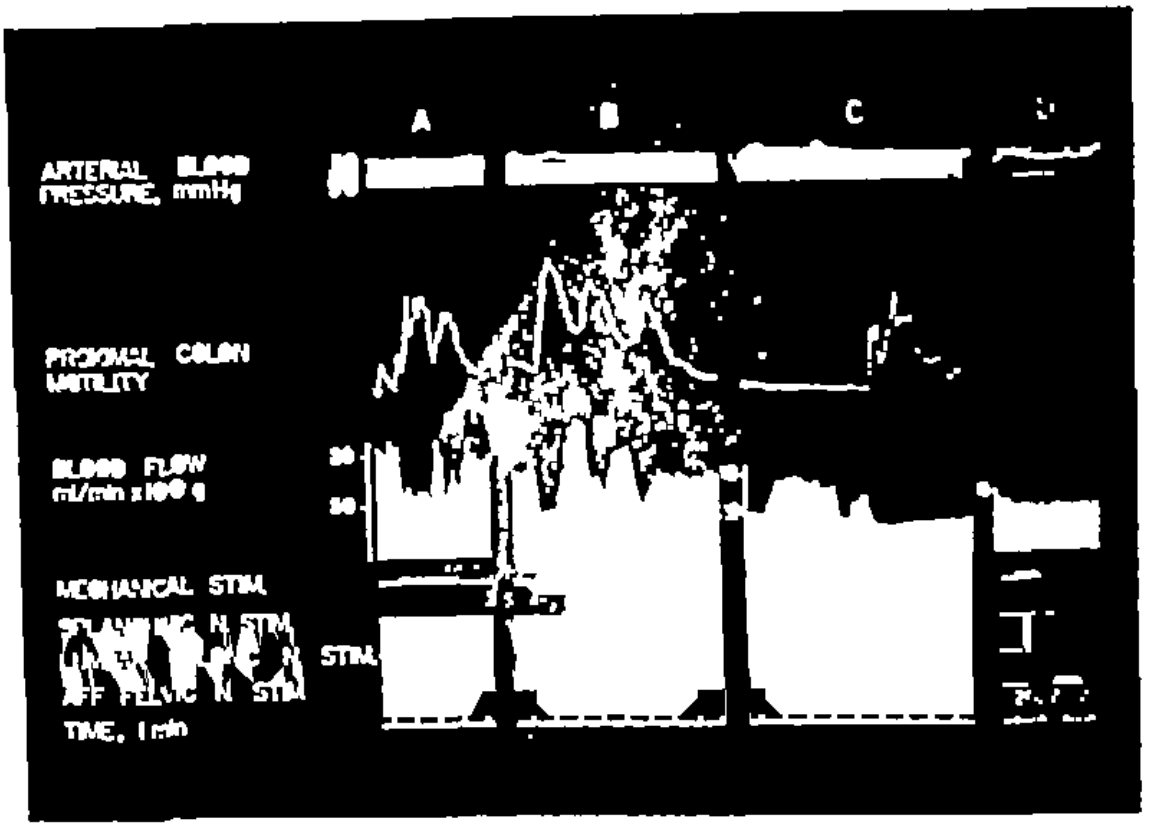

Fig. 4. Cat 4.4 kg. Chloralose. The effect of rectal frictional stimulation on motility and blood flow is shown in (A). In (B) is illustrated the effects of efferent sympathetic stimulation on the reflexly induced increase of colonic motility and blood flow. Note the immediate resistance increase of blood flow and simultaneous inhibition of motility. The effects of frictional stimulation on continuous increased sympathetic tone is illustrated in (C). Note that vasodilatation occurs readily whereas motility increase is not induced until cessation of the sympathetic stimulation. The pelvo-pelvic reflex responses are abolished when both pelvic nerves are severed (D).

Furthermore the pelvo-pelvic reflex responses often became pronounced if the spinal medulla was cut at the upper thoracic-lower cervical level despite the fact that the efferent sympathetic supply was left intact. This indicates that the suppressing tonic sympathetic discharge may be of *supraspinal* origin rather than a spinal intestino-intestinal reflex (see below).

The magnitude of the blood flow increase reflexly produced via the pelvic nerves by mechanical stimulation of the colonic or rectal wall was about two- or threefold from a resting blood flow of about 15–20 ml/min 100 g tissue. On repeated attempts to elicit these reflex responses they regularly faded and ultimately vanished only to return again after a resting period. In experiments where frequently repeated mechanical stimulation had caused the response to vanish *efferent* stimulation of the pelvic nerve still evoked a powerful motor and vasodilator response indicating that an adaptation of the receptors in the rectal wall, or/and of the reflex centres was mainly responsible of the fading reflex effect rather than any fatigue or adapta-

tra of t. efferent nervous links or of the effect wa. At the end of these experi
ments the colon contained rich amounts of muco especially in the distal sec
tion.

As mentioned, vagotomy never affected the reflex res ponse and it was also un
affected by severing the pudendal nerves or one of the pelvic nerves. Cutting both
pelvic nerves on the other hand abolished the response completely indicating that
both the afferent and the efferent fibers are confined to the pelvic nerves (see Fig.
4 D). This was the case even when the vagal and sympathetic supply was left
intact and the adrenergic fibers were blocked by guanethidine. However, mechan
ical stimulation of the rectal mucosa could sometimes result in a slight vaso-
dilatation, probably of local origin as it was also seen in a completely denervated
colon. To check whether the reflex effects described were dependent on a cholinergic
transmission mechanism, atropine in a dose of 1 mg/kg was administered intraven-
ously. Neither the motor nor the vascular response were substantially reduced by atro-pine.

Effects of afferent pelvic nerve stimulation

In another series of experiments the reflex arrangement of the pelvic nerves was further explored by graded afferent stimulation of one of the pelvic nerves, the other one being left intact.

As seen in Fig. 5 stimulation of *low* threshold afferent fibers in the pelvic nerves (3 volt, 0.05–0.2 msec) regularly produced a marked fall in blood pressure. This fall became gradually more enhanced with increasing rates of stimulation to reach a maximum at about 10 imp/sec and could be as great as 40–60 mm Hg. If the sympathetic nerves were left intact a moderate increase of colonic blood flow could occur concomitantly with the depressor effect, whereas no increase of motility was seen. The increase of colonic blood flow vanished when the sympathetic nerves were severed and instead a small reduction of flow was seen in connection with the reflex reduction in blood pressure, at the same time as a slight increase of colonic motility was sometimes recorded.

Afferent pelvic nerve stimulation at *high* nerve strength (8 volt, 5 msec) often induced a complex somatic defaecation reflex pattern including powerful contractions of the muscles in the abdominal wall during which colonic blood flow appeared to be temporarily reduced. This was evidently a result mainly or solely of the straining as the blood flow increase could often be traced in the venous outflow recording between the mechanical artifacts produced by the straining movements (see Fig. 4 C). When these were eliminated by administration of Flaxedil[®] the usual and typical increase of colonic blood flow and motility *often* appeared as a result of this type of afferent stimulation.

As is seen in Fig. 6 (left panel) *the reflex fall in blood pressure* as well as the pressor straining movements were *eliminated by transection of the spinal cord* and the reflex motility increase and *the characteristically phasic vasodilatation* became

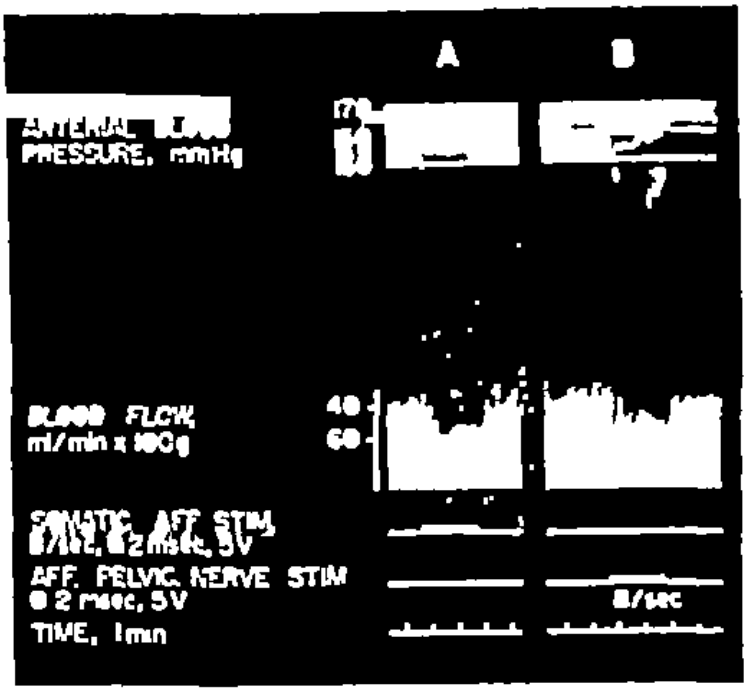

Fig. 5. Cat 4.4 kg. Chloralose. Effects of low threshold somatic depressor fibre activation (hamstring nerve) (A) compared with stimulation of low threshold afferent fibres in the pelvic nerves (B) on systemic blood pressure and colonic blood flow. Note the constant increase in blood flow. Effect of this type is abolished by guanethidine.

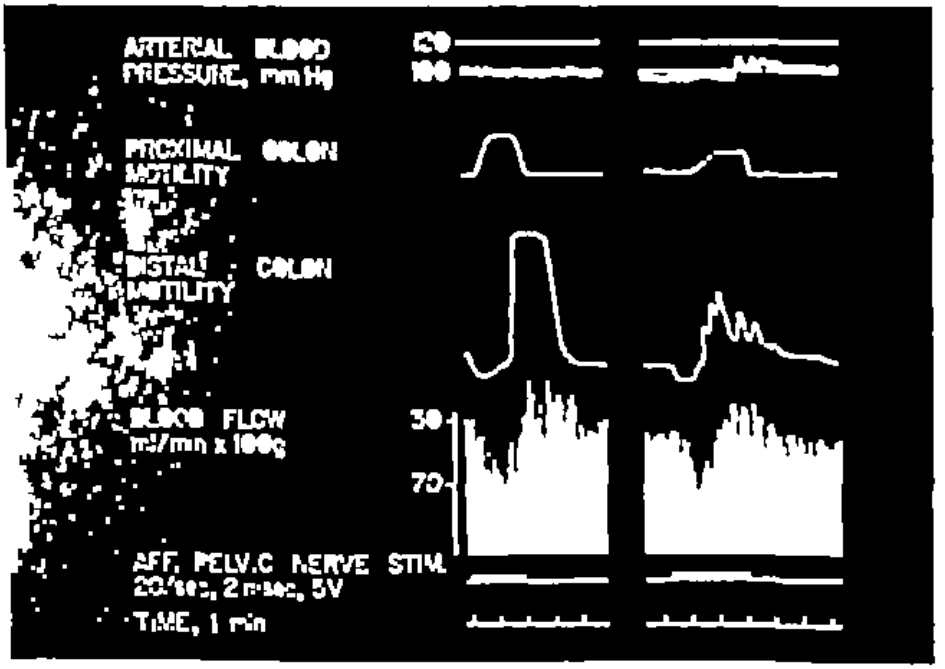

Fig. 6. Cat 3.6 kg. Chloralose. Effect of high strength afferent pelvic nerve stimulation on colon motility and blood flow before (panel left) and after (panel right) atropine administration 1 mg/kg. The spinal medulla had been cut in the upper thoracic level. Note the increase of blood flow and the readily occurring motility increase in proximal and distal colonic parts even after atropine treatment. Note also the transitory increase in colonic volume preceding the motor contraction, sometimes occurring in this situation.

The reflex vasodilator response to high strength afferent stimulation of the pelvic nerve was in a given animal largely comparable in size and general characteristics to that produced by frictional stimulation of the rectal wall when both pelvic nerves were intact. The presence of a superimposed sympathetic activity could however cause considerable differences between animals, but after blockade of this sympathetic activity intense vasodilator responses were readily obtained in almost all animals and they were sometimes comparable in magnitude to those induced by efferent pelvic nerve stimulation (chapter III and IV) Atropine (1 mg/kg) failed to abolish the reflex response (see Fig 6 right panel) and although guanethidine eliminated the reflex blood pressure fall upon pelvic nerve stimulation the colonic vasodilator response was unaffected or even enhanced

Cutting the remaining pelvic nerve abolished the reflex completely even if the vagal and sympathetic supply to the colon was left intact but the adrenergic fibres blocked with guanethidine This indicates that the pelvic parasympathetic fibres constitute the sole *efferent* pathway and that the cholinergic excitatory fibres in the lumbar sympathetic supply (see chapter II) or the vagal fibres are not involved in the defaecation reflex as induced from the rectum anus region.

C. Effects of activation of vagal afferents

To test the validity of the hypothesis that the gastro-colic "reflex may be mediated by nervous connections in the vagal nerves, a small series of experiments were performed where vagal afferents were activated either by means of gastric distension or by graded electrical stimulation of the central end of the cut left vagal nerve.

Neither separate distension of the fundus and antrum of the stomach nor afferent vagal stimulation, procedures known to produce e.g a profound reflex gastric relaxation (Jansson 1969) had no effect whatsoever on colonic motility despite the fact that afferent vagal stimulation was varied over a wide range and though the pelvic nerves were intact and the inhibitory influence exerted by the sympathetic adrenergic supply was blocked with guanethidine This indicates that neither the vagal fibres to the proximal colon nor the cholinergic fibres in the lumbar sympathetic supply to the colon or the pelvic efferents are reflexly excited by vagal afferents.

Sometimes however afferent vagal stimulation produced a complex response pattern with vomiting and a pronounced fall in blood pressure but colonic motility was never enhanced

D Effects of afferent somatic "pressor" and "depressor" fibre stimulation

As a comparison to the intestino-colonic and pelvo-pelvic reflexes, somatic" pressor and depressor afferents (see Johansson 1962) were stimulated in some experiments to see whether such afferents in a more *specific* way might reflexly affect colonic motility and blood flow

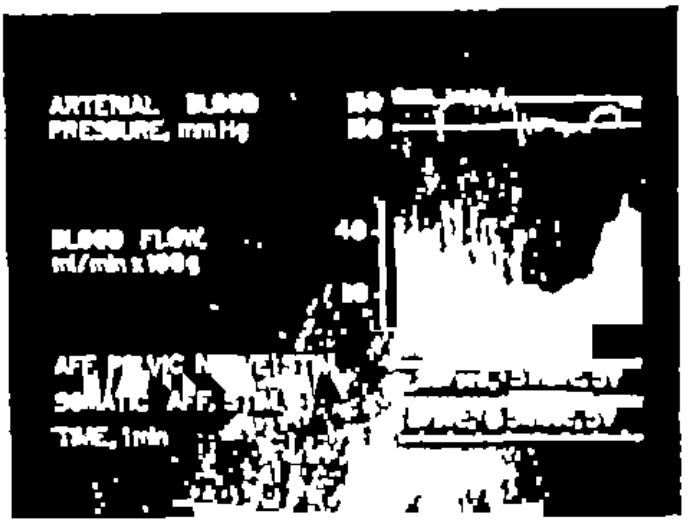

Fig 7 Cat 5.1 kg Chloralose Effect of superimposed activation of somatic *depressor* afferent (hamstring nerve) on the reflex response upon a *high strength* stimulation of pelvic nerve afferents. Note that the blood flow increase can be traced behind the mechanical artifact produced by straining movement which are eliminated by depressor activation at the same time the blood flow increase is somewhat enhanced

Activation of the fairly *low* threshold somatic depressor fibres produced similar reflex effects on the colonic blood flow as did the *low* threshold afferent fibres in the pelvic nerves Thus a moderate increase in colonic blood flow occurred associated with the reflex fall in blood pressure (Fig 5) The blood flow increase was abolished when the sympathetic fibres to the colon were cut indicating that it was due to a reflex inhibition of sympathetic vasoconstrictor fibre activity and not due to pelvic nerve activation Colonic motility was not essentially changed again indicating that the parasympathetic supply was not reflexly activated The same seems to hold for the cholinergic motor fibres running in the lumbar sympathetic supply If however a reflex activation of the pelvic nerve supply was produced by afferent *high*-strength pelvic nerve stimulation producing straining associated with a partly masked pelvo-pelvic reflex vasodilatation a superimposed activation of somatic depressor afferents had a dramatic effect (Fig 7) The straining movements became largely inhibited while the pelvo-pelvic reflex vasodilatation was enhanced This finding may indicate that the somatic depressor fibres besides suppressing to some extent somatomotor reflex activity produce an overall sympathetic inhibition eliminating also the tonic sympathetic suppression of the pelvo-pelvic reflex

The somatic pressor fibres produced largely the same reflex effects as in other tissues (see Johansson 1967) with no evidence of any excitatory involvement of the colonic parasympathetic supply Thus the reflex pressor effects were associated with a moderate reflex vasoconstriction in the colonic vascular bed with no significant change of colonic motility It should here be stressed that the adrenal glands were in all experiments denervated so that any reflex release of bloodborne catecholamines

could not occur which might otherwise have affected the motility somewhat (cf Kock 1950)

IV COMMENTS

To facilitate the discussion of the results the reflex activation of the pelvic nerves will be dealt with first

In the present study it was shown that a motor contraction of largely the entire colon as well as a pronounced vasodilatation of the colonic vascular bed can be brought about by reflex activation of the pelvic nerves. These reflex activations of the specific parasympathetic supply could be induced only from the rectum anus region This seems to be the case also in man, whereas distension of the rectum produces an immediate desire to defaecate (Zimmerman 1900 Hertz 1911 and Golligher and Hughes 1951) this is not the case when distension is applied at proximal colonic levels, which would indicate that receptors specifically involved in the defaecation reflex are restricted to the rectal part of the large bowel Exactly where in the wall these specific" receptors are localized is not known. Painting the mucosa with anaesthetic solutions (Garry 1933 Schmidt and Fülgraff 1963) is said to block the reflex response but as the anaesthetic solution might affect the muscle coat as well, the suggestion that the receptors are located to the mucosa cannot be taken for granted.

Frictional stimuli were in this study by far the most efficient ones in bringing about reflex colonic activation. Pure distension was less effective in this respect at least until spinal transection was performed. Moreover distension appeared—when powerful—to superimpose another type of reflex response involving mainly a generalized reflex sympathetic inhibition with a consequent blood pressure fall coupled to a slight colonic vasodilatation. These two types of reflexes could often be better distinguished by graded afferent pelvic nerve stimulation where the fibres producing the depressor effects had distinctly the lowest stimulation threshold.

Cannon (1902) came to the conclusion that the adequate stimulus for propulsive activity and emptying of the large bowel was not likely to be mere distension only He suggested that frictional movements of colonic contents might supply a most essential stimulus. In fact, a frictional stimulus applied to the urethra by the movement of a catheter or of fluid is in a similar way suggested to facilitate reflex micturition responses in the cat, whereas pure distension in the same region had no effect whatsoever (Barrington 1921) It was pointed out by Garry (1933) that the effective stimulus for eliciting a colonic reflex response in anaesthetized cats was friction and he tried to explain the inadequacy of mere distension of the rectum as a stimulus by the acuteness of the experiments and consequent shock to the nervous system.

The reflex parasympathetic responses, especially the pelvic nerve effect on colonic motility were often suppressed by tonic sympathetic activity This evidently emanated mainly from supraspinal centres rather than being preferentially a spinal intestino-

colonic reflex as the suppression seemed to be much reduced by high spinal section. This was the case also after section of the sympathetic supply directly or by guanethidine blockade (3 mg/kg). Intestino-intestinal inhibitory reflexes are if anything known to be enhanced by high spinal section (Johansson *et al.* 1966, 1968). After sympathetic blockade or especially when high spinal section was performed the reflex vasodilatation and motility increase mediated by the pelvic parasympathetics could sometimes be almost of the same magnitude as those produced by maximal efferent pelvic nerve stimulation (see chapters II and III). The often particularly marked pelvo-pelvic reflex responses after high spinal section might indicate that also the sacrospinal reflex centres become released from a supraspinal inhibitory influence and not only the synapses in the colonic wall. This was also illustrated by the fact that rectal distension produced a clearcut increase of colonic motility and blood flow only when the spinal cord was cut at the upper thoracic level, which also eliminated the earlier mentioned reflex depressor response. The pelvo-pelvic reflex effects were usually not substantially decreased and certainly not abolished after atropine administration.

The autonomic part of the defaecation reflex was shown to be solely dependent on the integrity of the pelvic nerves confirming the results of Garry (1933) and Wright *et al.* (1938). Both the afferent and efferent paths for this reflex appear to be confined to these nerves and there was no evidence that either the vagal nerves or the cholinergic motor fibres running in the lumbar sympathetic colonic supply were involved.

The term gastro-colic reflex introduced by Hertz was originally thought to be a specific reflex mechanism activated by distension of the stomach during feeding and resulting in a reflex activation of the colon preceding defaecation. Afferent electrical stimulation of the vagal nerves or distension of the stomach has in some experimental series been observed to elicit a response of this general nature (Lehmann 1913, Galapeaux and Templeton 1937). Recent investigations have however failed to confirm the presence of such a specific reflex arrangement and it has been suggested that other mechanisms are involved (Pearcy and van Liere 1956, Douglas and Mann 1940, Logan 1967, Connell 1968, see also chapter I).

In the present study neither gastric distension nor afferent vagal stimulation which produce powerful reflex effects on the stomach (Jansson 1969) influenced colon motility although all parasympathetic pathways were intact and the sympathoinhibitory influence blocked in the course of the study. Thus neither the vagal and pelvic nerves nor the cholinergic sympathetic fibres to the colon appear to be involved in this type of response. Furthermore, there was no evidence that the afferent vagal stimulation might enhance colonic motility by inhibiting reflexly the suppressing effect of prevailing adrenergic activity. These findings cast further doubt on the existence of a strictly nervous basis for the gastro-colic response.

This does by no means imply that the vagal nerves which certainly influence proximal parts of the colon (see chapter II) should not be engaged in the reflex control of colonic motility. They are evidently not involved in either the gastro-

colic "reflex" or in the defaecation reflex but they may well be engaged along with the excitatory vagal supply to the stomach and small intestine in connection with e.g meals, thus enhancing the mixing type of motility in these parts favouring digestion and absorption It is likely as discussed in chapter II that the proximal colon is mainly involved in absorption events where a neurogenic enhancement of mixing movements seems rational

With respect to the spinal sympathetic inhibitory reflexes of the intestino-intestinal and intestino-gastric type these are generally *enhanced* by the elimination of a tonic bulbospinal activity that suppresses their spinal reflex coupling These sympathetic reflexes exert an inhibitory action on gastro-intestinal activity mainly perhaps only at the cholinergic ganglionic level at least in the cat (Kewenter 1965 Jansson and Martinsson 1966) In the present study intestino-colonic reflex inhibition induced either by graded jejunal distension or by afferent mesenteric nerve stimulation, produced a clearcut inhibitory effect on the parasympathetically induced motility in the proximal colonic part—whether induced by the vagal or the pelvic nerves. However it appears as if the sympathetic lumbar colonic nerves are far less perhaps not at all, activated in this particular type of spinal inhibitory reflex. The effects produced by high spinal cord transection also agree with such a view since this procedure appeared to eliminate a tonic inhibitory effect conveyed by the lumbar colonic nerves rather than enhancing such an influence which is the case when the intestino-intestinal type of reflex is released from supraspinal control. Thus the pelvo-pelvic motility and vasodilator response occurred more readily after a spinal transection while the reverse is true for reflex vagal excitations of the stomach and the small intestine (Johansson *et al.* 1965 1968 Jansson 1969)

As a comparison to the described parasympathetic and sympathetic reflexes, "specific" in the sense that they were elicited from the colon itself or from adjacent gastrointestinal parts, reflex effects emanating from somatic pressor and depressor afferents (see Johansson 196") were also explored to some extent. These types of afferents—most of which seem to mediate "superficial and deep pain, respectively —apparently did not directly engage either the parasympathetic fibre supply to the colon or the cholinergic fibres supposed to run in the sympathetic colonic supply As in other tissues the somatic pressor fibres produced reflex vasoconstriction and the depressor fibres reflex inhibition of vasoconstrictor fibre tone in the colonic vascular bed In this respect the somatic depressor afferents thus produced effects similar to those of the low threshold afferents present in the pelvic nerves (see above) In the "resting colon neither type of somatic afferent fibres produced any significant effects on motility However as is the case with the stomach (Jansson 1969) activation of somatic depressor afferents under circumstances of a prevailing reflex activity in the parasympathetic supply enhances the excitatory effect of this supply This was in the present experiments clear from the "release of the reflex vasodilatation induced via the pelvic nerves (Fig 8) This seems to be the result of the well known generalized inhibitory effect on sympathetic tonic activity that these fibres exert (e.g Johansson

1962 Jansson 1969) This overall reflex reduction of a tonic sympathetic inhibitory influence, which in the colon is exerted mainly via the intramural ganglia will enhance the impact of the pelvic nerves on colonic motility and blood flow It is not a result of any reflex excitation of the pelvic parasympathetic fibres induced by the somatic depressor fibres because the mentioned enhancement was entirely abolished when the sympathetic fibres were cut or blocked by guanethidine

Summarizing the results in the present study it appears evident that the motor and vascular responses as induced by efferent stimulation of the pelvic nerves (see previous chapters) are also achieved by reflex activation of these nerves, which only seems to be produced by specific pelvic afferent This pelvo-pelvic reflex constituting the autonomic part of the defaecation reflex involves the motility of largely the entire colon and appears to be activated by specific mechano-receptors These are most easily activated by frictional stimuli but also by distension and they are situated in the rectal anal section It also appears as if there exist supraspinal inhibitory mechanisms which adjust and regulate the activity in the micro-spinal reflex arc both at the spinal relay and at the parasympathetic ganglionic level in the colonic wall in the latter case conveyed by the inhibitory action of the lumbar colonic nerves. Neither the vagal fibres nor the cholinergic fibres in the sympathetic supply are involved in the defaecation reflex

The vagal fibres to the proximal colon are probably reflexly involved along with those to the small intestine to facilitate digestion and absorption The functional significance of the cholinergic sympathetic fibre supply remain unknown Neither fibre type is involved in the gastro colic reflex nor are the pelvic nerves.

Intestino-colonic inhibitory reflexes probably of spinal nature and via splanchnic efferents suppressing the vagally or pelvically induced activity in the proximal colon appear to be of the same nature as the intestino-gastric and intestino-intestinal inhibitory reflexes The lumbar colonic nerves supplied to largely the entire colon, appear to be less, perhaps not at all activated in this particular type of reflex indicating a somewhat different functional role for the sympathetic inhibitory control of proximal and distal colonic parts They seem to convey a centrally induced inhibitory influence at least in the present experimental situation

Thus, the results in the present reflex study agree with the view outlined in earlier chapters that the colon may be composed of two functionally different parts. It seems probable that the proximal part though relatively small in the cat and apparently of importance mainly for the absorption of water and salts possesses a nervous control different from that of the rest of the colon but closely related to that of the small intestine as it is supplied by vagal parasympathetic and splanchnic sympathetic fibres. These nerve fibres, distributed to the proximal colon only are apparently involved in similar patterns as are the nerves to the small intestine but are not engaged directly in the reflex responses that mainly involve the distal parts of the colon. Here the nervous control is exercised by the pelvic parasympathetic nerves and the lumbar sympathetic colonic nerves although these nerves partly extend

also to the proximal colon but only with respect to the motility control. The distal colon and its nervous control is mainly involved in the evacuation mechanism and associated with this there occurs in this part a reflex production of protective and lubricating mucus and a mucosal vasodilatation. All effects are conveyed by *pelvic* efferents.

However as pointed out in chapter II the difference in motility patterns of the proximal and distal colonic parts—so obvious in the reflex patterns—can also be traced in the inherent activity of the colonic wall. This does by no means deny that the mode of action of the vagal and pelvic parasympathetic fibres may in somewhat different ways affect the intrinsic plexuses. Thus the vagal effects on the proximal colon differ from those of the pelvic nerves since the vagal effects are easily blocked by atropine whereas the pelvic effects are not.

CHAPTER VII

GENERAL CONCLUSIONS AND COMMENTS

The aim of the present study was to shed further light on the classical concept that the large bowel may be comprised of two functionally different parts. This concept is based mainly on theoretical and embryological ground but only incompletely supported by functional analyses as clear from the most recent reviews of the field (Connell 1968, Gillespie 1968, Schuster 1968, Wakeloff 1968). As a matter of fact current opinions about the nervous control of colonic motility are in many respects controversial and incomplete and little is known about the nervous regulation of colonic blood flow and secretion (see Chapter I). The main interest was therefore focused upon the distribution mode and extent of action as well as reflex involvement of the cranial and sacral parasympathetic supply (vagal and pelvic nerves) as compared with the sympathetic supply (splanchnic and lumbar colonic nerves) with respect to colonic motility, blood flow and secretion.

In the preceding chapters these different aspects were sequentially dealt with and discussed. The present chapter will therefore be devoted to a brief review of these earlier chapters and to a general discussion of the functional significance of the results. However it is justified in this context to first consider some general methodological problems even though the experimental procedures are described in connection with each chapter which should be consulted for detail.

I METHODOLOGICAL CONSIDERATIONS

In order to analyse in more detail the autonomic nervous control of a visceral organ like the colon the effects of nervous section or blockade and of graded efferent stimulations of the out nerves should be sequentially explored together with the various types of reflex and central involvement of the intact nervous pathways. Furthermore since the parasympathetic and sympathetic effects on the colon can in various ways interfere with or even entirely mask each other it is also necessary to perform analyses of their respective influence both when the antagonistic pathway is intact and when it is blocked. These different steps have all been utilized in the present series of studies. As however several autonomic neuroeffector systems are

involved and closely intermingled—visceral smooth muscles glands, blood vessels—their separate analyses calls for quantitative recordings of appropriate effector responses rather than of the nerve fibre activity for exploration of the general organization of the neurogenic patterns involved Electrophysiological recordings alone can hardly provide full insight into all these aspects, although such techniques are of course of greatest importance when aspects like synaptic organization occlusion facilitation etc in the autonomic nervous system are to be studied (cf Job and Lundberg 1952 Oscarsson 1955)

In the present study colonic motility and various aspects of the vascular responses have been separately recorded in the proximal and distal parts of the colon. As far as possible not only qualitative but also quantitative aspects of the responses have been dealt with. This type of recording implies a "randomization" of the neurogenic influences on the respective effector cells. The frequency response characteristics of the different effectors were also studied furthermore it is known that there is a marked degree of convergence and divergence in autonomic fibre supply to *functionally* homogeneous effector groups. It appears therefore as if such groups are more or less, neurogenically directed as "functional units" For such reasons this type of recording may provide good insight into the general characterization of the viscero-motor control if certain precautions are taken (see below) This methodological approach is, in fact related to that used by Sherrington in his classical studies of the spinal-supraspinal somatomotor control.

The equivocal and divergent results often obtained in previous studies of colonic function can partly be explained by the fact that unphysiological rates and strengths of electrical stimulations of the nervous supply have mostly been utilized, which—when partly antagonistic nerve supplies are involved—may lead to erroneous information. For example stimulations of this type can imply such a massive impact on the effectors that it may entirely mask a normally wellgraded reciprocal control Many earlier workers were also aware of these facts and have therefore preferred to study only the effects of nerve section Again however the information arrived at in this way depends on whether the fibres cut were tonically active or not and in this respect anesthesia, surgical trauma with consequent pain fibre activation, etc. may greatly influence the situation Thus, the surgical trauma often leads to increased sympathetic activity (e.g Jansson 1960) which may in various ways greatly affect other regulatory mechanisms, e.g by way of the spinally relayed intestino-gastric intestino-intestinal and intestino-colonic reflexes. Furthermore during anesthesia the resting parasympathetic discharge is usually low or even absent and supraspinal control mechanisms may of course be grossly affected.

Recently considerable insight has been gained into the normal discharge range of the autonomic nervous system, both during "rest and in various situations of excitation and inhibition and also into some of its more important patterns of reflex and central nervous involvements (e.g Folkow 1955 Uvnäs 1960 and Folkow *et al* 1965) Therefore also in acute experiments where anesthesia and trauma is m

volved such new information somewhat reduces the difficulties in exploring the mode of action and the involvement of the extrinsic nerves to a visceral organ. For example, the various links involved can now more easily be activated in a well graded fashion or selectively and temporarily blocked, which facilitates the analysis of e.g. the reciprocal relationship between parasympathetic and sympathetic nerves. Moreover, the greatly improved knowledge concerning the various types of smooth muscle aids in studies of their nervous control.

For evaluating the colonic motility in the present study a device was utilized (chapter II) which made a double set of volume recordings. Even though this simple technique only allows for a semiquantitative estimation of the average volume changes in the two colonic parts, it no doubt reflects directly the important reservoir function of the colon. Colonic pressure changes, which have often been utilized in earlier studies, especially as regards studies on colonic function in man, will less well reflect this essential function of the colon. Furthermore, it randomizes the individual effector responses which, as mentioned, is of advantage for the present analysis of the main principles of neurogenic control. This does, of course, by no means deny some obvious shortcomings of the recording technique. Thus, more detailed studies of the individual smooth muscle layers, etc., call for quite different techniques. Concerning the recording techniques used for the analysis of the colonic vascular responses, these have been widely used in this laboratory and have been critically discussed, e.g. by Mellander (1960), Kjellmer (1965), Wallentin (1966) and Lundgren (1967).

II. MAIN RESULTS OF THE PRESENT STUDY

In *chapter I* a survey of the literature was presented and the aim of the present study was summarized.

In the experiments described in *chapter II* it was studied whether and in which ways the innervation of the colonic musculature is differently organized in proximal and distal part, and whether the sympathetic inhibitory influence is exerted mainly at the parasympathetic ganglionic site, as suggested by histochemical studies (Norberg 1964, Jacobowitz 1965, Schofield 1968). The results strongly suggest that both the parasympathetic excitatory and sympathetic inhibitory control of colonic motility are in fact organized to form two different but partly overlapping antagonistic fibre systems. Thus, the vagal and splanchnic nerve supply affects only the proximal 1/3–1/4, while the pelvic and lumbar colonic nerves affect almost the entire colon, i.e. also that part to which the vagal and splanchnic sympathetic supply is restricted.

However, the consequent double control of the proximal colonic part appears to be functionally different in important respects. Thus, vagal activation induced a response here that was characterized by motility waves of increased amplitude and frequency superimposed on a slightly elevated average tone, a motility pattern that would favour mixing of contents rather than their expulsion. Pelvic nerve activation

on the other hand excited the entire colon in a way that was different both with respect to its effect on the proximal and distal colonic sections and especially in comparison with the vagal influence on the proximal section. Thus the volume recordings showed that the pelvic nerves produced intense and apparently sustained luminal reductions in both colonic parts favouring expulsion. However direct inspection revealed that the response in the proximal part started as pronounced and frequent annular contractions but soon these fused into a sustained overall contraction that greatly reduced the lumen, such effects were never seen when the vagal supply was activated. The distal two-thirds of the colon exhibited from the start of the pelvic nerve activation a sustained and intense contraction which could virtually abolish the lumen. Another difference between the two types of parasympathetic supply which in terms of frequency response characteristics were fairly similar was that the vagal effects were easily blocked by atropine while this drug had little or no influence on the motor response to pelvic nerve stimulation.

The sympathetic supply appeared to exert its inhibitory influence on colonic motility at the intramural ganglionic level. The splanchnic fibre supply was almost exactly identical with the vagal supply while the lumbar colonic nerves took the same distribution as the pelvic nerves. Thus the proximal colonic part also has a double supply of sympathetic fibres, with respect to the motility control.

Chapter III was devoted to the distribution and type of vascular effects that were produced by graded stimulation of the various extrinsic nerves to the colon. Simultaneous stimulation of the two sets of sympathetic vasoconstrictor fibres the splanchnic and lumbar colonic nerves, led to intense and uniform blanching of the entire colonic mucosa which remained strongly blanched throughout the period of stimulation. Selective activation of the splanchnic vasoconstrictor fibres blanched the mucosa of the proximal third only and the remaining two thirds were similarly affected when the lumbar colonic nerves were subsequently activated usually with only little overlap between the two fibre supplies. Thus the lumbar colonic nerve fibres controlling the vessels do not overlap with the splanchnic fibres to the proximal third in contrast to the situation with respect to their influence on colonic motility.

In contrast to the well maintained blanching of the colonic mucosa upon vasoconstrictor fibre stimulation such stimulation did not produce any sustained marked increase of overall colonic blood flow resistance. Thus the initially intense flow reduction decayed within few minutes of continued stimulation until a new steady state level of moderately increased flow resistance was reached. Analogous to the situation in the small intestine this phenomenon was referred to as an autoregulatory escape from the vasoconstrictor fibre influence and the concomitant maintenance of the constriction in superficial mucosal parts may suggest a secondary intramural redistribution of blood flow probably to deeper mucosa-submucosal layers.

With respect to the parasympathetic supply even intense vagal stimulation over a wide range of frequencies had no effect whatsoever on colonic blood flow resistance or on the mucosal vessels suggesting that these nerves do not convey any specific

vasodilator fibres to the colon or that they in other ways significantly affect the blood vessels. This finding is in agreement with that of Lewenter (1965) concerning the small intestine.

In contrast pelvic nerve stimulation produced an intense flushing of the colonic mucosa but mainly in its distal two thirds i.e. largely corresponding to the part supplied with vasoconstrictor fibres via the lumbar colonic nerves. Concomitantly with this mucosal vasodilatation and largely restricted to the same parts a mucoid secretion appeared while the entire colon contracted as described in chapter III. Corresponding in time with this mucosal flush there was an intense but transient increase of venous outflow often followed by a phasic flow reduction.

The phasic reduction of colonic resistance was also reflected in the arterial inflow and pelvic nerve stimulation could produce blood flow figures as high as 150–200 ml/min×100 g tissue which is close to maximal vasodilation. Therefore the greatly increased venous outflow induced by pelvic nerve stimulation no doubt reflects a true and powerful colonic vasodilatation and cannot be ascribed to any squeezing of the intramural capacitance vessel produced by the simultaneous colonic contraction.

Intravenous administration of atropine in a dose of 1 mg/kg did not significantly interfere with the vasodilator mucosal motility responses to pelvic nerve stimulation indicating that both may have been brought about by some non-cholinergic mechanism. Administration of a ganglion blocking agent (Ecolid® 2 mg/kg) abolished all responses to pelvic nerve stimulation suggesting that a ganglionic synapse is present in the neurogenic pathway. The apparently identical level of stimulation thresholds for the pelvic fibres which produced colonic contraction and vasodilatation and their atropine-resistance might indicate the involvement of some indirect mechanism e.g. the release of kinin like substances as shown to be the explanation *of the atropine resistant vasodilatation in salivary glands (see below). However* an important difference was demonstrated in the distribution of the pelvic nerve effects producing vasodilatation and motor contraction (see Fig. 1).

The observation that two sets of colonic vasoconstrictor fibres control different parts of the colonic vascular bed does not mean *per se* that these parts should be functionally differentiated. It could as well be explained by the embryological development of the colon, the proximal part being derived from the midgut and consequently supplied by fibres from the thoracic sympathetic outflow and the distal part emanating from the hindgut and controlled by the lumbar sympathetic outflow. However the absence of vagal vasodilator influences combined with the fact that the pelvic nerves produce mucosal vasodilatation which is essentially confined to distal colonic parts, suggests that the two parts may be functionally differentiated. In general the blood flow control of the gastro-intestinal tract appears to be closely linked to the functional characteristics of its different compartments. This is also obvious when the stomach is compared with the small intestine (see chapter I). No doubt the colonic mucosal vessels in the proximal and distal parts are controlled

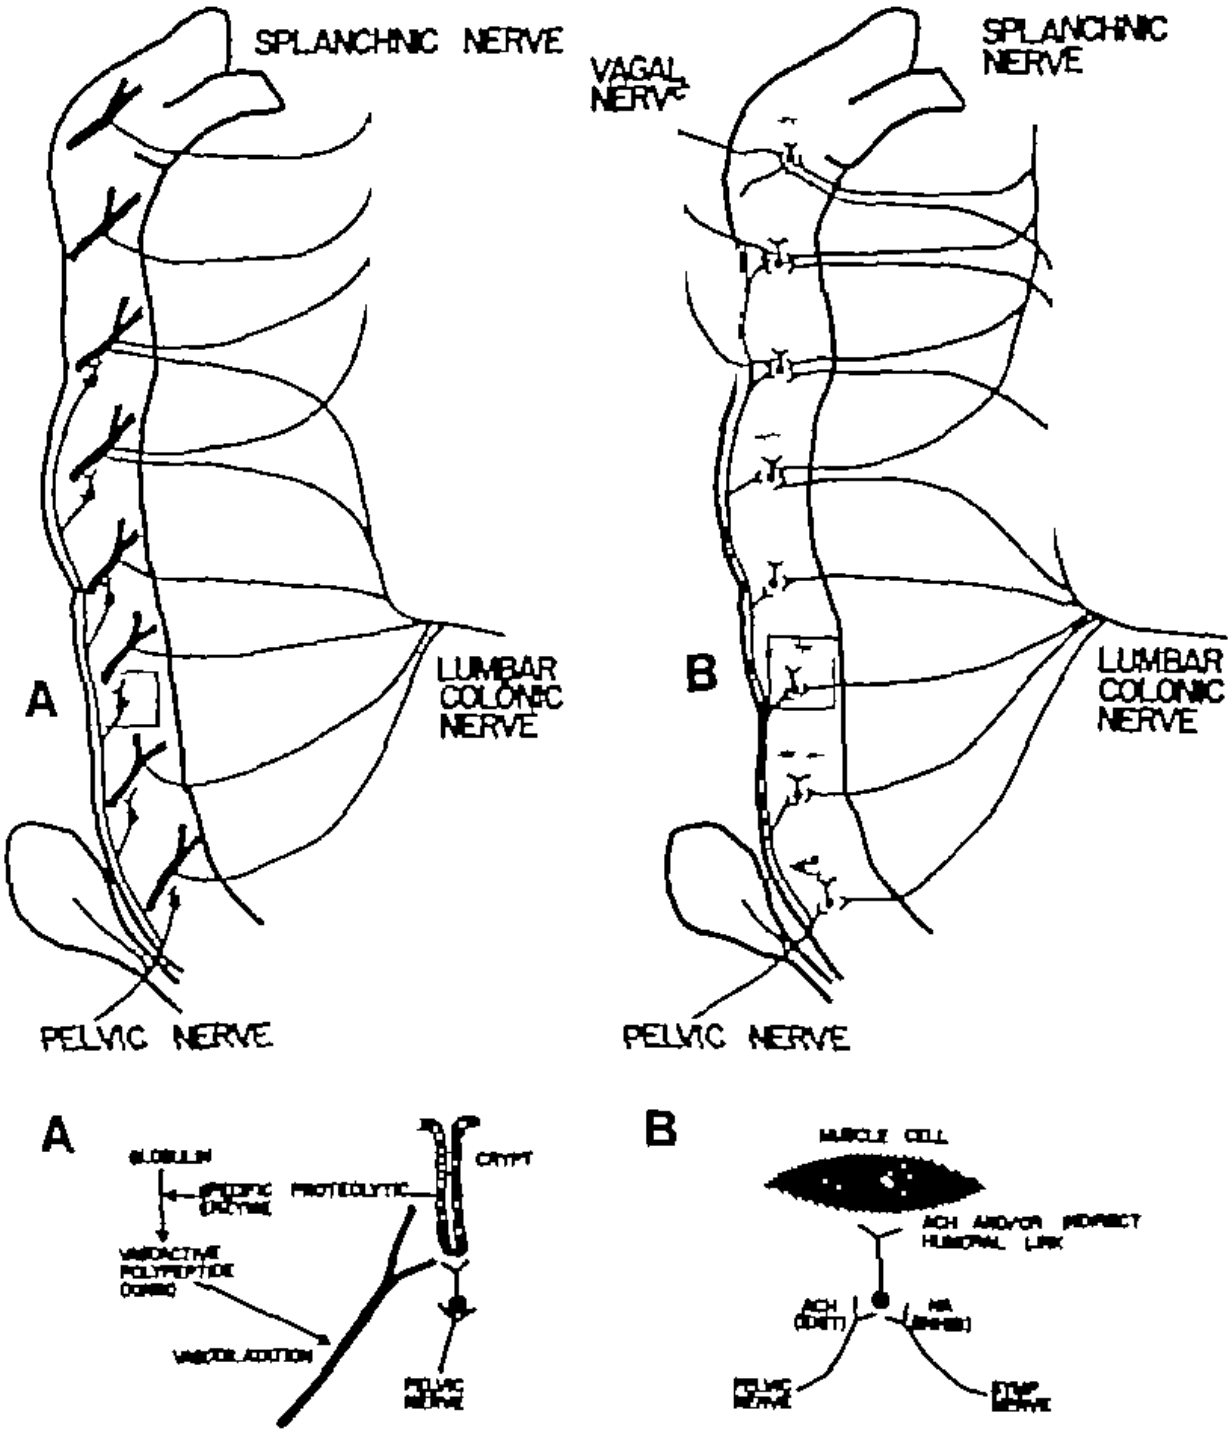

Fig. 1 Schematic drawing of the nervous control of colonic blood flow (left panel) and motility (right panel). A, shows the possible background of mucosal vasodilatation B that of intramural motility control. As described in text, the functional significance of the reciprocal vagal-splanchnic nerves control and the partly overlapping pelvic-lumbar colonic nerves control seems to be different.

differently In this respect they resemble the vessels of the small intestine and the stomach respectively

The aim of the experiments presented in *chapter II* was to study the effect of vasoconstrictor fibre and pelvic nerve activation on the consequtive sections of the colonic vascular bed The vasoconstrictor fibre effects were shown to be largely similar to those occurring in the small intestine in corresponding situations (Wallentin 1966). Thus stimulation of all colonic vasoconstrictor fibres at high physiological frequencies caused an initial increase of regional vascular resistance from 4 0 PRU_{100} "at rest to about 20–30 PRU_{100}. This was followed by a second phase a decrease in resistance which after 2–3 min attained a new steady state level still well above the control. As mentioned above a redistribution of blood flow appeared to take place in connection with this autoregulatory escape" with a fairly well maintained constriction of the vessels in the outer mucosa as was further tolled in the subsequent chapter The capacitance response of the colonic vessel which could expel at least a third of the regional blood content was well sustained during the entire stimulation period. These observations suggest that the escape involves mainly precapillary resistance vessels and not at all the venous capacitance vessels. As a result of the precapillary "escape the pre/post capillary resistance ratio remain largely unchanged during prolonged vasoconstrictor fibre activity implying that mean capillary pressure is hardly altered Furthermore neurogenic blood volume mobilization from the colonic part of the splanchnic vascular bed will be sustained

Compared with the small intestine both resting and maximal blood flow levels and CFC values were lower in the colon which might be expected as its mucosa is thinner devoid of villi and appears to be less abundantly involved in absorption Furthermore while CFC in the small intestine can be markedly reduced by vasoconstrictor fibre activation despite a considerable escape of the resistance vessels CFC in the colon was hardly reduced more than the corresponding reduction in blood flow during the escape period

The vasodilatation induced by longlasting pelvic nerve activation gave rise to an initial volume increase corresponding to the peak flow increase but was then followed by a second slower phase of steady volume increase concomitant with recurring periods of vasodilatations. After atropine administration the *initial* phasic increase of blood flow and tissue volume was largely unaffected while the second phases were both eliminated The second volume phase may therefore reflect a neurogenic colonic secretion. Since increase of the venous outflow pressure only partly reduced the magnitude of the capacitance response occurring concomitantly with the *initial* vasodilatation a neurogenic effect acting on the smooth muscles also of the veins cannot be excluded.

Chapter V deals with a study of the blood flow in the different wall layers of the colon i e the mucosa-submucosa and the muscularis respectively as analyzed both at "rest and during changes induced by the vasoconstrictor fibres and the pelvic nerves. For these measurements, the technique of recording the wash-out of topically

injected ^{85}Kr or ^{133}Xe was used while total colonic blood flow was concomitantly recorded

At least 80 per cent of the total blood flow at rest appears to be distributed to the mucosal-submucosal sections, and even when total colon blood flow was only moderately increased by pelvic nerve activation very marked increases of blood flow occurred in the superficial mucosa submucosa but hardly any change occurred in the deeper part of these sections Evidently certain parts of the mucosa perhaps those located at the base of the secretory crypts appear to be especially well perfused with huge increases of blood supply occurring here upon pelvic nerve stimulation. By indirect calculation maximal blood flow in the superficial mucosal parts may be of the order of 400 ml/min × 100 g of tissue or even higher

At most 20 per cent of the total blood flow appears to be diverted to the muscularis at "rest being of the order of 7–14 ml/min × 100 g of tissue Even supramaximal activation of the pelvic nerves which greatly increased mucosal-submucosal blood flow usually had insignificant effects on the blood supply to the muscularis. This suggests that the pelvic nerves essentially affect only the vessels of the secretory absorptive parts of the colonic wall their vascular action being closely associated with the secretory response in the colon

Vasoconstrictor fibre activation led to an initially drastic reduction of mucosal submucosal blood flow as well as a reduction of flow in the muscularis In connection with the autoregulatory escape" from the vasoconstrictor fibre influence described above the blood flow reduction appeared to be relatively well maintained in the outer mucosa and in the muscularis, compared with the escape reflected in the recording of total colonic blood flow This observation suggests that the autoregulatory escape is due to an intramural blood flow redistribution presumably towards some sections in the deeper mucosa-submucosa.

Chapter VI deals with the reflex control of colonic motility and blood flow An intestino-colonic reflex inhibition was found to influence preferentially the motility of the proximal colon being conveyed by the splanchnic nerve supply to this region. No clearcut intestino-colonic reflex inhibition, conveyed via the lumbar colonic nerves was observed however not even after high spinal transection which is known to facilitate the appearance of intestino-intestinal inhibitory reflexes. Again, these findings suggest a somewhat different organization of the control in proximal and distal colonic parts. The intestino-colonic inhibitory reflex in the proximal colon conveyed via the splanchnic supply and localized to proximal parts only appeared to exert its effect mainly and perhaps only at the parasympathetic ganglionic level as it could be clearly demonstrated only when the colonic muscles were excited via their intramural ganglia This is analogous to the effects produced by direct sympathetic stimulation.

High strength afferent pelvic nerve stimulation produced a reflex increase of motility in largely the entire colon and a mucosal blood flow increase, in a similar way as when efferent pelvic nerve stimulation was performed The reflex response

also involved an increased mucus secretion as evidenced by a huge amount of mucus content within the colonic lumen at the end of these experiments. As long as at least one of the pelvic nerves was left intact this reflex response pattern was also induced by mechanical stimulation of the rectum. Gentle to-and-fro movements were more effective than even pronounced distension.

This pelvo-pelvic reflex response favouring colonic emptying also involved a somatic component in the form of straining activity. However this latter component appeared to be dependent on supraspinal centres for its full expression—presumably in the form of descending facilitatory influences as it was completely eliminated by high spinal transection a procedure which usually enhanced the autonomic part of the pattern. Furthermore the autonomic pelvo-pelvic reflex response was considerably facilitated by elimination of prevailing sympathetic tone. This sympathetic inhibitory influence could be abolished either by guanethidine administration by peripheral section of the sympathetic supply or at least in part reduced by high spinal transection. This latter observation indicates that supraspinal structures exert an inhibitory influence on colonic motility via the lumbar colonic nerves at least in the present experimental situation. In addition supraspinal structures might also exert an inhibitory influence upon the parasympathetic reflex centres" in the sacral medullary parts. If so higher centres may damp the pelvo-pelvic reflex both by an intraspinal inhibitory influence and by means of the adrenergic nerves, at the intramural ganglionic level conveyed via the lumbar colonic nerves.

Activation of vagal afferents either by distension of different parts of the stomach or by direct stimulation of such afferents—which causes prompt reflex activation of the vagal relaxatory fibres to the stomach (Jansson 1969)—did not excite either the vagal efferents to the proximal colon or the pelvic efferents to the distal colon. Therefore in agreement with other recent studies these results suggest that the clinically well known gastro-colic reflex is not mediated by any bulbo-spinal reflex coupling between gastric vagal afferents and vago-pelvic efferents to the colon. The pelvic nerves could be reflexly excited only from the lower colon itself and particularly from the rectum but it was impossible to also activate reflexly the vagal efferents to the proximal colon. Presumably these latter type of fibres are engaged in connection with situations where the vagal excitatory supply to the small intestine is involved. In fact little is known as to which gastro-intestinal receptor mechanisms may produce reflex activation of this group of efferent vagal fibres, although they are well known to be involved during e.g. meals; central autonomic structures seem to be to a great extent responsible of such patterns (see e.g. Eliasson 1960). For example topical stimulation of the "hunger centre" in the hypothalamus of the cat produces a vagal activation of intestinal motility (Folkow and Rubinstein 1965).

III INTEGRATIVE ASPECTS

As briefly outlined above the nervous effects exerted on the musculature and on the vascular bed of the colon are somewhat differently organized in the proximal and distal colonic parts both in terms of the efferent pathways and their reflex involvement. Some functional implications of these observations will now be briefly discussed

To understand the rather complex and differentiated nervous control of colonic motility and blood flow it must be related to the functions known to be exhibited by the colon viz absorption storage secretion and expulsion It is generally held that the colon in carniverous and omniverous animals as in the cat and man is involved in absorption of water and salts. However compared with the small intestine this absorptive function appears to be small and no doubt the colonic surface area is far smaller due to the villous arrangement of the jejuno-ileal mucosa In man by far most of the fluid (intake and secretion amounting to 6–8 l per day) is reabsorbed in the small intestine It has on indirect grounds been calculated that in man perhaps 500–800 ml of approximately isotonic chyme enters the proximal colon daily (Smiddy et al. 1960 Davenport 1966) With an average faecal water content of some 150–200 ml colonic fluid absorption would amount to about 300–700 ml per day This figure has however been challenged by Levitan (1962) who suggests that the daily water absorption in the human colon is at least three times larger and equally efficient in both the proximal and distal colonic parts On the other hand both in cat and in man the colonic contents are as a rule solid or semi-solid when reaching the distal colon. Thus normally most of the liquid seems to be absorbed proximally which of course does not deny that a substantial absorptive capacity may be present but seldom utilized in the distal colon as well. Such a view is supported by the clinical observation that even extensive resections of the colon have but little effect on the absorptive function In any case the proximal part appears to be normally involved in the final water electrolyte absorption, a process which would be enhanced by the characteristic churning and mixing or even antiperistaltic motility observed in this part of the colon in intact organisms The present findings show that this type of motility pattern is to some extent basically inherent in the proximal colon and greatly facilitated by the vagal innervation which is restricted to this part.

The vagal innervation is on the other hand evidently not involved in the defaecation reflex. It seems likely that these fibres which are reserved for the absorptive part of the colon, are involved in a similar way as the vagal innervation of the jejuno-ileum appears to be involved, in the motility control and hence indirectly in absorption in this compartment.

In contrast to this vagal colonic supply the sacral parasympathetic nerves seem to be specifically involved in the expulsive function of the colon, whereas the associated secretion and mucosal vasodilatation in the distal parts mainly appear to serve protective and lubrication purposes. Defaecation is normally preceded by a general increase of gastro-intestinal activity including the proximal colonic parts, a response that is often so obviously associated with feeding that the concept of a gastro-colic

reflex has been widely accepted However as mentioned in chapter I and VI recent investigations indicate that the gastro-colic reflex may be mediated by a humoral factor perhaps gastrin thus constituting a neuro-hormonal activating mechanism—where even the afferent link may be strictly intramural—rather than a classical reflex arc It may be consistent with such a view that complete vagotomy in man if anything increases colonic motility following feeding and may hence accentuate the defaecation response

This would mean that the functional involvement of the extrinsic nervous control of the gastro-intestinal tract in general differs considerably in its various compartments thus including also the proximal and distal colonic parts The vagal relaxatory fibres to the stomach constitute an efferent link that causes prompt and apparently well graded reflex adjustments of the reservoir section of the organ to food intake (see e.g Jansson 1969) On the other hand the vagal excitatory influence in the stomach the small intestine and the proximal colon appears rather to be involved in facilitating mixing and churning of the contents mainly to subserve digestion and absorption rather than primarily executing propulsive activity which is normally fairly slow and continuous in these parts Once the contents have passed beyond these digestive-absorptive sections however a reflex pattern ensues which is of immediate effect and aimed at active emptying of the distal reservoir

The gastric and colonic reservoirs at the two ends of the gastrointestinal system have therefore much in common with respect to their extrinsic nervous control Apart from a vagal excitatory influence probably in both organs aimed at facilitating mixing of the contents for digestion and absorption there are specific fibre sets for adjusting the reservoir function of the two organs in appropriate directions. Thus active widening occurs in the stomach and active expulsion occurs from the colon both responses being conveyed by specific parasympathetic fibre sets. Further both exhibit neural vasodilator responses in the mucosa which may well be secondary to the neurogenic secretory responses because the blood flow increase seems to be mainly restricted to those mucosal sections where the increased secretion occurs

The sympathico-inhibitory fibres appear to exert their suppressing effect on gastrointestinal motility mainly or perhaps only at the intramural ganglionic level and this is evidently also the case in the colon. However their reflex involvement appears to differ somewhat in the proximal and distal colon. Thus spinal sympathetic reflex arcs ("intestino-gastric intestino-intestinal and intestino-colonic inhibitory reflexes respectively) which are exposed to tonic supraspinal inhibition and involve splanchnic afferent and efferents promptly inhibit cholinergic motility in the stomach (e.g Jansson and Martinsson 1966) and the entire small intestine (e.g Johansson and Langston 1964) but only the proximal part of the colon. The sympathetic lumbar colonic nerves affecting the entire muscularis of the cat colon via the intramural ganglia, appear to be little if at all involved in such spinal inhibitory reflexes. This sympathetic supply which overlaps in the proximal colonic parts with the splanchnic supply rather appears to mediate tonic activity of mainly supraspinal

origin. Thus, the parasympathetic pelvo-pelvic reflexes are if anything released from this type of sympathetic inhibitory influence by high spinal transection. This procedure normally enhances the intestino-intestinal type of sympathetic inhibitory reflex that is mediated by the splanchnic efferents

Associated with the pelvo-pelvic reflex increase of motility there occurs, as mentioned an increase secretion and a mucosal vasodilatation. This has also been observed in man (Grace *et al* 1951) Previously specific vasodilator fibres were supposed to be widely distributed in the gastrointestinal tract but recent investigations including the present one indicate that the parasympathetic vasodilator mechanisms are restricted to the salivary glands, the stomach and distal parts of the colon The mechanism behind this atropine-resistant gastro-intestinal vasodilatation has been extensively studied in recent years in salivary glands. Even though specific vasodilator fibres may also be present in this particular organ it appears that the main part of the neurogenic vasodilator response is *not* due to such fibres but rather due to the local formation of a potent vasodilator polypeptide kallidin to which the effect of unspecific "vasodilator metabolites may to some extent contribute

It is possible that similar indirect mechanisms may be responsible of the vasodilatation occurring not only in the gastric mucosa during vagal stimulation (see Martinson 1965) but also that occurring in distal colonic parts during pelvic nerve stimulation. Preliminary observations (Hultén and Jodal) suggest that the colonic secretion, like the saliva, contains a factor that on injection into the colonic circulation causes a profound vasodilatation. However much further study is needed before it can be settled whether this vasodilator principle is in any way related to the kinin-producing enzyme kallikrein present in the saliva In any case the situation in the colon resembles that of the salivary gland and also the gastric mucosa in the respect that the intense *initial* parasympathetic vasodilator response is largely unaffected by atropine, although the *recurring* blood flow increases probably associated with the secretory response is eliminated by this drug (see chapter IV)

From a circulatory point of view the colon can be looked upon as an abundantly perfused glandular tissue enclosed by a less well perfused smooth muscle coat One important function of this glandular tissue especially in the distal colonic parts, is to rapidly produce a mucoid secretion that presumably serves to lubricate inspissated faecal contents in association with defaecation. As the raw material for any secretion formation is ultimately blood plasma, an increased blood flow is necessary to cope with the suddenly increased fluid demands connected to this neurogenic mucoid production to which comes the increased glandular metabolism The pelvic nerves can in fact produce virtually maximal vasodilatation in the mucosa of the distal colon, where flow figures around 400 ml/min $\times$ 100 g of tissue appear to be reached in its superficial parts at intense pelvic nerve activation.

The gastro-intestinal vascular bed is as mentioned, also under the influence of vasoconstrictor fibres which in e.g the colon can produce fairly intense and well maintained flow reductions in the outer mucosa. Indeed vasoconstrictor fibres are

present to about an equal extent in all consecutive compartments of the gastrointestinal tract In contrast to the more restricted neurogenic vasodilator mechanisms. Thus antagonistic vasomotor mechanisms are only present in the stomach and the distal colon and this might be of importance in some pathophysiological situations For example strong emotions and psychic conflicts are known to cause considerable gastro-intestinal disturbances and it appears as if motility blood flow and secretion are especially affected in the stomach and the distal colon In fact the mucosal colour in the two organs may reflect emotions as expressively as the blanching and flushing of the face (Wolf and Wolff 1947)

In both these compartments the parasympathetic control of the mentioned functional parameters is pronounced and at the same time the sympathetic vasoconstrictor fibre influence is powerful not the least with respect to the outer mucosa This might constitute a potential source of especially pronounced disturbances of function and blood supply in the stomach and distal colon e g in situations of centrally elicited increases of autonomic discharge For example vasoconstrictor fibre activation increases flow resistance but the increased resistance in the postcapillary vascular section appears to be better maintained than that in the precapillary section In the resting gastrointestinal tissue this causes capillary hydrostatic pressure to remain largely unchanged during vasoconstrictor fibre activity while in e g skeletal muscle it is much lowered If however parasympathetic activation is superimposed upon an enhanced constrictor fibre tone in the stomach or and colon leading to increased secretion coupled to a preferential precapillary dilatation of mucosal vessels the vasoconstrictor fibre influence will be counteracted mainly on the precapillary side This will in turn result in a considerable increase of mean hydrostatic capillary pressure at the same time as most mucosal capillaries are probably opened up by the parasympathetic influence A mucosal edema may then ensue especially if capillary permeability is increased which seems to be the case when kinins are locally released from local sweat glands Often repeated bouts of marked mucosal edema would implicate large increases of the diffusion distance between blood and tissue Especially if this is combined with intermittent neurogenic reduction of mucosal blood flow this may in the long run have harmful effects on mucosal nutrition. This is, of course just a theoretically possible sequence of events even if mucosal control in the two organs is so organized that each single event is entirely plausible It remains to be shown that e g often repeated emotionally evoked autonomic activations produce the required interactions between parasympathetic and sympathetic influences However it might be more than a coincidence that gross mucosal disturbances and even ulcerative lesions are not only fairly common but almost exclusively confined to the stomach and the colon which are the only compartments of the gastrointestinal tract which exhibit the mentioned type of nervous control of mucosal secretion and blood flow

SUMMARY

The extent to which the parasympathetic nerves (the vagus and the pelvic nerves) and the sympathetic nerves (the splanchnic and the lumbar colonic nerves) influence motility and blood flow in various parts of the colon was studied in a series of experiments on cats. The results suggest the following general organization of the extrinsic nervous control

1 The parasympathetic excitatory and sympathetic inhibitory control of colonic motility is so organized as to form two different sets of partly overlapping antagonistic systems. These two fibre systems appear to be functionally differentiated in the sense that the vagal fibres, antagonized by both sets of sympathetic fibres facilitate mixing and churning in the *proximal* colon only here evidently favouring absorption processes rather than mere expulsion The pelvic nerves executing expulsion from virtually the *entire* colon, are in the distal colonic parts antagonized by the lumbar colonic nerves only In the proximal colon the expulsive influence of the pelvic nerves overlapping the mixing influence of the vagal fibres, is antagonized by the two sets of sympathetic fibres distributed to this part

2 The sympathetic supply appears to exert its inhibitory influence on colonic motility mainly perhaps only at the intramural ganglionic level. The splanchnic fibres are distributed only to the proximal colon, while the lumbar colonic fibres, affecting motility reach largely the entire colon.

3 The splanchnic nerve supply is strongly engaged in the inhibitory intestino-colonic reflexes as is the case also in the intestino-gastric and intestino-intestinal reflexes. The lumbar colonic supply on the other hand appears to be less involved in these types of spinal reflexes mediating instead a tonic centrogenic inhibitory influence that particularly affects the motility in distal *colonic parts*.

4 The pelvic nerves induce a largely maximal vasodilatation in superficial mucosal sections, but in the distal colon only Blood flow figures of 400 ml/min × 100 g mucosa may here be reached and it appears as if the vessels surrounding the secretory crypts are particularly involved. This powerful vasodilator response seems to be closely linked to the secretion of mucus In contrast the vagal nerves do not induce any vasodilator effects in proximal colonic parts, analogous to the situation in the small intestine

5 The splanchnic and lumbar colonic nerves carry vasoconstrictor fibres to proximal and distal colonic parts, respectively with only slight overlap in contrast to their overlapping inhibitory influence on colonic motility The colonic resistance vessels exhibit like those of the small intestine an "autoregulatory escape from the vasoconstrictor fibre influence, which seems to imply a redistribution of blood flow from superficial to deeper mucosal-submucosal parts.

6 The pelvic nerve effects on motility mucosal blood flow and secretion constitute a coupled response that may be mediated by one and the same group of preganglionic fibres. Only the secretory response is readily blocked by atropine. The vasodilator

response might at least in part be induced by locally formed specific vasodilator agents like kinin as a result of the glandular activation.

All the three pelvic nerve effects are readily induced by a sacrospinal "pelvo-pelvical reflex constituting the defaecation reflex in which no other autonomic excitatory fibres appear to be involved However the defaecation reflex which strongly contracts the entire colon, can be markedly damped by the lumbar colonic nerves by means of their inhibitory influence on the parasympathetic intramural synapses

7 There is no evidence that the vagal fibres to the proximal colon should be involved in either the so-called gastrocolic reflex or in the defaecation reflex These fibres, which are readily blocked by atropine are probably activated together with the vagal excitatory fibres to the stomach and small intestine in such reflex and central autonomic patterns that are involved in connection with digestive activity and feeding responses"

8 The combined results thus suggest that the colon is comprised of two functionally different parts, where each exhibits a differently organized control of motility blood flow and secretion but where some overlap exists at least with respect to the motility control.

The motility control of the proximal colon seems to have much in common with that of the small intestine and there is here like in the small intestine no sign of any direct parasympathetic influence on either blood flow or secretion.

The extrinsic nervous control of motility blood flow and secretion in the distal part of the colon is on the other hand in important respects arranged in a very similar way as in the stomach. Thus both organs have a reservoir function, where the nervous control of the stomach is specialized for rapid reception and storage and that of the colon for storage and prompt expulsion In each organ a specific set of parasympathetic fibres appears to cause an appropriate motility adjustment—relaxation (vagal relaxatory fibres) and powerful contraction (pelvic fibres) respectively—which is closely linked to secretion and enhanced mucosal blood supply

ACKNOWLEDGEMENTS

To professor Bjorn Folkow I wish to express my sincere gratitude for active help and invaluable advice throughout this work. I am also very grateful to professor Ragnar Romanus for his support during the study To my collaborators docent Ove Lundgren and dr Mats Jodal I am greatly indebted for their valuable help and guidance. I am also grateful to docent Jan Kewenter who directed my interest to gastro-intestinal physiology and who has given me continued advice

For most skilful assistance I thank Mrs Birgitta Vallander Miss Elsa Fredriksson Dagny Johansson, Mrs Kerstin Andreasson, Göste Magnusson, Frans Planath and Thomas Palm Thanks are also due to Miss Ann Britt Johansson for skilful typing the manuscripts.

Financial support was granted by the Air Force Office of Scientific Research through the European Office of Aerospace Research O\R United States Air Force under Contract F61032-68-C-0044 by a grant from US Public Health Service (HE-05075-07 08) and from the Swedish Medical Research Council (B69-14X 16-05A) by the Faculty of Medicine University of Göteborg by Göteborgs Läkaresällskap and the Foundation of Doctor Albert Wallin

For generous supplies of drugs I am indebted to CIBA (Ismelin® Ecolid®) Hässle (Aptin®) Merck (Atropine sulphate) and May & Baker (Flaxedil®)

Storage of Histamine in Mast Cells Evidence for an Ionic Binding of Histamine to Protein Carboxyls in the Granule Heparin-Protein Complex

By

BÖRJE UVNÄS, CARL HUGO ÅBORG and ANDERS BERGENDORFF

STOCKHOLM 1970

Kungl Boktryckeriet P.A. Norstedt & Söner
Stockholm 1970

The basophil granules of rat peritoneal mast cells contain two main constituents, heparin and protein. In histamine-free granules these two constituents account for over 95 per cent of the granule dry weight other constituents such as ATP lipids, phospholipids etc. amounting to only a few per cent (Lagunoff *et al.* 1964) The mast cell granules are insoluble in water and in physiological saline but dissolve in 1—2 M KCl solution, and at pHs above 10—11 (Lagunoff 1965 Thon and Uvnäs 1966) Protein and heparin can be separated from the resulting solution by column chromatography When the protein and heparin fractions are recombined in water a precipitate is formed (unpublished observation)

The heparin of rat mast cells shows similar characteristics to commercial heparin preparations. Its strongly negative charge is due to the presence of ester sulphate groups In rat mast cell heparin 3 13 such groups are present per mole of hexosamine (Schiller and Dorfman 1959) The granule protein is composed of basic polypeptides with an I.P around 9 (Lagunoff *et al.* 1964 Bergqvist *et al* unpublished) To all appearances then the matrix of the mast cell granules consists of a water insoluble heparin-protein complex held together by the strong attractive forces between two oppositely charged macromolecules, the acid heparin and the basic protein.

As reported in previous papers, granules isolated from mast cells lysed in distilled water were able to retain histamine as long as they were suspended in water When the granules were suspended in physiological sodium chloride solution the histamine was immediately released (Uvnäs 1964 Uvnäs and Thon 1965) and in exchange, sodium was taken up Aborg, Novotny and Uvnäs 1967) The pH-dependence of the histamine storage mechanism, with its almost complete breakdown already around pH 4 indicated a binding of histamine to weakly acid groups (Thon and Uvnäs 1966 Aborg *et al.* 1967) It remained an open question, however whether these groups belonged to the heparin or to the protein part of the granule complex.

The granule protein is composed of basic polypeptides with a minimal molecular weight around 5 600 (Bergqvist Samuelsson and Uvnäs, to be published) Studies on the histamine binding properties of a water-insoluble complex formed *in vitro* by reaction of a basic polypeptide with a molecular weight around 4 000 (clupein—a protamine) and heparin have recently been reported (Aborg and Uvnäs 1968) Quantitative observations on the uptake by this complex of sodium, histamine and other biogenic amines, as well as titration studies, yielded data not only about the nature and number of the ionic binding sites but also about their location. The histamine taken up by the heparin-clupein complex at pH 7 was apparently exclusively linked to the free terminal COO^--groups of the protamine. The suggested gross structure of the heparin-clupein histamine complex at pH 7 is shown in Fig 1 a.

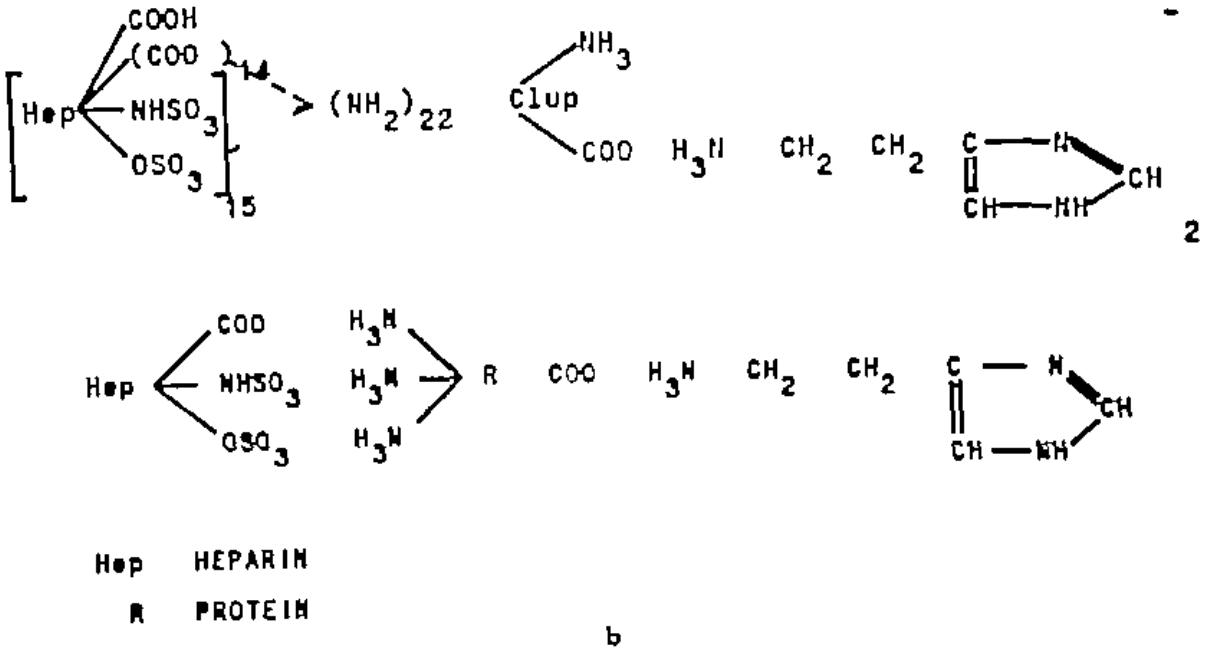

Fig. 1 Assumed gross-structure of
a. heparin-clupein-histamine complex formed *in vitro* at pH 7 (from Åborg and Uvnäs 1968)
b. heparin-protein-histamine complex of mast cell granules at pH

The similarities in physico-chemical properties of the heparin protein complex in the mast cell granules and the heparin-clupein complex formed *in vitro* suggested to us a possible gross structure of the granule heparin protein-histamine complex as shown in Fig. 1 b. According to our hypothesis, in the intact complex at pH 7 the acid groups of heparin should be linked to the amino (imino) groups of the basic protein, leaving only COO^--groups of the protein available for histamine binding.

In the present paper experimental data will be presented to support this hypothesis. In section A of the paper evidence will be given to support the assumption that histamine is stored in the granules in ionic linkage with COO^--groups. In section B data will then be presented to demonstrate the cation binding capacity of the granule ionic sites. Finally in section C titration experiments will show the protein carboxyls to be the most plausible binding sites.

Methods

Isolation of mast cells

Mast cells were isolated from the abdominal and thoracic cavities of male Sprague-Dawley rats weighing 300—400 g as described by Thon and Uvnäs (1967). The slight modification was made that after differential centrifugation the cells were not washed in isotonic sucrose solution.

Isolation of mast cell granules

Mast cells from several—usually 20—rats were pooled, washed in 0.9 % NaCl solution, 2 ml per rat, and centrifuged at 400 × *g* for 10 min. The precipitated cells were suspended in deionized water (2 ml per rat) and the pH was adjusted to 7.1 with 0.1 M NaOH. The suspension was gently shaken for 5 min and the resulting slightly acid medium again carefully adjusted to pH 7.1. The shaking and the adjustment to pH 7.1 were repeated a further twice and the suspension of lysed mast cells was then centrifuged at 400 × *g* for 10 min to precipitate coarse material. The granule-containing supernatant was centrifuged at 3000 × *g* for 20 min. All procedures were performed at room temperature. About mg of granules (dry weight) were obtained. Due to scarcity of granular material most of the uptake and release studies described below are based upon single point determinations.

Note. The suspension fluid was adjusted to pH 7.1 since previous experience had shown this pH to give an optimal yield of granules. These have a strong tendency to adhere to cell membranes, thereby forming aggregates which precipitate with coarser cell material. This tendency is minimized—although not abolished—at pH 7.1.

Preparation of histamine and sodium free granules

Histamine-containing granules obtained from mast cells lysed in deionized water as described above were suspended in 10 mM sodium phosphate buffer pH 7 (2 ml per rat) and gently shaken for 15 min. This procedure results in an almost total release of the granule histamine and an influx of sodium into the granules (Fig. 9). The sodium-charged granules were recovered by centrifugation at 3000 × *g* for 20 min and then suspended in deionized water (2 ml per rat). After gentle shaking they were recentrifuged and resuspended in deionized water. The washing procedures were repeated a further twice and—as checked in experiments with the admixture of ^{22}NaCl—the now sodium- and histamine-free granules (Fig. 5) were collected by a final centrifugation.

Depletion with deionized water of sodium or histamine recharged granules

Sodium

Granules were depleted of histamine and sodium as described above. About 2 mg of such granules suspended in 2 ml of deionized water were recharged with sodium by suspension in 10 ml of 30 mM sodium phosphate buffer pH 7 containing ^{22}NaCl. After incubation with gentle stirring for 15 min, 1 ml aliquots were taken and centrifuged at 3000 × *g* for 20 min. The supernatants were sucked off the granules dissolved in 0.1 M NaOH and the radioactivity of the resulting solution recorded in one of the samples. To each of the remaining samples 1 ml of deionized water was added. The suspensions were gently stirred for 5 min and, after centrifugation, the radioactivity of the precipitate was again measured in one of the samples. The washing procedure was repeated 3—4 times.

Out of the 0.1 M NaOH solution of the granules used for radioactivity measurements 0.4 ml from each sample was taken for the determination of granule protein (in pepsin units). The protein values were needed to follow the losses of granules during the resuspension procedures (about 10 per cent loss per procedure) and to allow reliable calculations of the sodium content of the remaining granules.

Histamine

The procedures were the same as described bov for sod um cept for a few details. The granules were first depleted of histamine by sodium exchange nd then of sodium by repeated washing in deionized water. Such histamine and sodium-depleted gr nules were incubated in 0.5 mM histamine solution pH 7 (a mixture of histamine base and histamine dihydrochloride) containing ^{3} C-histamine. The histamine refilled granules were the washed repeatedly as described abov for the sodium harged granules.

In other experiments, about 1 mg of histamine- and sodium-depleted granules were incubated i 15 ml of 1 mM histamine solution ntaining 75 μCi ^{3} C-histamine with gentle stirring for 15 ml at room temperature w th ontinuou adjustment of the pH to 7 with 1 mM Hi-base. After centrifugation and resuspen ion in 15 ml of deionized water the granules were spun down and resuspended in 0.5 ml of wh wat To 10 μl of the homogeneous suspension (in cut hematocrit tubes) was dded 10 30 0 150 μl of deionized water. After 10 min incubation followed by centrifugation t 3000 g 10 μl of the supernatant was added to 15 ml f scintillation fluid ontaining 0 d of 1 M NaOH. As controls tubes containing 10 μl of granule suspension 15 ml of sci t ll t fl id and 0.2 ml of 1 M N OH were used.

Depletion with deioni d u at f dium or histamine-charged Amberlite IRC 50

Amberlite IRC 50 in sodium form was converted i t hydrogen form with M HCl, washed in deionized water until consta t pH (bout 6.2) and dried t tac over P_2O_5. Before use the dried material was educed to a f ne powder order t facilitate the preparation of homogeneous suspensions.

Amberlit IRC 50 s stated t ha maximal content of COO -groups of about 10,000 mueq/mg (t pH 10—12). The mast cell granules hav cation binding pacity at pH 7 of about 1000 mueq/mg (p. 20 p 1). To facilitat comparison of the Amberl te and the granule studies 0.2 mg of the resin and mg of the granule material were used in each experiment.

0.2 mg of Amberlit was suspended ther in 1 ml of 30 mM sodium phosphat buffer pH 7 containing ^{22}N Cl r in 0.5 mM histamine solution (histamine base + histamine di hydrochloride t pH 7) containing ^{14}C-histamine. The suspensions were then gently stirred for 15 min, divided into 1 ml aliquots, centrifuged t 3000 × g for 20 min and the radioactivity in the supernatant of one of the samples was determined. The other samples were sequentially washed and rewashed as described above for gra ule material.

Influence of pH on the granule histamine store

Granules recharged with histamine in vitro

About 2.5 mg of granules (0.1 ml of suspension) depleted of histamine and sodium were recharged with histamine by incubation with gentle stirring for 10 min at room temperatu and pH 7 in 15 ml f 10 1.0 or 0.1 mM histamine solution, containing ^{14}C-histamine. In these concentrations of histamine the granule histamine stores will be filled t about 95 %, 75 % and 50 % respectively of the maximal ptake at pH 7 (around 1000 mueq/mg, see Fig. 7).

After one wash in 15 ml of deionized water the granules were resuspended in 30 ml of water and the suspension was continuously acidified d ring gentle stirring with 5 M HCl. The increase in volume was negligible. At desired pHs, 2 ml aliquots of the suspension were removed for centrifugation and 1 ml of the resulting supernatant + 0.1 ml 1 M N OH was used for recording of C-activity.

As a control 1 ml f solution containing 1 ml f granule suspension (out of the 30 ml mentioned above) 1 ml of 0.1 M NaOH (which dissolves the granules) and 0.1 ml of water were used.

Influence of pH on the uptake of histamine and sodium by granules

Histamine

A 0 1 M sol tion of histamine base was gradually acidified with conc H_3PO_4 (Agla micro syringe) At desired pHs, 2 ml samples were taken and 100 µl granule suspension (0.. mg granules) added. After Incubation with gentle shaking for 10 min t room temperature the granules were spun down to enable thei ^{14}C-activity to be recorded.

Sodium

A fresh buffer solution was made by dissolving 70 mg of boric acid and 15 mg of citric acid in 60 ml of 10 mM NaCl sol tion containing $^{22}NaCl$. The pH was adjusted t 9 with 10 mM N OH and then gradually acidified with 5 M HCl (Agla micro syringe) At desired pHs 2 ml samples of the buffer solution were pipetted into plastic tubes and 0.2 mg of granules (0.1 ml) added. After Incubation with gentle shaking for 10 min at room temperature the granules were precipitated by centrifugation and the ^{22}Na acti ity of the precipitate recorded.

Uptake studies

For each experiment about 2 mg of histamine and sodium-free granules (dry weight) was suspended in 2 ml of deionized water and gently shaken to secure a homogenous suspension. About half of the granule suspension was used for uptake and release studies, the other half for determining its granul content (dry weight) in order to allow uptake and release figures to be related to granule weight. An exactly measured vol me (between 500—1000 µl) was evaporated to dryness in *vacuo* over P_2O_5 and the residue weighed. In some experiments such dried granules were resuspended nd used for further experimentation, since dried granules were found to retain thei cation storing qualities unchanged (Fig. 12)

Sodium

A fresh sodium phosphat buffer was made by titrating 100 mM NaOH with conc. H_3PO_4 to pH 7 This stock solution was used for preparing 30 10 3 1 0.1 0 03 and 0.01 mM dil tions. To 9 ml samples of each of these dilutions was added 0 1 ml of ^{22}N Cl sol tion. 2 ml samples f the ^{22}N Cl-containing sodium phosphate buffer solutions were pipetted into weighed polypropylene tubes with plastic stoppers. T each tube was added 100 µl of granul suspension. After 10 minutes' incubation at room temperature the granules were sedimented by centrifugation t 5000 × *g* for 20 min. The supernatant was carefully sucked off except for 1—2 drops which were left in the tube. The pH of the supernatant was determined. The tube was reweighed to allow calculation of the volume of the remaining fluid and thereby calcula tion of th contaminating radioactivity The granul precipitate was dissolved in 0.5 ml of 1 M N OH. 200 µl of the granule solution was then added to 15 ml of scintillation fluid and the ^{22}Na activity recorded.

For each granule sample control sample was made up. 1—. drops of the corresponding $^{22}NaCl$-containing sodium phosphate buffer solution were pipetted into weighed polypropylene tube. After reweighing to determine the volume, 0.5 ml 1 M NaOH was added, the tube reweighed and 200 µl taken for recording ^{22}Na activity (in 15 ml of scintillation fluid) The values obtained fo the ^{22}Na activity per µl of the control samples were used for calculating the uptake of sodium in the granules (in nmoles per mg granules)

Histamine

For determining histamine uptake the granules were incubated in ^{1} C-histamine-containing media and the samples treated as described above for sodium uptake.

Release studies

Histamine- and sodium-free granules were recharged with histamine containing ^{14}C-histamine as described above. After precipitation at 3000 × *g* 2 ml of 10 mM sodium phosphate solution pH 7 was added to each sample and the granules spun down again. 1 ml of the supernatants were removed for recording the ^{14}C-activity and for calculating the sodium induced release of histamine. Similarly by using ^{22}NaCl instead of ^{14}C-histamine the uptake of sodium was calculated.

Incorporation of ^{14}C histamine into mast cell granules

Mast cells from 10 rats were incubated for 2 hours at 37° C in 15 ml of isotonic salt solution containing 10 % v/v Sörensen phosphate buffer pH 7.1 mg human serum albumin per ml and 10 µl of ^{14}C-histidine (Slorach and Uvnäs 1968).

Radioactivity measurements were made with a Packard Tri-Carb liquid scintillation spectrometer model 2002. The liquid scintillation fluid contained 0.4 % 2,5-diphenyl oxazole and 0.01 % 1.4-bis-2(4 methyl-5-phenyloxazol) benzene in a mixture of equal volumes of toluene and ethylene glycol monoethyl ether.

The amounts of radioactive material added in the uptake and release studies were ^{22}Na about 1 µCi per ml, ^{14}C-histamine about 0.1 µCi per ml.

Titration of mast cell granules

Mast cell granules (from 30 rats) depleted of histamine and sodium (see p. 5) were suspended in about 2 ml of deionized water. Using a Carlsberg pipette 1.00 ml was transferred to a weighing bottle dried over P_2O_5 in vacuo and weighed. 1.00 ml was transferred to a titration vessel and during gentle stirring exposed to a stream of nitrogen gas for 5—10 min until the pH was constant (pH 5). The acidity is probably due to the fact that in washed granules the cationic sites are occupied by hydrogen ions. The pH was adjusted to 3 with 0.1 M HCl. Titration from pH 3 to pH 10 was then performed with 0.1 mM KOH (or histamine base) adding 1 µl between each pH determination. For titration of dissolved granules 75 mg of KCl was added together with 1 ml 1 M KCl solution. The granule heparin went into solution and the pH shifted to 9.2. Titration to pH 3 was then performed with 0.1 M HCl.

For the blank titration 1.00 ml of deionized water was exposed to a stream of nitrogen gas until the pH was constant (pH 6). Titration was performed to pH 3 with 0.1 M HCl and then to pH 10 with 0.1 M KOH. The blank values were deducted from the titration values of the granule suspension (Kerschington 1960).

For all titrations and pH adjustments an Agla micrometer syringe was used.

Protein assay

Protein was assayed by the method of Lowry *et al.* (1951) and the results are expressed in terms of the crystalline pepsin standard used.

Results

A. Qualitative observations indicating the binding of histamine to COO -groups in mast cell granules

Influence of pH on the granule histamine stores

If histamine was stored in the granules in ionic linkage with COO -groups the storage capacity of the granules should vary with the degree of dissociation of these groups. We therefore studied the influence of pH on the histamine content of granules.

Histamine and sodium depleted granules were recharged with histamine to about 95 % 75 % and 50 % of their maximal uptake capacity at pH 7 by incubation in 10 1 0 and 0 1 mM histamine solution respectively as described on p. 6. Irrespective of the degree of saturation the histamine stores showed the same pH dependence. The content steeply fell when the pH was reduced from 6 to 4 (Fig 2)

In order to meet the argument that granule histamine stores recharged with histamine *in vitro* should behave differently from granule histamine stores containing endogenous histamine the influence of pH was also studied on granules isolated from mast cells containing ^{4}C-histamine. This histamine had been endogenously formed during incubation of mast cells in a ^{14}C-histidine containing medium according to Slorach and Uvnäs (1968) and the granules were isolated by water lysis of such cells as described at p 5 The granules were then resuspended in 30 ml of water and the suspension was gradually acidified with HCl as described above for the *in vitro* recharged granules. The store of endogenously formed histamine showed the same pH dependence as observed for exogenous histamine (Fig 2)

Influence of pH on the uptake of histamine and sodium by granules in vitro

The ionization of histamine varies with pH ($pK_{a_1} = 5.9$ $pK_{a_2} = \sim 10$). At pH 7 histamine is monobasic but the ionization increases rapidly below neutrality and it becomes dibasic at pH 4—3. (See titration curve in Åborg *et al.* 1967 Fig. 6.) Consequently the affinity of histamine for cationic binding sites will increase with falling pH. On the other hand the ionization of the carboxyl groups in the granules will be reduced with increasing acidity thereby diminishing the histamine binding capacity of the granules. Consequently the histamine uptake by the granules should be expected to show a pH-dependence curve reflecting the influence of two oppositely changing dissociation curves — a falling dissociation of carboxyl groups and an increasing dissociation of amino groups.

On the other hand a monovalent cation *e.g.* sodium ion, should be expected to run an uncomplicated course, simply reflecting the dissociation of the carboxyl groups

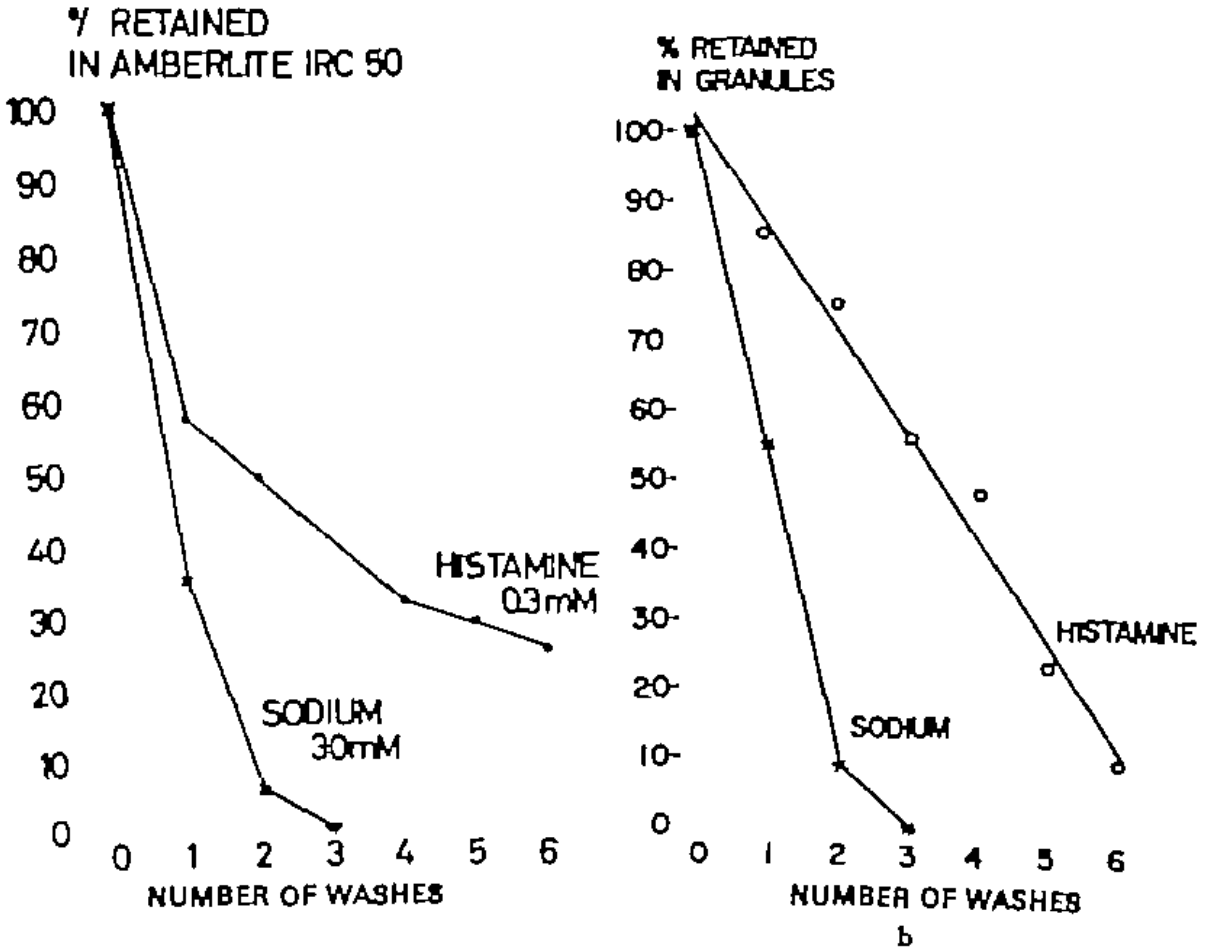

Fig. 5 Depletory action of washing) Amberlite IRC 50 and b) mast cell granules in deionized water on thei contents of
sodium (×—×—×) and
histamine (o—o—o)

The materials were charged by suspension f 30 mM sodium and 0.3 mM histamine solutions respectively

in the granules. It should form the mirror image of the carboxyl titration curve. The sodium uptake curve was in fact found to fulfill the criteria. It runs an uncomplicated course and when reversed the carboxyl titration curve followed the sodium uptake curve very closely (Fig. 3) In contrast, the histamine uptake showed a more complicated two phase course (Fig 4) In Fig 4 is also plotted the dissociation curve for the secondary amino group of histamine (the curve is constructed from the titration values given by Aborg and Uvnäs 1967 with its origin at pH 7) In the same figure are plotted the values obtained on titration of granules with histamine base By deducting the granule titration values from the histamine dissociation curve values a histamine uptake curve was constructed. This constructed curve followed fairly well the found uptake curve, supporting the assumption that the complexity of the pH dependence curve for the histamine uptake into granules is due to the increasing protonization below neutrality of the secondary amino group of histamine

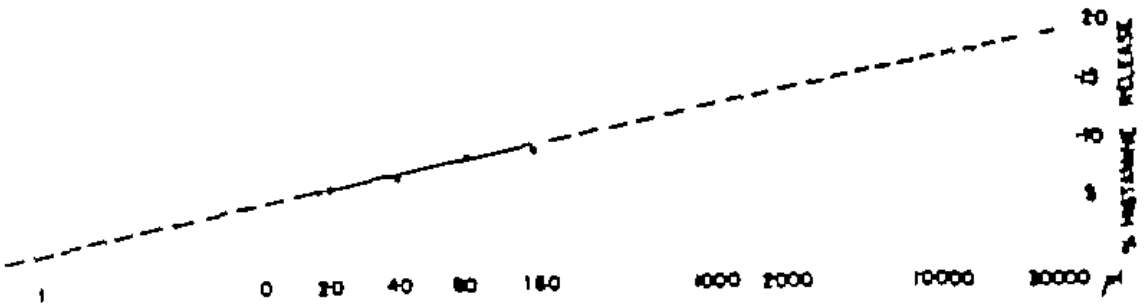

Fig. 6. Influence of suspension volume (deionized water) on the ratio between histamine retained in the granules and histamine released to the suspension medium (ratio "bound" histamine/"free" histamine) × indicates values obtained from the "wash experiment" plotted in Fig. 5 b.

the increasing affinity of histamine to ionic sites counteracting the effect of the diminishing ionization of carboxyl groups.

Depletory effect of deionized water on granules and on Amberlite IRC 50 charged with sodium or histamine

The assumption of the mast cell histamine being stored in ionic linkage with COO groups and being exchangeable against other cations e.g. sodium ions means that the mast cell granules should have the properties of a weak cation exchange material. Some experiments were therefore made to compare the cation storage abilities of mast cell granules and the carboxyl ion exchange resin Amberlite IRC 50.

At pH 7 the granules took up about 1000 the Amberlite about 2000 mμeq of anions/mg dry material (see Fig. 7 respectively Åborg *et al.* 1967 Fig. 5). When washed repeatedly in deionized water as described at p. 5—6 the sodium stores were completely emptied in both materials within 2—3 washes (Fig. 5). The histamine stores were more difficult to deplete. After 6 washes 10 % was still retained in the granules and about 25 % in the Amberlite.

An ionic binding of histamine to granule sites will be influenced by the histamine concentration in the granule suspension medium. With increasing suspension volume i.e. diminishing extragranular histamine concentration the amine should be released from the granules. Fig. 6 shows a linear correlation between the suspension volume (deionized water) and the percentage release of granule histamine.

Discussion

The influence of pH on the granule storage of exogenous as well as of endogenous histamine suggests a binding of the histamine to weakly acid groups, which become protonized and thus increasingly unavailable for binding with falling pH. The dissociation curve of protein carboxyls comprises the pH range 6.5—2 (Kenchington

1960) a fact which makes such groups the probable candidates for the binding sites. It is true that since at pH 3.5 10—20 per cent of the histamine has still not been released from the granules (Fig 2) the results do not exclude the possibility that below this pH part of the granule histamine is linked to more acid groups, *i.e* sulphate groups of the heparin. However it should be emphasized that COO groups cannot be expected to be completely undissociated until the pH approaches 2.

Furthermore, with the technique used granule histamine released with falling pH will accumulate in the incubation fluid and this histamine will compete with the hydrogen ions for granule ionic sites. For example when completely depleted of their histamine those granules which have been loaded by suspension in 10 mM histamine solution will have released into the suspension fluid at pH 3.5 an amount of histamine sufficient to give a concentration there approaching 0.1 mM (Fig 2) The accumulation of released histamine in the suspension medium therefore prevents the complete depletion of the granule histamine stores. The fact that the released histamine at pH 3.5 will be divalent with increased affinity for cationic binding sites further counteracts the depletory actions of the hydrogen ions.

The pH curve for the sodium uptake forming below pH 7 the mirror image of the carboxyl titration curve, is in complete agreement with an ionic binding of sodium ions to granule carboxyl groups, so is the pH curve for the uptake of histamine, due regard being taken to the increasing valency of histamine below neutrality

Our deionized water was slightly acid—around pH 6.0—since no precautions were taken to prevent CO_2 uptake from the air The depletion of the sodium and histamine stores of the granules on washing with this slightly acid water is well in accordance with the assumption of an ionic linkage of sodium and histamine to weakly acid groups in the granule heparin-protein complex. The more rapid depletion of sodium than of histamine from the granule stores indicate a weaker affinity of sodium than of histamine for the granule ionic sites.

The ratio between granule-bound histamine and supernatant histamine varied with the suspension volume as should be expected if histamine was ionically bound to weakly acid groups in the granules. The slope of the curve indicates that at infinitesimal volumes, as can be expected to occur intracellularly and especially intragranularly in the mast cell, free histamine is likely to exist in only minute amounts. This observation has a bearing on the question whether or not "free" histamine occurs in mast cells (see Discussion p 25)

The similarities in the behaviour of the granule and Amberlite sodium and histamine stores on exposure to deionized water are also striking

In conclusion The influence of pH on the storage of histamine in mast cell granules *in vitro* points to COO^--groups of the heparin-protein complex as the cationic binding sites.

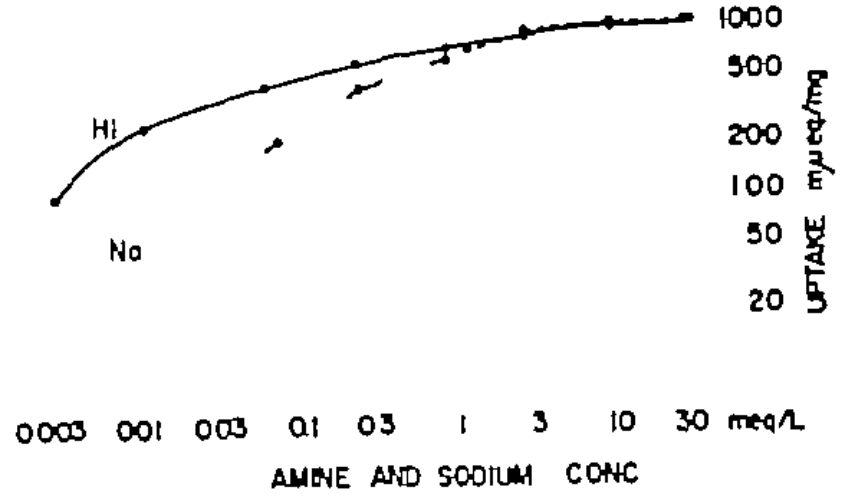

Fig. 7 Uptake of histamine and sodium in rat cell granules suspended in sodium and histamine solutions of various concentrations (pH and at room temperature. Corrections were made for concentration reductions due to granule uptake of histamine and sodium.

B Quantitative aspects of the uptake and release of cations by granules in vitro

Uptake at pH of histamine and sodium in granules (Fig 7)

Histamine and sodium-free granules were resuspended in histamine- or sodium-containing solutions with concentrations ranging from 0.03 to 30 mM. There was an appreciable uptake (100 mμeq/mg) already at the lowest histamine concentration used (0.003 mM) while the sodium uptake was still only around 30 mμeq/mg in 0.01 mM sodium concentration. Both uptake curves rose with increasing extragranular histamine and sodium concentrations to merge and level off at an uptake of 1000 mμeq/mg in 10—30 mM solutions. Uptake studies in histamine or sodium concentrations above 30 mM became unreliable since the granules began to dissolve at such concentrations.

Competitive uptake of histamine and sodium at pH 7

Histamine and sodium-free granules were incubated in media with a constant histamine concentration of 10 mM but with sodium concentrations ranging from 5—30 mM. To measure the uptake of sodium and histamine two parallel experimental series were performed one with the admixture of ^{22}NaCl, another with the admixture of ^{14}C-histamine.

The uptake of histamine fell and the uptake of sodium rose with increasing sodium concentration in the incubation medium (Fig. 8). Irrespective of the mutual concentrations of histamine and sodium the sum of the corresponding uptake values for histamine and sodium approached the same level as that observed with histamine

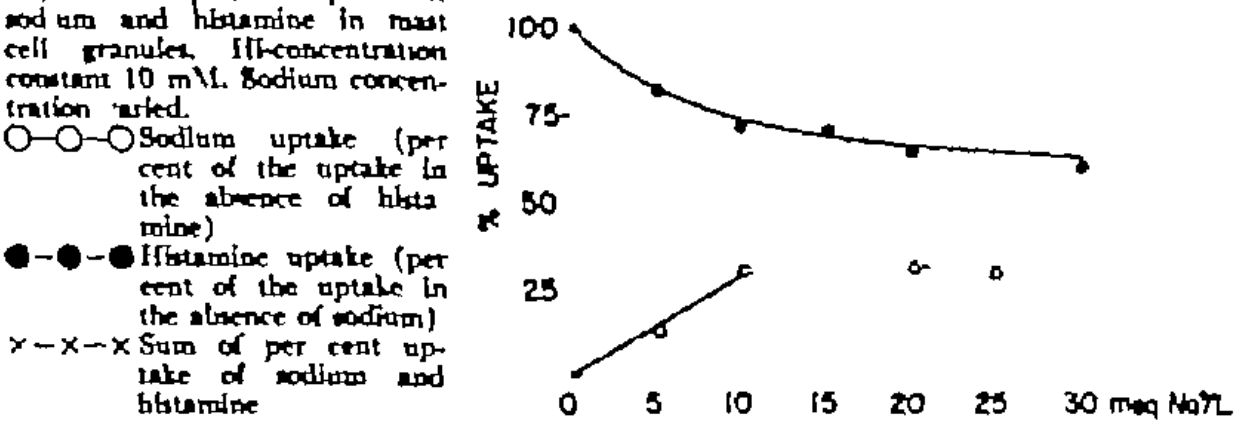

Fig. 8. Competitive uptake of sodium and histamine in mast cell granules. Hi-concentration constant 10 mM. Sodium concentration varied.
○–○–○ Sodium uptake (per cent of the uptake in the absence of histamine)
●–●–● Histamine uptake (per cent of the uptake in the absence of sodium)
×–×–× Sum of per cent uptake of sodium and histamine

alone in the incubation medium. Observations with sodium concentrations above 25—30 mM were not possible since the granules began to dissolve at such high concentrations.

Molar exchange ratio between Na uptake and Hi release at pH 7

As reported previously (Åborg *et al* 1967) and as illustrated in Fig. 9 a sodium induced release of histamine occurs with a molar ratio of sodium uptake/histamine release around 2 or higher

On the assumption that the sodium induced release of histamine was the result of a competition for identical ionic sites in the granules between sodium and histamine one might expect the molar exchange ratio Na /Hi to be 1 The higher exchange ratios found by Åborg *et al* therefore deserved further investigation.

The susceptibility of the granule histamine storage mechanism to washing in water as shown in Fig 3 suggested to us that the unexpectedly high molar exchange ratio was due to a partial desaturation of the granule histamine binding sites caused by the repeated washing of the granules during their isolation. Experiments were therefore designed to recharge granules with histamine to various degrees of saturation.

Two series of experiments were made In one series histamine and sodium-free granules were incubated in histamine solutions of concentrations ranging between 0 1—10 mM containing ^{14}C-histamine. These histamine recharged granules, designed to be 25—100 % saturated with histamine (see Fig. 9 a) were then suspended in 10 mM sodium chloride and the sodium induced release of histamine calculated from the ^{14}C-activity appearing in the supernatant as described under Methods p 8

In a parallel series granule samples were incubated in the same concentrations of histamine as above but no labelled histamine was added. Instead the histamine-containing granules were exposed to 10 mM sodium phosphate buffer containing ^{22}Na Cl After centrifugation the uptake of sodium was calculated from the ^{22}Na activity of the various precipitates.

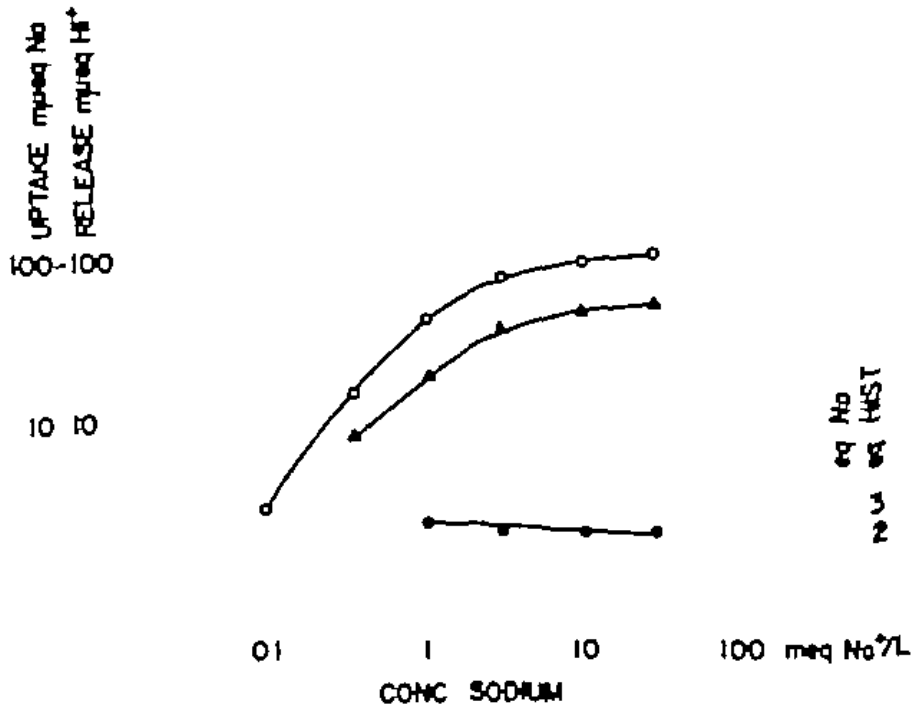

Fig 9 a) Uptake of sodium and release of histamine in granules isolated from water-lysed mast cells and suspended in sodium phosphate buffers of various concentrations. ○—○—○ uptake —○—○—○ H release —△—△—△ Not the ratio Na uptake / H release between 2—3 ●—●—●
(The figure taken from Åborg et al 1967)

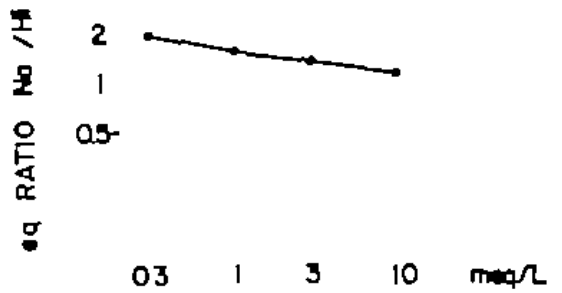

Fig 9 b. The influence of granule histamine content (degree of saturation of histamine binding ionic sites) on the ratio Na uptake/ H release The higher the saturation of histamine stores the closer is the Na /H ratio to 1

The results showed that when the granules were incubated in high concentrations of histamine (10 mM) the molar exchange ratio Na /H approached 1 With declining histamine concentrations in the incubation medium, *i.e.* with expected incomplete saturation of granule ionic sites with histamine the exchange ratio Na /H increased, approaching 2 at the lowest histamine concentrations used

Uptake of Cl ions

0 135 mg of histamine- and sodium-depleted granules were suspended in 2 ml of 0.9 4.5 9 and 20 mM NaCl solutions containing $Na^{36}Cl$ No significant uptake of ^{36}Cl was observed.

Discussion

Equal maximal uptake by the granules of two cations is to be expected if these are linked to identical ionic sites. The confluence of the histamine and sodium uptake curves at the same maximal level of 1000 m/eq/mg (Fig 7) therefore supports the assumption that histamine and sodium are located at identical granule storage sites.

The fact that when histamine and sodium are simultaneously present in the incubation medium the granule uptake of the two cations added together approaches the same level irrespective of the mutual concentrations of the two ions (vide Fig 8) is also consistent with their binding to identical sites.

The relative courses of the uptake curves in Fig 7 indicate a lower affinity of sodium than histamine for these sites. However quantitative evaluation of the relative affinities of the two ions—histamine and sodium—for the granule sites is complicated by the slight acidification of the granule suspensions that occurs at low concentrations of these ions. This acidification is due to the low buffering capacity of the histamine and sodium containing solutions which allows the acidity of the deionized water and the depleted granules to break through. As is evident from Fig 2 even such a slight acidification as to pH 6.5—6 will noticeably reduce the granule storage capacity for sodium and histamine *i.e.* the sodium and histamine ions have to compete with the hydrogen ions for the same granule ionic sites. This pH influence will increase with decreasing extragranular sodium and histamine concentrations and will be most evident for the sodium ion which has the weaker affinity to the granule sites.

The experiments illustrated in Fig 9 show that the Na /Hi ratio increases with decreasing histamine concentrations in the granule suspension medium and consequent increasing unsaturation of the granule histamine binding sites. This supports our assumption that the molar exchange ratios Na /Hi above 1 as seen in our experiments reflect the degree of depletion of the granule histamine stores caused by washing the granules in deionized water during the isolation procedure.

1 2 and 3 washes reduced the histamine content of "histamine refilled" granules to about 85 75 and 55 per cent respectively (Fig 5) of the starting level. Similar effects were observed on the endogenous histamine stores of granules isolated from water lysed mast cells (Thon and Uvnäs 1966) Since the granules used in our experiments were routinely washed at least 2—3 times in deionized water a considerable proportion of the histamine binding sites in our granules probably were depleted of histamine and the sites occupied by H ions. On suspension of such granules in a sodium containing medium Na ions would exchange with both Hi and H ions at the granule sites. The more often the granules were washed, the more of the histamine should be expected to be replaced by hydrogen ions, and consequently the higher should be the molar exchange ratio Na /H In Fig 5 it can be seen that three washes deplete the saturated granules of about 50 per cent of their histamine. A molar exchange ratio around 2 should be expected which is in fact the approximate value found in most of our experiments. A similar explanation may

be given for the increase of the Na /H1 exchange ratio in low sodium concentrations as seen in Fig 9 The insufficient capacity of the sodium phosphate buffer allows the pH of the suspension to approach 5.5—6. Histamine is released and the granule ionic sites become increasingly occupied by H ions. Consequently the exchange ratio Na /H1 increases.

The values of the exchange ratio above 1 therefore are considered to be experimental artefacts not invalidating our hypothesis of the histamine release from the granules as being the result of an equivalent ion exchange between sodium and histamine at identical ionic sites.

Conclusion

The mast cell granules have the properties of a weak cation exchange material with a maximal binding capacity at pH 7 of 1000 mueq/mg

C. Titration experiments on mast cell granules

Attempts were made to determine by titrations the capacity and the localization of the cation binding sites of the mast cell granules. For details of the titration procedures see Methods p 8

——— Net consumption between pH 3—10 of KOH by granules suspended in deionized water (from Fig. 10)
Gross consumption of HCl between pH 9—3 of granules (from above) dissolved in 1 M KCl.

On titration with 0.1 M KOH a suspension of granules depleted of histamine and sodium was found to consume between pH 3—7 about 1000 mμeq/mg (Fig. 10). After dissolution of the granules in 1 M KCl the consumption of HCl on back titration to pH 3 with 0.1 M HCl was found to have increased considerably (Fig. 11). Drying the granules *in vacuo* over P_2O_5 did not change the titration curve (Fig. 12).

The granule heparin protein complex is composed of about 30 % heparin and 70 % protein wt/wt (Lagunoff *et al.* 1964, Bergendorff *et al.* unpublished data). On the assumption that the heparin of rat mast cell granules is similar in its composition to bovine heparin (Schiller and Dorfman 1959) titration of an equivalent amount of bovine heparin should give an approximate value for the number of acid groups present in rat mast cell heparin. Titrations were made on granules dissolved in 1 M KCl (curve a in Fig. 13). Provided that after dissolution of the granules in 1 M KCl titration with HCl records all the available free acid groups in both the protein and the heparin of the granule complex at pH 7 the deduction from the titration values of the dissolved granules of those of the calculated amount of bovine heparin should give an estimate of the cationic binding capacity of the granule protein at pH 7. This operation gave curve c in Fig. 13 with a calculated consump-

Curve a corrected according to the formula 1 — antilog (pH$_2$—pH$_1$) (Cohn and Edsall 1943)

tion of the protein between pH 3—7 of about 1000 mμeq/mg granules. This value corresponds well with the value obtained from the titrations on suspended granules (Fig 10)

Lysozyme is an arginine rich basic protein with an i p at 10.5—11 and a mol. wt of 14—17 000 When mixed with heparin in water an insoluble complex forms this complex dissolves in 1 M KCl

Fig. 14 shows titrations of solutions in 1 M KCl of lysozyme (a) sodium heparinate (b) and a mixture of lysozyme and sodium heparinate (c) with 0 1 M HCl. The calculated protein carboxyl curve (d) obtained by deducting the titration values of the heparinate from those of the heparin-lysozyme mixture agreed fairly well with the values obtained by direct titration of the lysozyme. Our calculations above concerning the cationic binding capacity of the heparin-protein complex and its components based on the titrations (Fig 12) therefore to all appearances seem to be valid.

Discussion

The titration studies show that at pH 7 the mast cell granules have a cation binding capacity corresponding to about 1000 mμeq/mg and agree with the assumption that the cation binding sites are located to the protein part of the heparin-protein

complex. Heparin probably does not contribute to any appreciable extent to the cationic binding capacity of the granules at pH 7 since the acid groups of heparin at this pH are occupied with the basic groups of the protein (Fig 1 b)

General discussion

The present observations lend further support to previous proposals from our laboratory that histamine is stored in the mast cell granules in ionic linkage to weakly acid sites in the granule heparin protein complex.

The present and previous experiments are in accordance with the hypothesis that histamine and sodium are linked to identical ionic sites. The uptake capacity at pH 7 of the two ions is the same (1000 mueq/mg granules) and the molar exchange ratio between Na and Hi in histamine-saturated granule stores approaches 1 When present simultaneously these cations compete for ionic sites and the sum of their uptakes is constant irrespective of their relative proportions in the suspension medium (Fig 8) The observed variations in the equivalent exchange ratio Na /Hi is discussed and explained on p 17

An ionic binding of the mast cell histamine in the granules has been proposed earlier by several authors (for references see Thon and Uvnäs 1966) The main new principle of our postulate is the binding of histamine to the protein part of the granule heparin-protein complex—not to heparin as previously assumed—in such a weak linkage that histamine is immediately released when the mast cell granules on mast cell degranulation become exposed to the extracellular ionic milieu.

Previous suggestions as to an ionic binding of histamine to the heparin of the mast cell granules were based on the fact that in *vitro* heparin and histamine form a rather stable complex. In this complex the amino groups of histamine are attached to the acid groups of heparin. Due to the strength of the attractive forces of the sulphated groups of heparin the heparin-histamine complex is stable down to pH 2—3 In contrast as demonstrated in the present and previous studies from our laboratory the granule histamine stores are far more sensitive to acidification. The sensitivity to pH and the resulting incapacity of the granules to store histamine below pH 3 eliminate the sulphated groups of heparin as the main histamine binding sites in the granules In fact as indicated by our titrations, in the granules these groups of the heparin are masked by electrostatic binding to basic groups of the granule protein

The protein of the granule heparin-protein complex consists of basic polypeptides with a minimal molecular weight around 5600 Among the 16 amino acids identified are three basic amino acids—arginine lysine and histidine—and 2 dicarboxylic amino acids—aspartic and glutamic acid (Bergqvist, Samuelsson and Uvnäs to be published)

The granule complex is insoluble in water but dissociates in the presence of cations, *e.g* in 1 M NaCl solution. The two components heparin and protein can be

separated by electrophoresis or by column chromatography On mixing they again form a water insoluble complex (Bergqvist, Samuelsson and Uvnäs to be published)

Åborg and Uvnäs (1968) have recently studied the properties of another water insoluble complex betwen heparin and a basic polypeptide. The complex was able to bind histamine as well as other biogenic amines, and inorganic cations. The histamine was released in the presence of sodium chloride, the release being due to an equivalent ionic exchange between histamine and sodium In fact qualitatively the *in vitro* formed heparin-clupein complex showed the same storage properties as did the mast cell granules.

Titration of the heparin-clupein complex as well as quantitative studies of its sodium and histamine binding capacity showed that the only ionic sites available for cationic binding in this complex at pH 7 were the terminal carboxyls of the clupein. The acid groups of the heparin—the sulphated groups as well as the carboxyls—were all occupied by the basic groups of the clupein. In other words, in the heparin-clupein complex the cationic binding sites were exclusively localized to the carboxyls of the protein part of the heparin-protein complex (Fig 1 a)

If we make the assumption that the histamine binding sites in the granules are carboxyl groups the question remains where these are located. Both the heparin and the protein part of the heparin-protein complex contain such groups. However our lack of knowledge about the exact structures of the heparin and protein composing the heparin-protein complex makes it impossible to decide directly to which carboxyl groups histamine is located. However indirect evidence suggests that they are localized to the granule protein.

Titration of the acid groups of the undissolved granules with HCl showed a consumption of 1000 mμeq/mg granules (dry weight) between pH 7—3 This figure agrees well with the maximal capacity of the granules to bind histamine and sodium at pH 7 Both uptakes were found to approach 1000 mμeq/mg granules.

Protein and heparin carboxyls are completely dissociated at pH 6.5—7 (Kenching ton and Ward 1954 Åborg and Uvnäs 1969) The consumption of KOH between pH 3—7 by a granule suspension (1000 mμeq/mg) is therefore a measure of the main part of the COO^--groups available for cationic binding in intact granules at pH 7 The increased titration values after dissolution of the granules in 1 M KCl (Fig 11) to all appearances reflect mainly the unmasking of acid heparin groups as the result of the breakdown of the heparin-protein complex.

On deducting from the titration values of dissolved granules the titration val es of the amount of heparinate calculated to be present also about 1000 mμeq/mg granules could be attributed to the granule protein. The agreement between this indirectly obtained value of the protein carboxyls available for ionic binding with the values found by direct titration is good.

When dissolved in 1 M KCl the granule heparin occurs as potassium heparinate Fig 15 shows that titration of sodium heparinate and of a corresponding amount of heparinic acid (both in 1 M KCl) gave identical values. Taken together the titration results therefore agree with the assumption that in the intact granule the acid

1000 mueq per mg granules for both lots. Titrations of dissolved granules, heparinate lysozyme etc. supported the view that the granule cation binding sites are located in the protein part of the heparin-protein complex.

The storage of histamine ionically linked to protein COO^--groups in the granule heparin-protein complex is consistent with the observation that histamine is instantaneously released when mast cell granules are discharged from the cells and exposed to the cation-containing extracellular fluid. Free histamine in mast cells suggested by some others to exist in mast cells is considered to occur mainly as an experimental artifact.

INTRODUCTION

Major operations and clinical conditions, in which injury or necrosis of tissue occurs, are followed by an increased coagulability of the blood, sometimes leading to disseminated intravascular coagulation with concomitant thrombus formation or severe bleeding disorder

Tissue thromboplastin, released to the circulating blood from injured cells, is considered the most important trigger of intravascular coagulation (Hjort 1967) Plasma coagulation factors will be involved in a stepwise process leading to thrombin formation. Thrombin is a proteolytic enzyme, which converts fibrinogen to fibrin by release of the fibrinopeptides A and B from the fibrinogen molecule. The deposition of fibrin in intravascular coagulation may be compensated by a secondary induced fibrinolytic process and by the ability of the reticuloendothelial system to engulf fibrin particles. The dissolution of fibrin clots occurs through the action of fibrinolytic enzymes, with the concomitant formation of fibrin degradation products In states of disseminated intravascular coagulation, the blood concentration of fibrinogen and other coagulation factors may decrease considerably which together with the anticoagulant action of fibrinolytic degradation products renders the blood incoagulable and may give rise to bleeding. (For review on intravascular coagulation, see Penick and Roberts 1964 McKay 1965 Selye 1966, McKay and Müller Berghaus 1967)

In treatment of bleeding disorders secondary to intravascular coagulation, both anticoagulant and antifibrinolytic drugs have been used Treatment with anticoagulants seems most adequate, since these drugs prevent clotting and, consequently indirectly inhibit the secondary induced fibrinolytic process. The use of only fibrinolytic inhibitors seems not appropriate. However there are rather few reports dealing with deleterious effects of antifibrinolytic drugs in bleeding disorders.

Local thrombosis has since many years been treated by administration of anticoagulants or operative procedures. Recently reports on a therapeutic effect of an enzyme preparation purified from the venom of a Malayan snake have appeared (Sharp et al. 1968 Bell, Pitney and Goodwin 1968) The preparation has a thrombin-like activity *in vivo* but causes no bleeding tendency

The present investigation aims to a better understanding of the processes involved in intravascular coagulation It deals with experimental

in dogs, in which the coagulation system has been activated by intravenous administration of different procoagulants — thromboplastin thrombin and a thrombin like enzyme preparation (Reptilase) isolated from the venom of the snake Bothrops atrox. All these procoagulants induce a secondary fibrinolytic process The influence of heparin and fibrinolytic inhibitors on the induced intravascular coagulation has been investigated The *in vitro* effect of heparin epsilon aminocaproic acid and Trasylol on the clotting activity of thromboplastin preparations has been studied, in addition.

THROMBOPLASTIN AND THROMBIN INDUCED COAGULATION

Previous investigations

Buchanan observed 1845 that *tissue extracts possessed clotting-accelerating effects* when added to blood *in vitro* Since then a large number of investigations have been made on the nature of the coagulation promoting activity in tissue extracts with respect to its chemical and physical properties and its mechanism of action on blood coagulation *in vitro* and *in vivo*

Wooldridge (1886) regarded the *active principle* as a compoud of phospholipids and protein. Later Deutsch, Irrgler and Lomoschitz (1964) showed that tissue thromboplastin prepared from human brain is a lipoprotein. By separation they found the lipid part to contain the procoagulant activity and the protein part to be inactive in blood coagulation. Clarke and O'Meara (1966) investigated subcellular components of human chorion cells and found that the greatest coagulative activity was associated with the microsomal fraction.

A large number of hypotheses on the mechanism of *action of tissue thromboplastin* in blood coagulation have appeared. Morawitz (1904 1905) suggested that the tissue substance initiated and hastened the formation of thrombin from prothrombin in the presence of calcium in plasma. Biggs, Douglas and McFarlane (1953) found that brain extracts, factor V and factor VII took part in a reaction producing a prothrombin converting principle. According to Hjort (1957) a reaction product is formed between factor VII tissue thromboplastin and calcium. Nemerson (1966) prostulated that a rapid reaction between factor VII and tissue thromboplastin formed a product, which could activate factor X.

The methods for comparing the concentrations of the active compound in different thromboplastin extracts have been based on the *linear relation between log coagulation time and log thromboplastin concentration* as found by Mills (1921) In most investigations, the clotting time has been determined as the recalcification time of plasma thromboplastin mixtures (Astrup 1965 Clarke 1966)

In experiments *in vivo* Naunyn (1868) showed that intravenous injec-

tion of lysed red cells resulted in *intravascular coagulation* Wooldridge (1886) revealed that the intravascular coagulation, which occurred in animals receiving tissue extracts intravenously was proportional to the amount of substance injected and that in surviving dogs a period of hypocoagulability followed. Since then a large number of investigations have been made on *intravascular coagulation induced by thromboplastin prepared* from different organs and by thrombin (for reviews on induced intravascular coagulation, see Penick and Roberts 1964 McKay 1965 Hardaway 1966)

Placental extracts were infused into animals by Fulton and Page (1948) and Schneider (1950) They could reproduce the *defibrination syndrom* found in delivery and suggested that tissue thromboplastin from placenta may escape into the maternal circulation, giving rise to fibrinogen consumption, fibrin formation and concomitant incoagulable blood. Ratnoff and Conley (1951) infused homologous brain thromboplastin into dogs, and found that a thrombin inhibitory activity appeared in the plasma, but only after an appre iable fall in the concentration of plasma fibrinogen had occurred Lewis and Szeto (1962) identified an anticoagulant in blood after infusion of brain thromboplastin and found it identical to the antithrombin produced by fibrinolytic agents as described by Niewiarowsky and Kowalski (1958)

Basinger and Allen (1951) reported that the *fibrinolytic properties* of plasma increased following intravenous injections of thromboplastin and thrombin into dogs. Later investigations lend support to the opinion that the fibrinolytic process is induced secondarily to the coagulation process (Merskey et al. 1964 Kowalski et al. 1965 Girolami, Cliffton and Agostino 1966 Phillips, Margaretten and McKay 1968) In similar experiments Leandoer and Nilehn (1969) and Zetterqvist (1969) have demonstrated appearance of a variety of fibrinolytic degradation products.

Soluble complexes between fibrinogen and fibrin monomer or between these and fibrinogen degradation products are also involved in the pathophysiological phenomena observed during intravascular coagulation and fibrinolysis (Shainoff and Page 1962, Copley and Luchini 1964). Kopec et al. (1968) observed that the appearance of complexes between fibrin monomer and fibrinogen degradation products was accompanied by a considerable decrease of platelet adhesion and aggregation. This results in decreased disruption of platelets on thrombin action and, consequently decreased release of platelet factor 4 (PF4), which by Farbiszewski et al. (1968) was found to be a potent and specific trigger for platelet aggregation and blood clotting.

Evidence that the liver reduces the effects of artificially induced intravascular coagulation was reported by Spaet et el. (1961) They found in studies on rats that blood thromboplastin was selectively taken up by *reticuloendothelial cells* following intravenous injection and also demonstrated that blockade of the reticuloendothelial system (RES) resulted in enhancement of defibrination produced by blood thromboplastin. Later Gans and Lowman (1967) studied the uptake of Se^{75} labelled rat fibrin and of fibrin degradation products by an isolated perfused rat liver the loss of activity from the blood closely paralleled the increased activity recorded in the liver Clearance of the fibrin degradation products occurred at a much slower rate than that of fibrin Their findings confirmed the observation by Lee (1962) that cells of the reticuloendothelial system are involved in the elimination of free circulating fibrin and its metabolic products. In recent studies in heparinized dogs Gans, Stern and Tan (1969) have demonstrated that intravenously injected thrombin is rapidly removed by clearance predominantly in the liver

Present investigation

Homologus brain thromboplastin was injected or infused intravenously in dogs in order to study the early (IV) and late (II) effects on various coagulation factors. Thrombin was infused for studies of the early effects only (V)

Thromboplastin was prepared from dog brain essentially according to the method of Owren (1949) In order to determine the doses of thromboplastin given to dogs comparison between the different thromboplastin preparations in terms of concentrations of the active compound had to be performed (I) The thromboplastin was assayed *in vitro* by the one-stage prothrombin time method, essentially according to Quick (1935) The coagulation times of different thromboplastin dilutions were plotted for each batch on a double logarithmic graph as used by Astrup (1965) The concentrations of 10 thromboplastin preparations, expressed in arbitrary units, were found to range from 4 to 33 arbitrary units per ml of the preparation. One arbitrary unit was defined as the amount of thromboplastin producing a clotting time of 18.5 sec with dog plasma in the assay system used.

Experimental conditions

Dogs subjected to studies of the *early effects* of thromboplastin (IV)

and thrombin (V) were injected with iodine-labelled fibrinogen. When equilibration of the isotop with the extravascular space had occurred, experiments with procoagulants were made. After i.v anesthesia, dog brain thromboplastin was injected i.v for 10—20 sec, whereas bovine thrombin was infused for 1 hr In the studies of the *late effects* (II) thromboplastin was administered in different ways — by rapid or slow i.v injections of undiluted thromboplastin by infusion of thromboplastin in saline solution or by subcutaneous injection of undiluted thromboplastin. Only dogs given infusions were anesthetized Blood samples were collected for up to 9 days.

Hematocrit, platelet count, fibrinogen concentration fibrinolytic activity frequency of thromboemboli and occasionally heparin co-factor activity of plasma were determined. In the dogs used for studies of the early effects of thromboplastin and thrombin radioactivity in plasma and in fibrinogen clottable with thrombin was also determined

In *control* animals the basic half life time of radioactivity in plasma and fibrinogen the effect of iodinated fibrinogen without isotop and the influence of anesthesia and indwelling catheter were studied (V) In the studies of the late effects of thromboplastin dogs, injected or infused with heated thromboplastin and saline respectively were used as controls (II)

Early effects of thromboplastin and thrombin (IV V)

The immediate reactions of the dogs injected with thromboplastin within 10—20 sec were severe with respiratory distress, tachycardia and diarrhoea. Of 8 dogs given thromboplastin, 6 died within 20 hrs. Five of these 6 dogs showed occluding thromboemboli in the right side of the heart and pulmonary arteries. The dogs given thrombin infusions showed only slight reactions of the type described, only 1 died during the experiment and in this occluding thromboemboli were demonstrated at autopsy

In general, the effects after thromboplastin injection and thrombin infusion were of the same type, but occurred earlier and more dramatically after the rapid thromboplastin injections. There was very soon an increased disappearance rate of both plasma and fibrinogen radioactivity After 15—30 min the two radioactivity curves started to separate. The plasma radioactivity then increased to a maximum at 30 min to 2 hrs while that of the thrombin-coagulable fibrinogen remained low The fibrinogen concentration decreased in parallel with the fibrinogen radioactivity The platelet count was also rapidly lowered.

The fibrinolytic activity *in vitro* determined in 2 dogs of the thrombin group showed in 1 dog a slight increase immediately and at 1 hr after the start of the infusion. In the thromboplastin group the determination in 3 dogs showed an increased fibrinolytic activity at 15 min but normalization within 2 hrs.

Based on the pre-infusion specific activity of the fibrinogen radioactivity the secondary plasma radioactivity increase — representing degraded non-clottable fibrinogen fibrin (NCFP) — could be calculated as equivalent amounts of fibrinogen. At the time of the maximal plasma radioactivity increase the degradation products amounted to between 40 and 100 pr cent of the fibrinogen decrease up to that point. With increasing doses of thromboplastin and thrombin, the fibrinogen disappeared faster and proportionally larger amounts of non-clottable labelled fibrinogen products appeared in the circulation. This indicates an intimate relation between the intensity of the coagulation process and the mechanism for fibrinogen degradation.

Although in the experiments with thrombin no significantly increased fibrinolytic activity could be demonstrated in the circulating blood there were indications that the subsequent plasma radioactivity increase could be caused by a fibrinolytic process, probably induced secondarily to intravascular coagulation. Evidence for this has been given by the demonstration of fibrinogen degradation products in studies on separation of plasma by gel filtration and the immunological behaviour of serum (Zetterqvist 1969) as well as by the effects of simultaneously administered fibrinolytic inhibitors (IV V) This is also in accordance with the suggestions by Kowalski et al. (1965) In contrast to the findings in the thrombin experiments, an elevated fibrinolytic activity was recorded in the circulating blood after thromboplastin injections. Because of the shorter injection time of thromboplastin the coagulation trauma was probably more intense. This might explain why a fibrinolytic process could be more intensively evoked, and therefore demonstrable in the circulating blood.

Late effects of thromboplastin (II)

Four of ten dogs injected with thromboplastin for less than 20 sec died. The mortality was not correlated to the thromboplastin dose. All four dogs, which died during the experiment showed thromboemboli, three of which occluded the outflow of the right ventricle or the pulmonary artery In 5 of the 6 surviving dogs, killed 9 days later small to massive thromboemboli had occured.

The platelet count decreased even after small doses of thromboplastin however only slightly if thromboplastin was given slowly After rapid injections of large thromboplastin doses the platelet count was depressed for at least 7 days. The decrease in fibrinogen concentration during the first days was correlated to the dose injection rate of thromboplastin Slow rate injections of thromboplastin caused slight or no decrease in fibrinogen concentration In contrast to the fibrinogen reaction after thromboplastin injections at high dose injection rate, hyperfibrinogenemia developed already from the first day in anesthetized dogs infused with thromboplastin

Increased fibrinolytic activity occurred only in one of the dogs given rapid or slow injections of thromboplastin In the 2 anesthetized dogs, however infusion of thromboplastin was followed by moderately increased activity during 9 days After infusion of saline alone in 3 anesthetized dogs, slightly increased fibrinolytic activity was recorded

The heparin co-factor activity of plasma decreased only by 10—20 per cent after administration of thromboplastin.

Intravenous injection of heated thromboplastin and subcutaneous injection of thromboplastin did not cause any significant changes

The more pronounced and prolonged decrease in platelet count and fibrinogen concentration after rapid than after slow injections of thromboplastin is in conformity with the result of previous animal studies (Ratnoff and Conley 1951 Adelson Rheingold and Parker 1960 Lewis and Szeto 1962) Relatively small total amounts of thromboplastin, if given rapidly could be sufficient for consumption of platelets and fibrinogen and thrombus formation while slow injections of large amounts of thromboplastin were less harmfull The critical thromboplastin concentration seemed to vary in the individual dogs, probably due to differences in blood flow rate, anticoagulant activity of plasma, blockade of the reticuloendothelial system and general condition of the animal These differences might explain the poor correlation between thromboplastin dose on one side and the rate of thromboemboli and mortality on the other

The nature of the different reactions in fibrinogen concentration after rapid and slow dose injection rate of thromboplastin is unclear The slow thromboplastin infusions in anesthetized dogs may simulate conditions during operations, after wich supernormal fibrinogen values are a regular finding (Godal 1962) Thromboplastin in high concentration might interfere with metabolic and/or catabolic processes or with the synthesis of fibrinogen.

With one exception, hyperfibrinolysis occurred only in anesthetized

dogs infused with thromboplastin or saline alone This indicates that anesthesia, or fluid infusion, or a combination of both is responsible for the increased fibrinolytic activity

Effects of thromboplastin and thrombin in heparinized dogs (II V)

In dogs injected intravenously with heparin (1 000 IU/kg b w) before the trombin infusion, the early changes induced by thrombin were almost completely absent.

In heparinized dogs, thromboplastin produced no thromboembolic phenomena and no marked changes in platelet count and fibrinogen concentration.

Injections of heparin alone resulted in a slight initial decrease in platelet count followed on the third day by an increase. The fibrinogen concentration increased. As the increased fibrinogen level remained for more than 1 week this phenomenon can hardly be explained by an inhibition of a permanent coagulation process occurring normally in the circulating blood.

The heparin co-factor decreased by 35 per cent after intravenous injection of 2,500 IU heparin This effect of heparin was observed by Olsson (1963) and explained as being caused by a complex formation between heparin and its co-factor When thromboplastin was injected after heparin, the co-factor decreased, however only to a small degree, indicating a competition for heparin between the co-factor and thromboplastin.

Summary

The *early* effects of intravenous administration of dog brain thromboplastin and bovine thrombin were studied in dogs injected with iodine-labelled fibrinogen. In general, thromboplastin and thrombin provoked similar effects There occurred, however earlier and more dramatically after the rapid thromboplastin injections than after the slow thrombin infusions. There was a decrease in platelet count, fibrinogen concentration and radioactivity of plasma and coagulable fibrinogen. A following secondary increase of the plasma radioactivity was assumed to reflect the appearance of degradation products of fibrinogen or fibrin, obtained through a secondary activated fibrinolytic process. An increased fibrinolytic activity *in vitro* could be demonstrated only after the more rapid coagulation traumata. The effects were almost completely prevented when the dogs were heparinized before administration of procoagulants.

Present investigation

The aim of this study (VI) was to investigate whether the thrombin like enzyme Reptilase, like other procoagulants (IV V) would give rise to a secondary activation of fibrinolytic processes. The influence of Reptilase on platelets and the effect of daily injections of Reptilase for several weeks were also studied.

Experimental conditions

Dogs were injected with ^{125}I fibrinogen and at steady state catabolism, anesthetized and infused intravenously with Reptilase for 1 hr Two dogs were used for long term treatment with daily injections of Reptilase for 10 and 16 days, respectively Blood samples were collected for determinations of platelet count, fibrinogen concentration and radioactivity in plasma, fibrinogen and serum. Immunoelectrophoresis and immunodiffusion were performed on serum against rabbit anti-dog fibrinogen serum

The dose response and effects on general circulation and on some coagulation factors were studied in preliminary experiments.

Effects of Reptilase (VI)

In preliminary experiments, no influence on arterial blood pressure pulse rate or rectal temperature was observed There seemed to be at most a moderate decrease of prothrombin. Factor V as determined in a one-stage system decreased by 75 per cent for the first 8 hrs.

Reptilase caused an immediate decrease in fibrinogen concentration. By increasing the dose of Reptilase complete defibrination could be obtained within 2 hrs. Even after the highest doses of Reptilase the platelets never fell below 40 per cent of the pre-infusion value. The radioactivity curves were, in principle of the same type as after thromboplastin and thrombin administration. One hr after the start of the Reptilase infusion the serum radioactivity increased. At the same time the immunoelectrophoretic investigations showed precipitation arcs which were localized in the regions where the lytic degradation products of fibrinogen and fibrin are expected to be found (Nussenzweig, Seligmann and Grabar 1961) In the 24 hr sample, the precipitation bands had almost completely disappeared. The immunodiffusion investigation gave the same results. It is obvious that the non-clottable degradation products, containing the antigenic determinants,

were brought back to the circulation secondary to the defibrination pr cess. All dogs survived the experiment and no thromboemboli were foun at autopsy

Daily intravenous injections of Reptilase kept the fibrinogen concen tion on a rather constant level between 0 4 and 0 9 mg/ml of plasma t 16 days without adverse effects. After cessation of Reptilase treatmer the fibrinogen concentration rose to the initial level for 4—5 days The platelet count did not change markedly No significant bleeding tenden was observed.

Reptilase, like thromboplastin and thrombin, was capable of inducing intravascular coagulation The coagulation promoting activity remaine for at least 24 hrs, probably due to the absence of plasma inhibitors to Reptilase combined with a slow excretion rate of Reptilase. The coagula tion induced by Reptilase was followed by a fibrinolytic process with return of degraded fibrin into the circulation as indicated by radioactivity measurements and immunological investigations. The main cause of the maintained hemostasis must be that the platelet function is essentially undisturbed by Reptilase. The failure to demonstrate any thrombi at autopsy shows that a successive and complete removal of fibrin took place. As the action of Reptilase seems to be very similar to that of Arvin, Reptilase might be useful in clinical treatment of thrombot manifestations.

Effects of Reptilase in heparinized dogs

Heparin did not inhibit the Reptilase induced coagulation and the secondary fibrinolytic process Thus, the decrease in fibrinogen concentra tion, the radioactivity curves and the results of the immunological investigations were mainly in agreement with those obtained in unheparinized dogs. However the platelet count was essentially unaffected, while in the non-heparinized animals there was a moderate decrease. This may be due to traces of a thromboplastin-like activity in the Reptilase prepara tion.

Summary

The effect of the thrombin like enzyme preparation Reptilase, purified from the venom of Bothrops atrox was studied in dogs injected with ^{125}I labelled fibrinogen. Reptilase, like thromboplastin and thrombin was capable of inducing intravascular coagulation with secondary

of fibrinolytic processes This was evidenced by the results of radioactivity measurements and immunological methods By daily injections of Reptilase it was possible to keep the fibrinogen concentration on low levels for several weeks without adverse effects. No bleeding tendency was observ ed, probably because the platelet count was essentially unchanged. No thromboemboli occurred. On account of the demonstrated properties Reptilase may be useful in treatment of clinical thrombotic disorders.

EFFECTS OF FIBRINOLYTIC INHIBITORS ON INDUCED COAGULATION

Previous investigations

Concerning the states of pathological fibrinolysis, there have been conflicting views as to the underlying mechanisms, diagnosis and treatment (for review see Fletcher Alkjaersig and Sherry 1962) Important for understanding of the pathogenesis of fibrinolysis was the finding, that lysed fibrinogen, besides losing its clottability with thrombin, aquires anticoagulant properties (Niewiarowski and Kowalski 1958 Stormorken 1957 Triantaphyllopoulos 1958) Furthermore, fibrinogen degradation products inhibit polymerization of fibrin (Godal and Helle 1963) and decrease platelet aggregation, adhesiveness and viscous metamorphosis (Kowalski, Kopec and Wegrzynowicz 1964)

The connection between coagulation and fibrinolysis was emphasized by Schneider (1951) and Müllertz (1957), who found that when tissues are damaged by trauma or anoxia both processes are activated or accelerated by the release of tissue thromboplastin and/or fibrinolytic tissue activator Similar effects were seen after trauma (Bergentz and Nilsson 1961) and after administration of thromboplastin, thrombin (Basinger and Allen 1951) and certain snake venoms (Regoeczi, Gergely and Mc Farlane 1966) In investigations on the effect of thrombin in dogs, Kowalski et al. (1965) and Girolami, Cliffton and Agostino (1966) suggested that the increased fibrinolytic activity was secondary to the induced coagulation process. Phillips, Margaretten and Mc Kay (1968) showed in similar experiments that plasminogen decreased gradually and reached low levels after 24 hrs, when the fibrinogen had returned to normal.

Based on assumptions of a secondary compensatory fibrinolysis after coagulation trauma, studies have been made on the influence of the fibrinolytic inhibitors, epsilon aminocaproic acid (EACA) and Trasylol, administered simultaneously with procoagulants. *EACA* inhibits the activation of plasminogen to plasmin, but its antiplasmin activity is weak (Alkjaersig, Fletcher and Sherry 1959) Besides its antifibrinolytic activity EACA has been reported to retard the endogenic thromboplastin generation and to inhibit the prothrombin activation slightly (Rezakovic, Nikulin and Stern 1966, Blombäck, Blombäck and Olsson 1967) *Trasylol*

a polypeptide found in several organs, inhibits the proteolytic action of kallikrein (Frey and Kraut 1928) trypsin (Werle, Maier and Ringelmann 1952) chymotrypsin (Kraut and Körbel Enckhardt 1958) and plasmin (Marx et al 1959) Trasylol also inhibits the activation of plasminogen to plasmin (Berghoff and Glatzel 1963) Furthermore, in investigations *in vitro* Trasylol inhibits thromboplastin but not thrombin (Amris 1964 Godal and Theodor 1965 Blombäck, Blomback and Olsson 1966 Andersson Nilsson and Hedner 1967 Dubber et al 1968)

In animal experiments EACA given together with thrombin promotes the development of the generalized Shwartzman phenomenon (Lee 1962). Margaretten Zunker and McKay (1964) demonstrated persistence of fibrin in the glomeruli of the kidney as long as the infusion of EACA was continued. Gans (1966) found that EACA given simultaneous with thrombin into dogs, increased the mortality and frequency of thromboembolu Beller Mitchell and Gorstein (1967) tested the effect of different proteolysis inhibitors together with thrombin in rabbits and found that all of the inhibitors resulted in fibrin deposition in the glomeruli of rabbit kidney Mammen and Poucho (1966) reported that Trasylol prevented formation of thromboemboli in dogs injected with thromboplastin. In dogs given EACA before intravenous injection of extracts from snake venoms, Chan and Reid (1964) did not observe any adverse effects. Thus, in states of intravascular coagulation the use of fibrinolytic inhibitors has given varying results.

Present investigations

The problems of these studies were:

1 Do substances with antifibrinolytic activity influence upon the early and late changes obtained after intravenous administration of procoagulants?

2 Can an anticoagulant effect of Trasylol be demonstrated in different *in vitro* tests and also *in vivo* after injection of procoagulants?

3 How does the whole blood clotting time of dog blood mixed with Trasylol *in vivo* compare to that of dog blood mixed with Trasylol *in vitro*?

4 How does Trasylol affect the changes in blood pressure following rapid injections of thromboplastin?

Experimental conditions

In vitro the effect of Trasylol on the recalcification time of different

plasma—thromboplastin mixtures was compared to that of EACA and heparin (I) The effect of Trasylol on a one-stage thrombin titration test used for the determination of heparin co-factor activity of plasma (Blombäck et al 1963) was also examined (I)

The *in vivo* investigations were performed as described earlier with the modification that antifibrinolytic drugs were administered before or together with procoagulants. Dogs subjected to studies of the *early* effects were infused with EACA or Trasylol simultaneously with injections or infusions of thromboplastin (IV) thrombin (V) or Reptilase (VI), respectively In the studies of the *late effects* (II) dogs were treated intravenously with various doses of Trasylol prior to or in event of infusion, simultaneously with thromboplastin Dogs injected or infused with Trasylol and saline, as well as those given thromboplastin alone as described in a previous chapter served as controls. Only dogs given infusions were anesthetized.

In order to study the influence of Trasylol on the *whole blood clotting time* (I) blood was collected from dogs into siliconized glass tubes containing saline or different concentrations of Trasylol Thereafter the dogs were infused with saline or Trasylol in amounts calculated to give the same concentration *in vivo* as those used *in vitro* Samples were taken frequently for 1 hr The times of beginning and of complete coagulation at 37 C were noted.

Finally in another series of dogs (III) polyethylen catheters were introduced into the aorta and the right ventricle or the pulmonary artery in order to follow changes in *blood pressure* after rapid injections of thromboplastin with or without pretreatment with Trasylol.

Effect of Trasylol in vitro (I)

It was found that the recalcification time of plasma—thromboplastin mixtures (one-stage prothrombin time) was successively prolonged with increasing concentrations of Trasylol. However this was only applicable to concentrations exceeding those corresponding to 1 000 KIU per arb unit of thromboplastin The inhibition by Trasylol seemed to approach its maximum at a concentration of about 2 000 KIU per arb unit of thromboplastin. It appeared that Trasylol, even in very high concentrations, could inactivate only part of the thromboplastin activity This differed from the effect of heparin, indicating that heparin acts in a different way Judging from these *in vitro* investigations, 10 000 KIU of Trasylol will, in the range of comparison, inhibit the same amount of

thromboplastin as 4—5 IU of heparin EACA was without effect on the one-stage prothrombin time In the test system used for determination of the heparin co-factor activity Trasylol in high concentrations showed slight antithrombin activity The effect of Trasylol was not related to the concentration of plasma This is also in contrast to the effect of heparin which, to a high degree, is dependent on the plasma content of heparin co-factor (Olsson 1963)

Influence of EACA and Trasylol on the early effects of procoagulants (IV V VI)

The divergence between the curves for plasma and fibrinogen radioactivity obtained after thromboplastin, thrombin and Reptilase, was abolished or delayed with large doses of EACA and Trasylol and the amount of calculated degradation products was reduced. However although a fibrinolytic activity seemed to be inhibited significant amounts of degradation products were still calculated and in Reptilase-infused dogs, there was immunological evidence for the appearance of degradation products. This is in accordance with the findings of Barnhart (1966) who identified and quantitated by means of immunological methods degradation products after combined administration of EACA and thrombin in dogs. She concluded that a dose of EACA, large enough to inhibit effectively a general plasma fibrinolytic activity could not block a local fibrinolysis proceeding in microthrombi in the circulation

Trasylol in large doses, has been shown to inhibit *in vitro* the activation phase of blood coagulation without affecting thrombin activity (Amris 1964 Blombäck Blombäck and Olsson 1966) In the present study no effect on the disappearance of fibrinogen in dogs given thrombin was found (V) which is in conformity with the results of the *in vitro* studies. After thromboplastin injections (IV), the initial decrease in fibrinogen radioactivity and platelet count was somewhat smaller if the dogs received EACA or Trasylol. This might be due to a slight retardation of the thromboplastin effect. The Reptilase-induced fibrinogen decrease was not influenced by EACA and Trasylol (VI) The moderate decrease in platelet count, however was prevented if the dogs were pretreated with EACA or Trasylol. It is assumed that some thromboplastin like activity contained in the Reptilase preparations and responsible for the platelet decrease was inhibited by EACA and Trasylol.

Among the dogs given thrombin as procoagulant, the mortality rate was highest in the Trasylol thrombin group With thromboplastin the

highest mortality was obtained in the group given only procoagulant. In both series EACA treated dogs showed the lowest mortality Thus, Trasylol seemed to protect against thromboplastin but not against thrombin while EACA seemed to exert some protection against both procoagulants. The higher mortality rate in Trasylol than in EACA treated dogs might be due to the fact that Trasylol, but not EACA, inhibits plasmin directly An inhibiting effect by EACA upon fibrin polymerization (Godal and Helle 1963 Godal and Theodor 1965) might also have contributed to the protective action by this substance. Concerning the effect of Trasylol, Mammen and Poucho (1966) suggested that the protective action of Trasylol in decreasing thrombus formation after thromboplastin injections was rather by interference with the cross linking of fibrin monomers than by its antithromboplastin activity When Reptilase was infused simultaneously with EACA or Trasylol all dogs survived

Influence of Trasylol on the late effects of thromboplastin (II)

Three of eight dogs given Trasylol before a rapid thromboplastin injection died. These 3 dogs had received large amounts of thromboplastin at a high injection rate. In groups with comparable thromboplastin doses, thromboemboli occurred in 9 out of 10 dogs given thromboplastin alone and in 2 out of 8 dogs injected with Trasylol before the thromboplastin injection. This "thrombus protective effect of Trasylol was also found by Mammen and Poucho (1966)

The decrease in platelet count seemed to be smaller after pretreatment with Trasylol, but this was not statistically verified. Small and large doses of Trasylol inhibited to about the same degree the fall in fibrinogen concentration, which is in conformity with the *in vitro* findings that Trasylol inactivates only part of the clotting activity of thromboplastin (I) In dogs given comparable doses of thromboplastin the decrease in fibrinogen concentration during the first 1—3 days was significantly less ($p<0.01$) after pretreatment with Trasylol. Intravenous injections of Trasylol alone in doses up to 100 000 KIU per kg b w had only slight or no influence on platelet count and fibrinogen concentration.

The less marked decrease and earlier return of platelets and fibrinogen, together with the lower incidence of thromboembolic complications in the Trasylol treated animals, suggest that Trasylol has an *in vivo* anticoagulant effect. *In vitro* Trasylol was found to inhibit the initial phase of coagulation (Amris 1964 Blombäck, Blombäck and Olsson 1966) Mammen and Poucho (1966), however postulated that *in vivo* the action of

Trasylol is directed against the final phase of coagulation causing an impaired fibrin clot formation. Trasylol, which inhibits a variety of proteases, may interfere with several reactions in the coagulation process. Trasylol is a weak anticoagulant compared to heparin

Trasylol, which is a potent antifibrinolytic substance (Marx et al 1959 Godal and Theodor 1965) had no influence on the slightly increased fibrinolysis, which appeared in anesthetized dogs after slow infusion of thromboplastin and of saline. Anesthesia, or fluid infusion or a combination of both might thus give rise to a type of hyperfibrinolysis which is uninfluenced by Trasylol or appears after the period during which Trasylol is effective

The small decrease of heparin co-factor following intravenous administration of thromboplastin seemed to be prevented by Trasylol pretreatment. Trasylol alone caused a small increase of the co-factor activity This is in conformity with the finding from the *in vivo* administration of Trasylol during surgical interventions in man (Olsson and Nordström 1964) The results of the present *in vivo* experiments are in contrast to the effect of Trasylol *in vitro* where no influence on the antithrombin system of plasma was observed (I) This suggests that the effect of Trasylol on the antithrombin activity is indirect

Influence of Trasylol on the whole blood clotting time (I)

The clotting time was determined in dog blood after addition of Trasylol *in vitro* and *in vivo* The coagulation times were prolonged with increasing Trasylol concentraton added *in vitro* The time of starting as well as of complete coagulation was doubled at a Trasylol concentration of 400 KIU per ml blood. The differences were highly significant ($p<0.001$) The maximal effect of intravenously injected Trasylol was recorded immediately after the injection At that time, however the effect of 1 000 KIU Trasylol added per ml blood *in vivo* was smaller than that of 400 KIU Trasylol added per ml blood *in vitro* Injection of 40 000 KIU Trasylol per kg b w., giving a calculated initial concentration of 400 KIU per ml blood, caused a slight prolongation of the clotting time for at least 1 hr The time of complete coagulation was more influenced by Trasylol than that of beginning coagulation

The difference in whole blood clotting time between blood mixed with Trasylol *in vitro* and *in vivo* is indicative of a fast distribution of Trasylol to the extravascular compartment. The fact that Trasylol prolonged the time for complete coagulation to a greater degree may support the

suggestion of Mammen and Poucho (1966) that the action of Trasylol is directed against the final phase of coagulation.

Influence of Trasylol on thromboplastin-induced changes in blood pressure (III)

Hemodynamic changes are an important manifestation of intravascular coagulation (McKay 1965 Hardaway 1966) Delin, Olsson and Teger Nilsson (1967) have shown that thrombin and thromboplastin cause peripheral vasodilatation followed by intravascular coagulation. By dialysis of tissue thromboplastin, they succeeded in separating a vasodilating activity from the procoagulant activity Consequently several mechanisms may contribute to the hypotension in thromboplastin-induced intravascular coagulation. Trasylol which inhibits the release of vasoactive kinins (Back 1966) and acts as a weak antithromboplastin (Amris 1964 *Blombäck, Blombäck and Olsson 1966) might, therefore, interfere with* the thromboplastin-induced hypotension.

The rapid intravenous injections of thromboplastin caused a decrease in platelet count and fibrinogen concentration, which is indicative of intravascular coagulation. As in previous investigations (II) pretreatment with Trasylol partly inhibited the decrease in fibrinogen concentration indicating an anticoagulant activity of Trasylol. The initial fall in aortic blood pressure to a lowest value after 1 min was less influenced by Trasylol. The return of systemic blood pressure was, however significantly faster ($p<0.01$) in Trasylol-treated than in untreated dogs. Ten min after the thromboplastin injection, the blood pressure had returned to 80 per cent of the pre-injection value in 6 out of 7 dogs given Trasylol, but in none of 6 dogs without pretreatment. In both groups of dogs, the pulmonary arterial pressure started to increase when the aortic pressure had reached its minimum value. The pulmonary arterial pressure returned to pre-injection levels within 5 min

The hemodynamic changes obtained in the present investigation resemble those after thrombin infusion as described by Olsson, Rådegran and Taylor (1969) They found the cardiac output unchanged at the time when the systemic hypotension was most pronounced, and suggested that the early effects are due to pulmonary vasoconstriction and systemic vasodilatation rather than to formed fibrin clots. On the other hand later hemodynamic events may depend on clot formation. From the results obtained in the present study the conclusion is drawn that the effect of Trasylol on the thromboplastin-induced hemodynamic changes might

depend on interference with coagulation processes as well as with release of vasoactive substances.

Summary

In vitro Trasylol was shown to prolong the one-stage prothrombin time, to exert some slight antithrombin activity in an assay of heparin co-factor activity and to prolong the time of beginning and complete whole blood coagulation although only at high concentrations. *In vivo* Trasylol inhibited partly the decrease in platelet count and fibrinogen concentration and reduced the frequency of thromboemboli after intravenous thromboplastin administration Trasylol also seemed to exert some slight influence on the antithrombin level in the circulating blood and to prolong the whole blood coagulation times It is believed that the anticoagulant effect of Trasylol is the result of partial inhibition of more than one reaction in the coagulation process Trasylol is a weak anticoagulant compared to heparin. Due to the weak effect and to the fast extravascular distribution of infused Trasylol large doses on repeated occasions would be needed for anticoagulant effect in humans.

Epsilon aminocaproic acid (EACA) seemed also to give some protection against thromboplastin induced intravascular coagulation. The coagulation process induced by thrombin and Reptilase was not appreciably influenced by EACA and Trasylol

The fibrinolytic process, activated secondary to the induced coagulation process by thromboplastin thrombin and Reptilase could be delayed but not completely abolished by EACA and Trasylol.

Trasylol accelerated the normalization of the decreased arterial blood pressure after thromboplastin injections. This effect of Trasylol is assumed to depend on interference with coagulation processes as well as with release of vasoactive substances.

GENERAL SUMMARY

The effect of the fibrinolytic inhibitors epsilon aminocaproic acid (EACA) and Trasylol was investigated *in vitro* and *in vivo* in dogs. Intravenous administration of homologous brain thromboplastin, bovine thrombin and the thrombin like enzyme preparation Reptilase resulted in a consumption coagulopathi accompanied by a secondary fibrinolytic process. This fibrinolysis was delayed and reduced, but not completely blocked, by simultaneous treatment with large doses of EACA and Trasylol. Pretreatment with heparin prevented the coagulation process induced by thromboplastin and thrombin but not that induced by Reptilase

Besides its antifibrinolytic effect, Trasylol was shown to exert some anticoagulant activity and to influence the hemodynamic changes following coagulation trauma. The anticoagulant effect of Trasylol is probably the result of partial inhibition of more than one reaction in the coagulation process Compaired to heparin, Trasylol is a weak anticoagulant. The antifibrinolytic activity of Trasylol is much stronger than the anticoagulant one, and at least as effective as that of EACA.

In long term treatment with Reptilase the fibrinogen concentration was kept at low levels without adverse effects. No bleeding tendency was observed, probably because the platelet count was essentially unchanged. On account of the demonstrated properties Reptilase may be useful in treatment of clinical thrombotic disorders.

ACKNOWLEDGEMENTS

This investigation was performed at the Thoracic Surgery Research and Coagulation Research Laboratories, Karolinska Institutet, Stockholm. Many persons, in a variety of ways, have helped me to realize the work I want to express my sincere gratitude to

The chiefs of the laboratories, Associate Professor Erik Berglund and Associate Professor Birger Blombäck for their deep interest valuable advice and never failing enthusiasm and support during the course of the investigation as well as for all facilities they placed at my disposal

Assistant Professor Per Olsson for introducing me into coagulation research, for positive criticism and stimulating discussions.

Assistant Professor Margareta Blombäck for valuable help interesting discussions and for the facilities of the Coagulation Laboratory Karolinska sjukhuset placed at my disposal

Assistant Professor Eric Zetterqvist and Doctor Nils Egberg for their friendly cooperation and all stimulating discussions.

My present chief Assistant Professor Bengt Göthman, Thoracic Clinic, Regionsjukhuset, Örebro who has encouraged me and facilitated my work by carrying a large burden of the clinical work.

Miss Ingrid Söderman for her never failing help and most skilful technical assistance.

The staffs of the Thoracic Surgery Research Laboratory the Coagulation Laboratories, Karolinska Institutet and Karolinska sjukhuset, Stockholm and the Photo Laboratory Regionsjukhuset, Örebro for generous help supply of facilities and skilled assistance.

Mrs Inger Bergström, Mrs Maj Christofferson Mrs Tina Esh, Mrs Marita Eriksson and Miss Hjördis Nilsson for excellent secreterial help.

Mr Ivor Perschke for correction of the English.

My Colleagues at the Department of Thoracic Surgery Karolinska sjukhuset, Stockholm and at the Surgical Clinics, Regionsjukhuset, Örebro for interest, generosity and inspiring discussions

Supports and grants were received from the Swedish National Association against Heart and Chest Diseases, the Swedish Medical Research Council Karolinska Institutet, Stockholm Örebro lans landsting Regionsjukhuset, Örebro Bayer Farma AB Stockholm and Pentapharm Ltd, Basel.

CHAPTER I

Introduction

In his paper "On milk and its acid" Scheele (1780–1786) described the isolation of lactic acid from sour milk. It was soon evident, however, that lactic acid could be isolated also from other material. Thus Berzelius (1812) demonstrated the presence of lactic acid in skeletal muscle, but it was not until about 100 years later that definite evidence of the relationship between muscle activity and production of lactic acid in the muscle could be provided (Fletcher and Hopkins 1907). That this lactic acid production constituted a final product in the glycolysis was shown first by Meyerhof and Hill (see Meyerhof 1930). Until the 1930's, when Lundsgaard (1930 and 1931) and Lohman (1935) demonstrated the significance of creatine phosphate and adenosine triphosphate, respectively, as source of energy in muscle contraction, lactic acid formation was assumed to be necessary in conjunction with the conversion of the chemically bound energy to mechanical energy in muscle contraction.

It has now been established that adenosine triphosphate (ATP) is the immediate source of energy for muscle contraction (Cain and Davies 1962). The store of ATP in the muscle is limited, however, so that a continuous resynthesis of ATP must take place. This resynthesis of ATP occurs mostly intramitochondrially in the oxidative phosphorylation, i.e. when NADH, NADPH and FADH formed in the breakdown of fat and carbohydrate are oxidized with oxygen as final electron acceptor. A small quantity of ATP is also regenerated in the cytoplasm in the breakdown of carbohydrate. If the pyruvate and NADH formed in this process cannot be oxidized intramitochondrially, the ATP synthesis can nevertheless be sustained since pyruvate, under formation of lactate, functions as electron acceptor for NADH. As this glycolytic resynthesis of ATP takes place anaerobically, production of lactate from working muscle may be caused by a deficiency or absence of oxygen, as for example during very heavy exercise (Gollnick and King 1969), during exercise at altitude (Hermansen and Saltin 1966) and in clinical conditions with impairment of the arterial inflow to the exercising muscles (Carlson and Pernow 1959). In a wider sense the lactate production may be considered to be caused by the fact that the oxidative resynthesis of ATP does not keep step with the

This term is used in the sequel since the pK_a value for lactic acid is more than 3 pH units lower than physiological pH.

consumption or that there is an unbalance between the glycolysis and the oxidative capacity in the muscle (Keul Doll and Keppler 1969) The limitation of the oxidative capacity would seem mainly to relate to the pyruvate oxidation (Holloszy 1967) and/or the electron transport through the mitochondrial membrane (Boxer and Devlin 1961 Alpert 1965) which is necessary for intramitochondrial oxidation of extramitochondrial NADH

The conversion of pyruvate to lactate is catalysed by the enzyme lactic dehydrogenase (LDH) The molecules of this enzyme are made up of four subunits of which there are two types M and H The proportion between these subunits in the molecule affects the activity of the enzyme (Dawson, Goodfriend and Kaplan 1964) LDH made up predominantly of M type subunits has a high turnover number for pyruvate It thus has a high pyruvate to-lactate conversion activity In tissues with high capacity for aerobic metabolism, and in tissues where lactate is normally converted to pyruvate LDH consists chiefly of H type subunit

The skeletal muscle is made up of white and red muscle fibres The white fibres are functionally adapted to resynthesize a large part of their ATP through glycolysis, while the red fibres are adapted for a chiefly oxidative resynthesis of ATP with the metabolism probably based largely on blood-borne substrate.

A comprehensive survey of the muscle metabolism has recently been presented by Keul Doll and Keppler (1969)

Production and to some extent uptake of lactic acid in human and animal skeletal muscle have been the subject of a large number of studies, both at rest and during varying types of exercise In these studies the above factors have been assessed both by analysis of arterio-venous concentration differences of lactate over individual muscles or groups of muscles and by observing variations in the arterial concentration of lactate Recently the lactate formation in muscle during exercise has been studied also by analysis of the lactate content in muscle tissue collected by needle biopsy technique immediately after exercise (Diamant Karlsson and Saltin 1968)

A release of lactate from skeletal muscle takes place already at rest (Kramer Quensel and Schafer 1939 Andres, Cader and Zierler 1956) This lactate production becomes greatly elevated in conjunction with muscular exercise The veno-arterial concentration difference, production and arterial concentration of lactate, all rise approximately exponentially with increasing intensity of work (Bang 1936 Pernow Wahren and Zetterquist 1965 Wahren 1966 Hermansen and Saltin 1966)

A significant rise of the lactate concentration in the venous blood from the forearm muscle is observable only a few seconds after the start of muscular exercise (Pernow and Wahren 1962) On continued exercise of long duration

at submaximal level the lactate production falls after an initial rise (Bang 1936, Bergström *et al* 1967 Wahren and Hagenfeldt 1968) which is not the case at high relative work intensities (Bang 1936 and others)

The skeletal muscle has the capacity not only to produce lactate but also to extract it. Thus Margaria, Edwards and Dill (1933) and Carlson and Pernow (1959) found that during muscular exercise an uptake of lactate took place in muscle not participating in the exercise. At high arterial concentrations of lactate there may be an uptake of lactate also in exercising muscle (Stainsby and Welch 1966, Freyschuss and Strandell 1967) Quantitatively this lactate uptake seems to be even greater when the muscle performs light exercise than when it is at rest (Rimmal and Ström 1949 Freyschuss and Strandell 1967) In the myocardium, where an uptake of lactate normally takes place even at normal arterial lactate concentration, the uptake of lactate increases with rising arterial concentration (Goodale, Olson and Hackel 1959) Whether a similar relationship exists in skeletal muscle is not known. Nor is it fully understood to what extent the lactate taken up in a skeletal muscle under these conditions is oxidized to CO_2 or metabolized by other means.

Our knowledge of the mutual relation between uptake and release of lactate in skeletal muscle, and of the metabolism of the lactate taken up, is incomplete. Studies of this kind would appear to be possible only with labelled lactate. In animal experiments with labelled lactate it has been shown that lactate taken up in the muscle is partially oxidized and gives rise to release of labelled CO_2 (Drury and Wick 1956) In a study of isolated perfused canine gastrocnemius Omachi and Lifson (1956) found that the fraction of the released carbon dioxide deriving from the added isotope-labelled lactate was larger in exercising than in resting muscle. A significant but quantitatively slight labelling of ^{14}C in muscle glycogen from administered ^{14}C-lactate has been observed (Drury and Wick 1956, Omachi and Lifson 1956, Koeppe *et al* 1964)

The objects of the present study were

1 to investigate whether simultaneous uptake and release of lactate occur in exercising human skeletal muscle,

2. to illustrate the mutual quantitative relations of these two—propably simultaneously occurring—processes both at different points of time during prolonged exercise and at varying arterial concentration of lactate,

3 to determine the extent to which lactate—if taken up—is oxidized to CO_2 or otherwise metabolized.

These questions appear to be best illustrated in studies with ^{14}C-labelled L(+) lactate. A method has therefore been devised for determination of ^{14}C-L(+) lactate in low specific activities in blood suited for analysis of large series of samples.

CHAPTER II

Determination of ^{14}C-L(+) lactate in blood

For determination of the specific activity of ^{14}C-lactate in blood urine and tissue, mainly two principles have been used 1 oxidation of lactic acid and measurement of the radioactivity in the products formed (Brin and Olson 1952 Friedman *et al* 1960 Pomerantz 1961) 2 separation by means of column (Forsander and Räihä 1960) or paper chromatography (Beaconsfield and Ginsburg 1966) Recently a gas radiochromatographic method has been described for determination of specific activities of individual organic acids (Hagenfeldt 196 Since the different oxidation methods described are not entirely specific (ery and Hastings 1931 Friedman *et al* 1960) a chromatographic metho metimes included in these procedures (Reichard *et al* 1961) Alth ic for lactate the chromatographic methods are not able to separat tereo-isomers of lactate of which only the L(+) form occurs n mammals. Furthermore the methods described are too ti t be suitable for analysis on a large scale.

L tat is today commonly determined by an enzymatic method (L t ndholm, Mohme Lundholm and Vamos 1963) When lactic deliv LDH) is used this method is specific for L(+) lactate (Lund h Lundholm and Svednyr 1963) It was the aim of the present i esti pply such an enzymatic method for the determination also of ^{14}C-L( ) L ate in blood.

The at in one sample may be oxidized to pyruvate by LDH and the pyruvate f ned precipitated as phenylhydrazone after addition of phenyl hydrazine hydrochloride and carrier The procedure is then repeated on another sample but without addition of LDH. The ^{14}C-radioactivity of the precipitates is then recorded and the difference between the two may be taken to reflect ^{14}C-L(+) lactate radioactivity

Materials

Sodium-DL-lactate 1 ^{14}C, sodium-L-ketoglutarate 1 ^{14}C and glucose-U ^{14}C were obtained from The Radiochemical Centre England and L(+)-lactate-1 ^{14}C from Volk Radiochemical Co USA. The radioactive substrates were

dissolved in sterile water (pyruvate in 0 6 M perchloric acid) dispensed into sterile ampoules and kept at −18° C.

The radiochemical purity of the DL-lactate tested by gas radiochromatography (Hagenfeldt 1968) and paper chromatography was found to be ⩾ 96 % when the crystalline substance had been freshly dissolved. No significant decomposition was found 3 months later In the calculations this substance was considered to be racemic. The radiochemical purity of the L(+) lactate supplied in water solution, was found to be more than 98 % To test its stereospecificity the labelled lactate was mixed with unlabelled lactate and converted to pyruvate by a modification of the enzymatic method for analysis of unlabelled lactate, with methoxyamine hydrochloride substituted for the hydrazine sulphate as pyruvate trap The reaction was found to be spectrophotometrically complete when compared with a standard solution. The residue was analysed by gas radiochromatography and found to contain more than 96 % of the activity as pyruvate and no significant radioactivity at the lactate position The purity of the sodium pyruvate was found to be about 95 % by gas radiochromatography when the crystalline substance was freshly dissolved. To avoid decrease in purity the pyruvate was stored in 0 6 M perchloric acid (Beatty *et al.* 1966)

Reagents

1 Glycine buffer 2 M glycine buffer containing 0.8 M hydrazine sulphate and 1.0 g EDTA per 100 ml adjusted to pH 10 0 with NaOH.

2. LDH (lactic dehydrogenase, from rabbit muscle) A crystalline suspension of 10 mg enzyme protein in 1 ml 2.2 M ammonium sulphate solution was used (Boehringer)

3 NAD (nicotinamide adenine dinucleotide) A 0 08% M NAD solution in water was used (Boehringer)

4 Phenylhydrazine hydrochloride, 4 g per 100 ml in water

5 Pyruvate carrier 1 M sodium pyruvate solution

6. Rinsing liquid. 0.2 M KCl HCl-buffer with pH 2.8

7 Scintillation liquid. Toluene containing 5 g per litre of 2,5-diphenyl oxazole (PPO) and 0.45 g per litre of 1 4-bis-2 (5-phenyloxazolyl)-benzene (POPOP)

Commercially available reagent grade chemicals were used The water was glass-distilled.

Procedure

5 ml blood was precipitated with an equal volume of ice-cold 0 6 M perchloric acid (PCA) within a few seconds. The blood and PCA mixture were carefully

stirred and then centrifuged for 5 min at 4500 rpm. The supernatant was centrifuged once again and 5 ml was taken off 1 ml 0 40 M K_3PO_4 was added and after cooling in ice for 10 minutes, the precipitated potassium perchlorate was eliminated by centrifugation. The blood extract prepared in this way was kept up to 6 days at 4° C until analysed.

In a test tube 2.5 ml blood extract were mixed with 3.5 ml glycine buffer 0 1 ml LDH solution and 0.5 ml NAD solution and incubated at 36° C

After 90 minutes the pH was adjusted to 2.8 by addition of 0 6—0.8 ml concentrated HCl. 0 6 ml phenylhydrazine hydrochloride solution and 0 1 ml pyruvate carrier were added and the phenylhydrazone was allowed to form for 20 min at room temperature. The precipitation was facilitated by rocking the test tubes.

The samples were cooled in ice for 20 min, whereafter the precipitate was filtered off and washed twice with 2 ml of the rinsing liquid The filter paper together with the precipitate was dried at room temperature for about 12 hours. It was then transferred into a glass vial for liquid scintillation counting 2 ml methanol and 12 ml scintillation liquid were added and the vial was shaken for 20 min. The radioactivity was determined in a liquid scintillation counter (Packard Tri Carb equipped with a Model 3003 spectrometer) Quenching was estimated by adding an internal standard

A blank was analysed in an identical manner but with the NAD and LDH solutions substituted by water and 2.2 M ammonium sulphate respectively

To determine the specific activity of lactate the total lactate concentration was analysed in 0 ml of the same blood extract by an enzymatic method based on the techniques described by Hohorst (1962) and Lundholm Mohme-Lundholm and Vamos (1963) as modified by Wahren (1966)

Statistical methods Most of the statistical calculations were analyses of variance as described by Dixon and Massey (1957) using a statistical model with one or two variables of classification and repeated measurements. The tests of individual means were performed according to Duncan as described in Documenta Geigy (1962) The following probability (p) levels of significance were used $p<0.001$ $p<0.01$ and $p<0.05$ Unless otherwise stated the results given in the text in this chapter are means ± standard error of estimate (M ± SE)

Experimental, results and comments

The recoveries reported are mostly expressed as per cent of the total radioactivity in the sample. The latter was calculated by counting 3 to 5 portions (0.5 ml) of the blood extract in a dioxane naphthalene scintillation liquid. Blanks were subtracted only when stated.

1 *Blood extract preparation*

A 5 ml and a 2 ml blood portion from 23 samples were deproteinized with equal volumes of ice-cold 0 6 M PCA. After stirring, cooling, centrifugation and perchlorate precipitation the lactate content was determined according to the method used for the determination of total lactate. No differences were found in lactate content or in blank extinctions when 5 or 2 ml blood was used.

Comments In order to be able to use small doses of the isotope it is desirable to extract the lactate for the determination of labelled lactate from fairly large blood volumes. It is impracticable, however to collect large volumes of blood each time since as a consequence of the rapid metabolism of lactate and pyruvate in blood cells, it is necessary to precipitate the blood proteins shortly after obtaining the blood sample. However the results from this experiment show that it is possible to increase the volumes of the blood samples to 5 ml without affecting the analyses of the concentration of total lactate in the blood.

2. *pH optimum for the enzymatic reaction*

0.5 ml blood extract containing labelled DL-lactate and about 2 mmoles/l L(+)-lactate was added to 10 different 1 M glycine buffers containing 0 4 M or 0 8 M hydrazine sulphate and 1.0 g per 100 ml EDTA and with pH adjusted to 7 0 8.0 9 0 10 0 and 11 0 Despite larger total volumes, the volume ratios, reagents and procedure were identical with the analytical procedure for total lactate The pH was determined after the addition of the PCA-extract and the enzyme solutions. The results are presented in Fig 1

The recovery increased markedly when the pH was raised above 7 In the pH interval 8.8—10 4 however the pH had no significant effect. No effect of the hydrazine sulphate concentration on the recovery was found.

3 *The eff ct on pH of type of buffer blood extract and reagents*

Four buffers with pH adjusted to 10.0 were used. They were 1 M or 2 M with respect to glycine and 0 4 or 0.8 M with respect to hydrazine sulphate and contained 1 0 g per cent EDTA. To 3.5 ml of the buffer were added 2.5 ml blood extract, 0.5 ml NAD solution (60 mg/ml) 0 15 ml 2.2 M ammonium sulphate and 0 02 ml 1 N HCl. The pH was determined after each addition.

With these experimental conditions the pH never fell below 9 6 when the weak buffer was used ($n = 10$) or 9 7 when the strong buffer was used ($n = 10$) The fall in pH was exclusively produced by the addition of the blood extract and the ammonium sulphate solution.

Comments From these studies it can be concluded that, using a 2 M glycine buffer it is possible to add 2.5 ml blood extract to 3.5 ml buffer using a 0.8 M

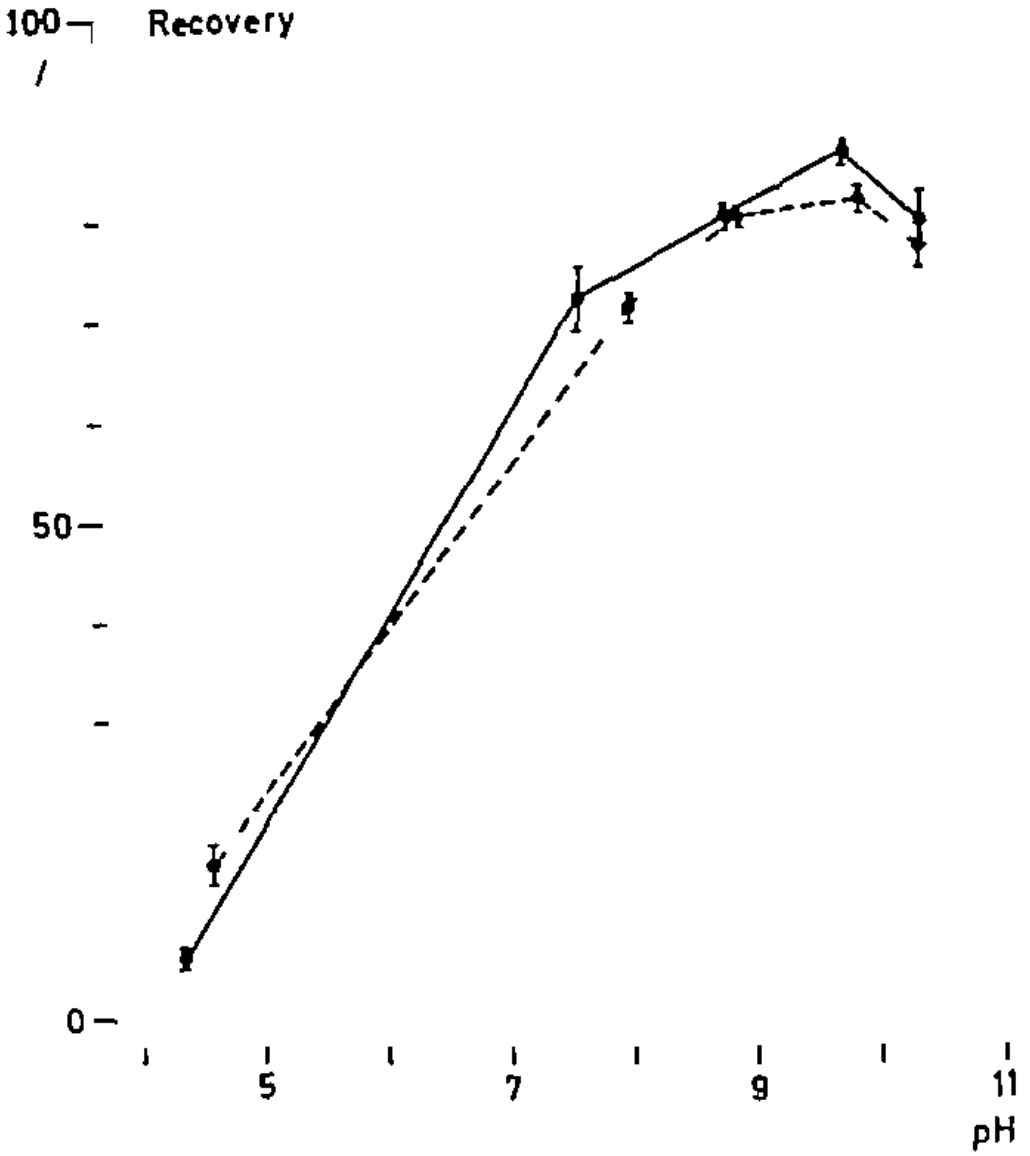

Fig. 1 Relationship between recoveries expressed as per cent of added L-L(+)-lactate and the pH in the enzymatic reaction with two buffers containing 0.4 M (●—●) and 0.8 M (● --●) hydrazin sulphate. For further explanation see experiment 2. Mean values and SE of 10 experiments of each series are given.

hydrazine sulphate concentration and 0.15 ml LDH solution and still keep the pH within the optimal range found for the enzymatic reaction. As shown in a later part of the experiments it is desirable to use the higher hydrazine sulphate concentration to improve the trapping of pyruvate.

Lundholm Mohme Lundholm and Vamos (1963) reported that the addition of the NAD and LDH solutions somewhat lowered the pH, and so did the free hydrogen ions formed at the reduction of lactate to pyruvate. The acidi-

fying effect of the LDH solution was found to be due to the 2.2 M ammonium sulphate solution in which the enzyme was suspended. The HCl was added in order to simulate the free hydrogen ions formed at the reduction of lactate. The fact that the addition of the HCl did not affect the pH significantly is of importance since the lactate concentration in the blood is not constant.

4 *The effect of the blood extract/buffer volume ratio on the recovery of ^{14}C-L(+)-lactate*

In this experiment the 2 M glycine buffer with 0.8 M hydrazine sulphate and 1.0 g per 100 ml EDTA was used. In three series increasing volumes of blood extract (0.5 2.5 and 3 0 ml) were added to 5.5 3.5 and 3 0 ml respectively of the buffer Labelled lactate was added to the blood extract in such a way that all samples contained about the same amount of radioactivity Also unlabelled lactate was added to the blood extract, corresponding to a blood concentration of about 10 mmoles/l. 0 15 ml LDH solution with 10 mg enzyme protein per ml was used The rest of the procedure was identical with that in the general description above. Three series of blanks were also analysed

The following recoveries were obtained 89.0 ± 1.8 86.8 ± 2.1 and 86.4 ± 1.3 % (n = 10) respectively The recovery decreased slightly with increasing volume ratios but the difference between the groups was not significant. No differences were found between the blanks.

Comments The lowest blood extract/buffer volume ratio used in this experiment is the same as in the method for determination of total lactate. In an additional experiment this method was spectrophotometrically found to give a complete recovery also at the lactate concentrations used in this experiment. The fact that no significant differences in recovery were found between the three series tested indicates that also in 3.0 ml blood extract, with a concentration of lactate corresponding to 10 mmoles/l blood, all the lactate was oxidized to pyruvate with the present procedure.

5 *Effect of the hydrazine sulphate and NAD concentrations on the recovery of ^{14}C-L(+)-lactat*

A. Three buffers containing 0 2 0 4 and 0 8 M hydrazine sulphate respectively were used in this experiment. Unlabelled lactate, corresponding to a blood concentration of about 10 mmoles/l, was added to the blood extract. Otherwise the procedure was identical with that in the general description. The recoveries were 83 1 ± 1 1 82.6 ± 0.9 and 86 0 ± 1.2 % (n = 10) respectively Although the recovery was highest in the series with the highest hydrazine sulphate concentration, no statistically significant difference was found between them

B Four buffers, one of them containing no hydrazine sulphate and the others 0 4 0.8 and 1 6 M hydrazine sulphate respectively were used in this experiment. Both unlabelled pyruvate corresponding to a blood concentration of about 10 mmoles/l and labelled pyruvate were added to the blood extract. The rest of the procedure was identical with that for the blanks in the general description.

The recoveries were 78.5 ± 0.9 78.6 ± 1 2, 75.8 ± 1 1 and 78.0 ± 1.3 % (n = 10) respectively No significant difference was found between the four series.

C. 0.5 ml of four NAD solutions (0 027 M 0 054 M 0 082 M and 0.108 M) were used. The rest of the procedure was identical with the general one.

The recoveries were 72.4 ± 2.3 82.9 ± 1 7 85.3 ± 1.8 and 84 2 ± 1 1 % (n = 10) respectively The means of the three groups with the highest concentrations of NAD were not significantly different.

Comments Lactate is oxidized enzymatically according to the reaction

$$\text{lactate} + \text{NAD} \xrightleftharpoons{\text{LDH}} \text{pyruvate} + \text{NADH} + \text{H}$$

The final position of equilibrium for this reaction can be kept to the extreme right by an excess of NAD and by trapping of the pyruvate as hydrazone in the presence of hydrazine sulphate. To compensate for high concentrations of lactate a high concentration of the hydrazine sulphate was used. This could be done since the results of these experiments indicated that the increased concentration of hydrazine sulphate did not exert a negative effect on the precipitation of the pyruvate as phenylhydrazone The results also suggest a slightly positive though not significant effect of an increased concentration of hydrazine sulphate on the recovery An improved recovery was found when the addition of NAD was increased up to 0.5 ml 0 054 M solution.

6. *Effect of the LDH concentration incubation time and temperature on the recovery of ^{1}C L(+) lactate*

A. The experiment included 12 series with 10 samples in each. In six series 0 15 ml LDH solution (10 mg/ml) was used and in the others 0 06 ml of the same solution plus 0.09 ml 2.2 M ammonium sulphate. Three incubation times (30, 60 and 120 min) and two incubation temperatures (25 C and 36° C) were used for each LDH concentration. Otherwise all steps were identical with the general procedure

The results are presented in Fig 2. Statistical analyses of the results showed that at 36° C maximal recovery was achieved after 60 min also when the lower concentration of LDH was used

B. 0.03 0 06 0 10 and 0 15 ml of the LDH solution (10 mg/ml) were used in this experiment 2 2 M ammonium sulphate was added in order to obtain

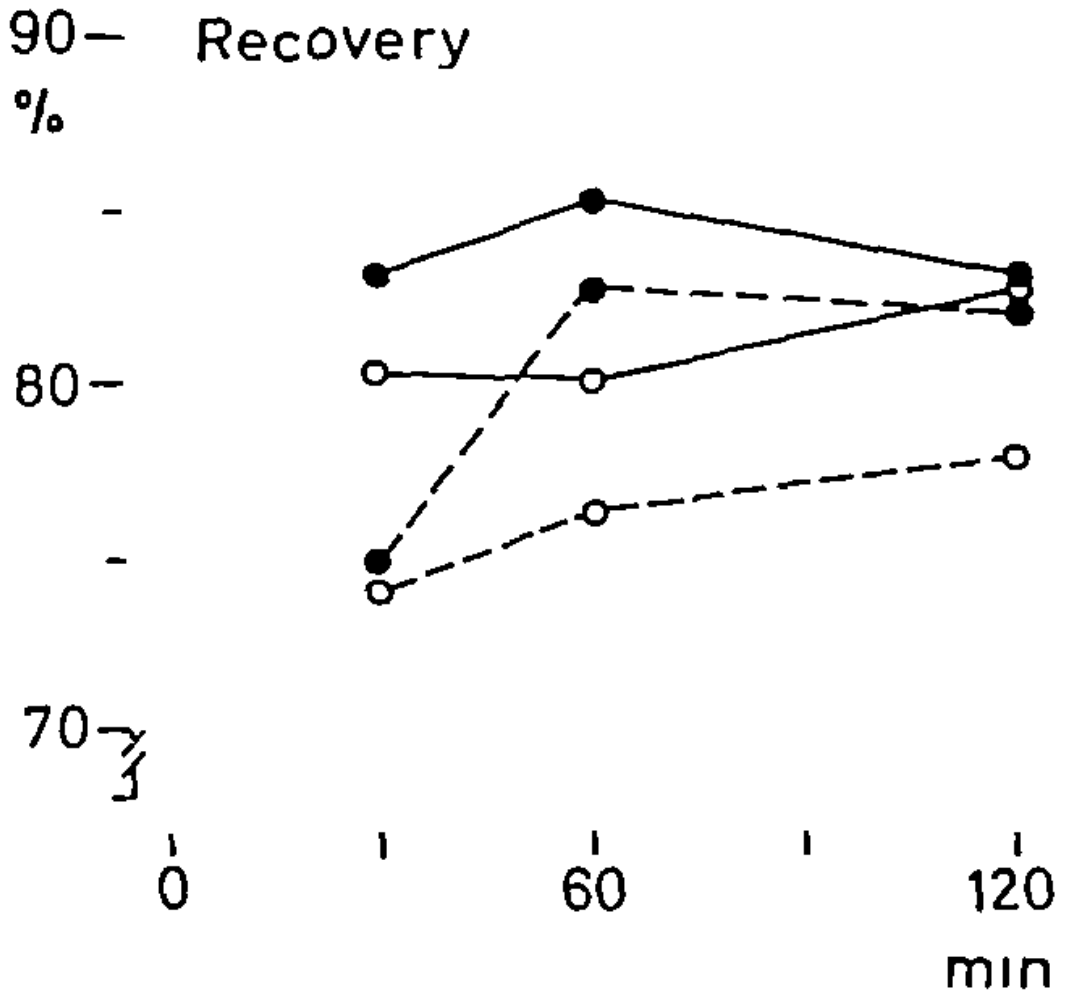

Fig 2. Relationship between recovery expressed as per cent of added ^{14}C-L(+)-lactate and incubation time t 25 C (○) and 36° C (●) and using 0.06 ml (— — —) and 0 15 ml LDH solution (———) Mean values for 10 experiments of each series are given. For further explanation see experiment 6 A.

identical volumes in the samples. As in the general procedure the incubation time was 90 min and the temperature 36° C. The recoveries were 79.9 ± 2.3 81 2 ± 1 4 84.9 ± 0.8 and 85.2 ± 1 4 % (n = 10) respectively The means of the three series with the highest LDH concentrations were not significantly dif ferent.

Comments As a consequence of the large amounts of lactate to be oxidized to pyruvate it is of importance that the reaction is allowed to occur at optimal temperature and that the LDH concentration is so high that it does not limit the reaction velocity As long as the enzyme is not inactivated, the reaction velocity can be expected to increase with temperature. In experiment A it was found that the optimal recovery was reached within 60 min at a reaction temperature of 36 C at both of the LDH concentrations used. At a reaction temperature of 25 C, however the optimal recovery was not obtained until

TABLE 1 The effect of pH on the precipitation of the phenylhydrazone of pyruvic acid expressed as fractional recovery For further explanation see the text t experiment 8 A. The probability (p) that the differences between the means were caused by random factors are indicated

pH	2.1	2.5	2 8	3 4	4 8—8.6
recovery % (Mean ± SE)	75.2 ± 0 7	77 0 ± 0.7	79.9 ± 1 1	79 0 ± 1 3	3 7 ± 1 1
n	10	10	10	10	10
analysis of variance		$p < 0.01$	—— $p > 0.05$ ——		

after 120 min incubation at the higher LDH concentration while the reaction was even slower at the lower enzyme concentration. These findings are not in agreement with the statement made by Horn and Burns (1956) that the LDH would be quickly destroyed at temperatures above 30° C. It was found that 0 1 ml of LDH solution containing 10 mg/ml of enzyme protein is enough for an optimal recovery if the reaction is allowed to occur for 90 min at 36° C.

7 *Effect of concentration of lactate*

Four portions of blood extract with different lactate concentrations were prepared but with the same concentration of labelled DL-lactate Samples from each of them were analysed for labelled lactate according to the general procedure. The total lactate concentration in the blood extract was also analysed and found to correspond to 2.7 5 1 7 9 and 11.8 mmoles lactate per litre blood. The recoveries were 87.3 ± 0 7 87 1 ± 1.3 86.7 ± 0.9 and 86.3 ± 0.9 % (n = 10) respectively No significant difference was found between the four means.

Comments In studies of lactate metabolism it is necessary that the analytical method permits a lactate concentration in blood of up to 10 mmoles/l. It is found in this experiment that the recovery is constant within the desired range.

8 *The precipitation of pyruvic acid as phenylhydrazone*

A series of experiments were performed to illustrate the different factors in the precipitation procedure. In all these experiments except in experiment D the oxidation procedure described was simulated by using labelled and unlabelled pyruvate. With the exception of the variable studied in each experiment the procedure was identical with the general procedure for the blanks.

A. Five volumes of concentrated HCl were added giving five series with different pH at the precipitation of the phenylhydrazone. The recoveries within the different series are given in Table 1

TABLE 2 The effect of the mount of added pyruvate carrier and phenylhydrazine hydrochloride on the precipitation of the phenylhydrazone of pyruvic acid expressed as fractional and absolute recovery (M±SE, n = 10) For further explanation see the text to experiment 8 B. The probability (p) that the differences between the means were caused by random factors are indicated

pyruvate carrier mmoles	0 06	0.08	0.10
phenylhydrazine hydrochloride mmoles	0 10	0.13	0 17
fractional recovery %	71 6±1 4	80.9±1.2	86.8±0.9
analysis of variance		p<0 01	———
absolute recovery cpm	10,950±250	11,580±150	11,330±100
analysis of variance		p<0.05	———
		——— p> 0.05 ———	

B. Increasing amounts of pyruvate carrier (0 06, 0.08 and 0 1 mmoles) and phenylhydrazine hydrochloride (0.10 0 13 and 0 17 mmoles respectively) were used the total volumes being kept constant. The recoveries within the different series are given in Table 2.

C. The filter paper with the precipitate was washed with either water or a 0 2 M KCl HCl buffer with pH 2.8 in both series with 2×1 ml, 1×3 ml or 2×2 ml The recoveries of total pyruvate were with water 83 1±0 9 80 0± 0 6 and 79 1±1 1 % (n=7) and with the buffer 84 6±0.8 84 1±1 9 and 84.3±2.8 % (n=7) respectively The difference in recovery between the washing liquids was significant (p<0 01) but not the effect of volumes.

D Labelled and unlabelled L(+)-lactate was added to the blood extract. The rest of the procedure was identical with the foregoing one, i.e. no LDH or NAD was added The remaining activity in the filter papers in per cent of the added activity was for water 2.07±0.05 1 74±0 04 and 1 05±0 06 % (n=8) and for the buffer 1.85±0 06 1 57±0.04 and 1.04±0.05 % (n=8) respec tively A significant interaction existed between type of liquid and volumes.

Comments The isolation of pyruvate by precipitation as phenylhydrazone was found to be superior to the generally used 2,4-dinitrophenylhydrazone (Sacks 1956 1961) since the yellow colour of the precipitate was so weak that liquid scintillation could be performed without preceding combustion.

As found in experiment A, it is necessary to adjust the pH to about 3 in order to precipitate the pyruvate as phenylhydrazone and the most complete precipitation was found at about pH 2.8. This agrees with the observation by Friedemann and Haugen (1943) that the reaction of nitrophenylhydrazines with carbonyl compounds only proceeds in acid aqueous solutions, a fact which

also explains why nitrophenylhydrazines or phenylhydrazine cannot be substituted for hydrazine as a pyruvate trap in the enzymatic reaction.

The fact that the labelled lactate is not completely recovered as phenylhydrazone is probably due mainly to an incomplete precipitation of the phenyl hydrazone. Considering the recovery as a fraction of added radioactivity it would consequently be favourable to add large amounts of pyruvate carrier and phenylhydrazone. Since the error at the liquid scintillation decreases with increasing cpm, it is better to adjust the procedure so as to recover as much as possible of the added radioactivity as cpm. As found in experiment B the fractional recovery increased with added pyruvate carrier and phenylhydrazine as expected. However the radioactivity recovered as cpm rather decreased when the highest concentrations of these reagents were used.

If the phenylhydrazone formation was allowed to occur for 20 min at room temperature an optimal recovery was reached. Under these conditions no phenylosazone formation with glucose was found

It is necessary to wash the precipitate and the filter paper to remove radioactivity not precipitated as phenylhydrazone. However since the phenylhydrazone of the pyruvic acid is to some extent soluble in water it is desirable to wash with small volumes in order to avoid a decreased recovery As found in experiments C and D a good washing effect is achieved with 2×2 ml of the buffer without a significant decrease in recovery

9 *Determination of the radioactivity*

Since the total weight of material on the filter paper to be counted is rather great (about 40 mg) it is necessary that the material is dissolved in the scintillation liquid in order to avoid "layering" (Blair and Segal 1962) In experiments performed it was found most favourable to add 2 ml methanol both with respect to fractional recovery and recovered cpm

Because of the weak yellow colour of the phenylhydrazone to be counted, a test was made to see whether a somewhat higher concentration of the scintillators than ordinarily used would increase the counting efficiency This was found to be the case to some degree for the POPOP but an increase of the concentration of PPO as well did not improve the efficiency The efficiency was found to be 65.1 ± 0.5 %

The internal standard technique is valid only if the quenching is the same for the activity in the sample as for the added standard This was found to be the case when tested by the channel quotient technique ($n = 30$)

The geometry of the filter paper in the vials in relation to the photomultipliers was found to have no effect on the counting efficiency Blair and Segal (1960) also conclude that the orientation of the paper is of minor importance.

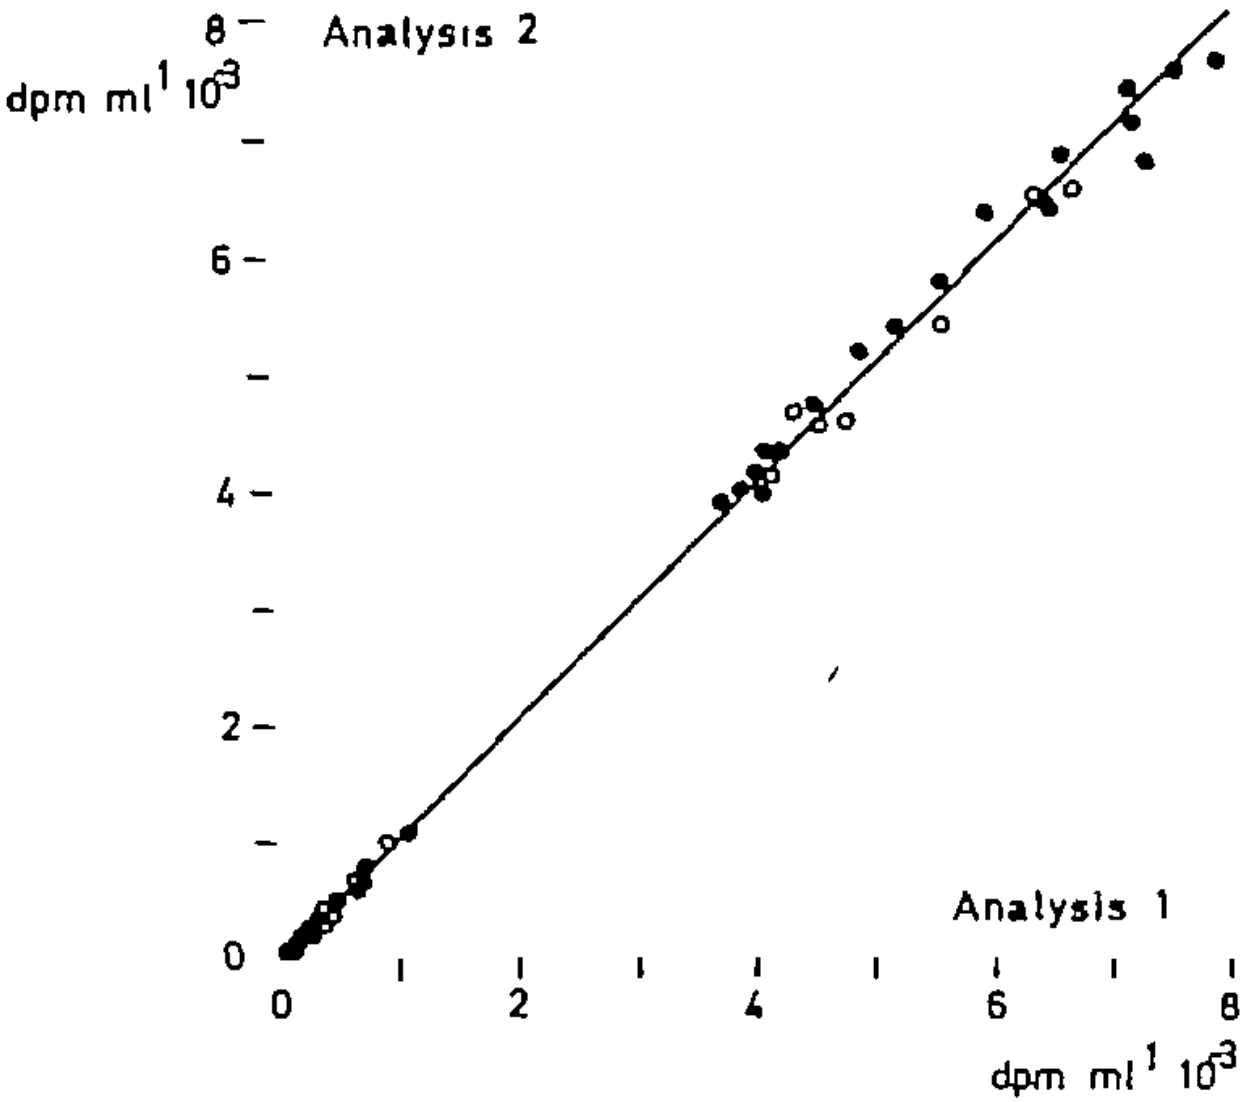

Fig 3 Comparison of duplicate analyses. Analysis 1 was performed after one day and analysis 2 after 2 (○) and 6 (●) days respectively The regression equations and correlation coefficients are

analysis 2 after 2 days $y = 1.01 + 4.6$ $= 0.99$
nalysis 2 after 6 days $y = 1.00x - 9.9$ $= 0.99^{*}$
otal $y = 1.00x - 7.4$; $= 0.99$

The line of identity is shown.

10 *Recovery and reproducibility*

A. Ten samples containing unlabelled L(+)-lactate corresponding to about 10 mmoles/l blood and ^{14}C-L(+) lactate were analysed The fractional recovery was 86.2 ± 4.0 % (mean ± SD) and the blank was 1.04 ± 0.14 % (mean ± SD) The total recovery was 85.2 ± 4.0 % (mean ± SD)

B. Duplicate analyses were performed on 64 blood samples from human studies. One determination was made after one day and the other after 2 and 6 days respectively In all cases the blood extract was prepared immediately

and then kept at +4° C. The results are presented in Fig 3 No statistical difference was found between analyses 1 and 2 in the two groups. The error expressed as the standard deviation (SD) for a single determination was found to be 156 dpm/ml and the corresponding coefficient of variation 2.8 % in samples containing more than 1000 dpm/ml and 72 dpm/ml and 7 2 % in samples containing less than 1000 dpm/ml.

Discussion

It is assumed that the enzymatic oxidation of lactate to pyruvate is complete. This is supported by the following facts

1) when the concentrations of LDH and NAD were increased, a constant level was reached for the recovery which could not be surpassed either by a further rise in enzyme concentration or by reducing the lactate concentration

2) when the analysis was repeated once again on the filtrate, no difference was found between the sample and its blank.

The loss in recovery is probably due to the incomplete precipitation of the phenylhydrazone. No other carbonyl reagent has been found, however which forms a colourless and more completely precipitable compound with pyruvic acid.

The specificity of the method is not entirely dependent on the specificity of the LDH used, since a product formed by interaction of impurities affects the results only if it is precipitated This is probably the case only for pyruvate. Of the substances tested by Lundholm, Mohme Lundholm and Svedmyr (1963) DL-glyceric acid was the only one which to an appreciable degree simulated lactate using LDH for enzymatic lactate determination. In this procedure the DL-glyceric acid would seem to be of importance only in case of a pathological metabolism of this substance (Williams and Smith 1968) In biological experiments, when labelled L(+)-lactate is infused, the blank values depend mainly of course on the labelled lactate converted to pyruvate In practical applications of the method the blanks have never exceeded 15 per cent of the "sample"

CHAPTER III A

General Procedures and Methods

Procedures

Catheterization The procedures for the catheterization of the forearm vessels agree with those described earlier (Wahren 1966) and are therefore only briefly outlined below After the hand and forearm had been immersed in hot water for 10 min a teflon catheter was inserted percutaneously into a cubital vein and manipulated into a deep forearm vein so far that its tip was no longer palpable. It had then been introduced approximately 3—9 cm. The radial artery was punctured at the level of the radial styloid process and the brachial artery at the intercondular line. Teflon catheters were inserted 2—5 cm in the proximal direction at both places. The right arm was used except in one subject who was left handed For administration of hypertonic sodium lactate solution (Chapter III.D) a teflon catheter was introd ced percu taneously into a cubital vein in the other arm and its tip was placed in the superior vena cava about 5 cm from the right atrium.

Exercise Rhythmic forearm exercise was performed on an adjustable hand ergometer according to the procedure described by Wahren (1966) The subjects were in the supine position and with the forearm horizontal at an angle of approximately 45 to the trunk. The elbow was extended and the volar side of the hand upwards. The resting position of the ergometer handles was adjusted until the middle phalanges of the second, third and fourth fingers were approximately vertical In all experiments the path of contraction was 30 mm and the exercise was performed with 60 contractions per min in time with a metronome. The work intensity was set to 10 kpm/min by using an average spring tension during contraction of 5 6 kp. The exercise performed was close to isotonic, the increase in tension during the contraction being 8 per cent of the mean tension. The movements of the ergometer handle were registered on an ink jet recorder (Mingograf 4? B Elema-Schönander) via a linear motion potentiometer connected to the handle and a direct current circuit.

Experimental design The experimental design of the studies in Chapter III-C and D is illustrated in Fig. 4 When the catheters had been inserted the subjects were allowed to rest for about 30 min before they started the exercise period, which lasted approximately 60 min. On two occasions during the

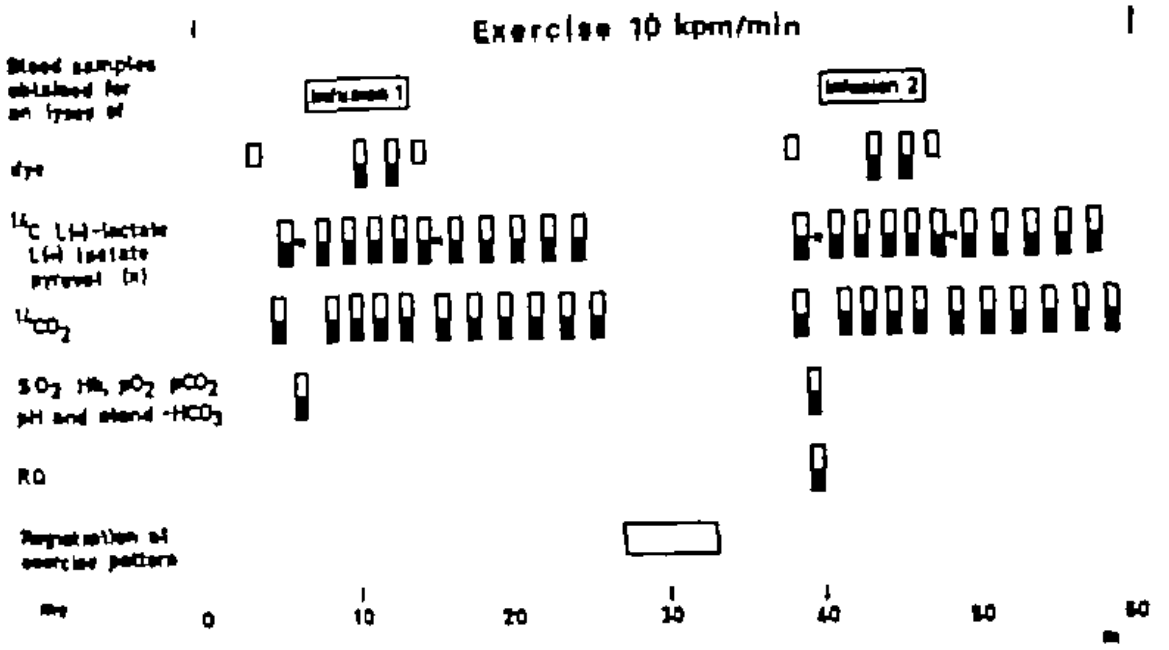

Fig 4 Th experimental design of th studies in Chapter III The pproximate occasions for blood sampling from th radial artery (□) and deep ein (■) are indicated. An asterisk denotes blood samples in which also the pyruvat concentration was analysed. For further explanation see text.

exercise period at about 7 and 40 min from the start (range 7—11 and 39—42 min respectively) infusions of a dye solution containing L(+) lactate-1 ^{14}C into the brachial artery for determination of blood flow and lactate turnover were started The infusions lasted 6—7 min. Background concentrations of dye ^{1} C-L(+)-lactate and $^{14}CO_2$ were determined before the infusion periods. The dye concentration of arterial and deep venous blood was analysed twice during the infusions and furthermore in arterial blood about 20 sec after the end of infusions Arterial and venous concentrations of ^{14}C-L(+)-lactate, total lactate and $^{14}CO_2$ were determined repeatedly during and up to 12 min after the infusions. The samples obtained just before and immediately after the infusions were also analysed for concentration of pyruvate. The total lactate and $^{4}CO_2$ values obtained during the infusions were corrected for dilution by the infused solution. Oxygen saturation hemoglobin concentration pO_2, pCO_2, pH and standard bicarbonate were determined in arterial and venous blood immediately before the infusions. The local respiratory quotient (RQ) was determined before the last infusion. The arterial and venous samples were obtained simultaneously and were thus not fully comparable. No correction was made for that fact.

The movements of the ergometer handle were registered in the interval be-

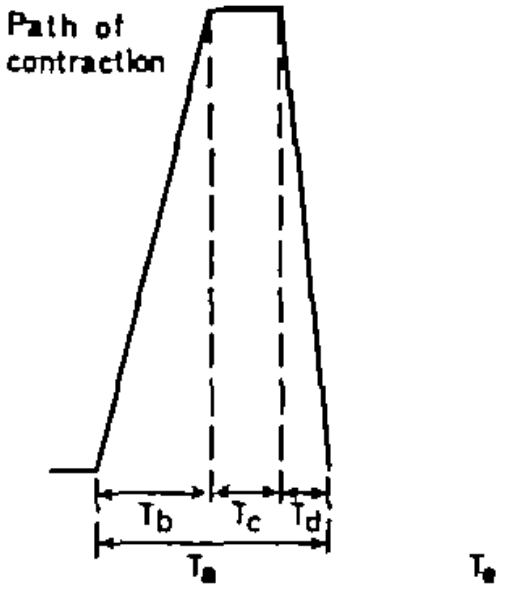

Fig 5. The symbols used for denoting the duration of the different phases of contraction and relaxation during exercise. The square root of the sum of the squares of the coefficients of variation for T_a, T_b, T_c, T and the contraction distance was calculated as an expression for the variability in exercise pattern.

tween the infusion periods. The symbols used for denoting the duration of the different phases of contraction and relaxation appear in Fig 5

Labelled lactate Sodium L(+)-lactate-1 ^{14}C, which was the only type of labelled lactate infused, was obtained from Volk Radiochemical Co., USA, and New England Nuclear Corp. USA. According to the suppliers the radiochemical purity of the substance was 98 %. When the labelled lactate was decarboxylated to acetaldehyde and CO_2 according to Brin and Olson (1952) the radioactivity in the aldehyde-dimedon complex obtained was less than 0.1 per cent of the radioactivity in the CO_2. This verifies that the lactate was labelled only in the carboxyl carbon. In all studies the radiochemical and optical purity of the substance used was tested by the analytical method described in Chapter II. Within the error of the method all the radioactivity was recovered as ^{14}C-L(+) lactate if it was taken into consideration that the recovery of the analytical method was 85.2 %

Unlabelled lactate The hyperosmotic sodium lactate solution which was used in the study described in Chapter III.D was obtained from Pharmacia, Sweden. When analysed enzymatically 90 % of the lactate was found to consist of the L(+) isomer

Forearm blood flow at rest ($\dot{Q}$ ml/min) was calculated from observed values of total forearm volume (TV ml) wrist circumference (W cm) and forearm skinfold thickness (S mm) using the following equation (Wahren and Hagenfeldt 1968) $\dot{Q} = 0.053\ TV + 9.20\ S - 7.45\ W + 70.3$ *The volume of the forearm* was measured by water displacement. The circumference of the wrist was measured with a tape just proximal to the radial styloid process. *Skinfold thickness* was measured with a skinfold caliper (Harpenden)

Forearm blood flow during exercise was determined as described by Wahren (1966) with the exception that a modification was introduced for background calculation during prolonged infusions (see Chapter III.B) *Muscle blood flow during exercise* ($\dot{Q}_m$) was calculated as the brachial artery blood flow determined by indicator dilution technique, minus half the resting forearm blood flow (Wahren 1966)

Maximal force of finger flexion was tested according to Tornvall (1963) using a strain gauge dynamometer and a measuring bridge (Philips PT 1200/01) This equipment was calibrated against known forces.

Statistical methods Most of the statistical calculations were performed according to Snedecor (1956) The following probability (p) levels of significance were used $p<0.001^{***}$ $p<0.01^{**}$ and $p<0.05^{*}$ Unless otherwise stated, the results given in the text in this Chapter are means $\pm$ one standard deviation ($M \pm SD$)

Blood analyses

Sampling Blood samples were drawn into disposable plastic syringes for the analyses performed on a perchloric acid blood extract and for the indocyanine green analyses. All other blood samples were collected in 10 or 20 ml siliconed glass syringes. The dead space in each syringe was filled with heparin solution (5000 I U /ml, Vitrum, Sweden) The hemoglobin concentration values were corrected for dilution by the heparin.

The *errors of the methods* are presented in Table 3.

^{14}C L(+)-lactate and total lactate concentration see Chapter II It was found that the presence of dextran (about 10 g/l) and indocyanine green (about 10 mg/l) did not influence ^{14}C-L(+) lactate or total lactate concentration analyses

Pyruvate concentrations were analysed enzymatically mainly according to Segal Blair and Wyngaarden (1956) and Bücher *et al* (1962)

$^{14}CO_2$ in blood was determined as described by Hagenfeldt (1967) It was found that the recovery in this method depended on the volume of the blood sample used. The recovery was complete up to 3 ? ml blood but then decreased linearly by 9 0 % per ml blood. On this account every sample was corrected for the incomplete recovery The blood samples used in the present studies were smaller than 5.5 ml. Lactic acid was used to liberate the CO_2 from blood in order to avoid oxidation of the ^{14}C-lactate present in the blood.

Oxygen saturation was determined spectrophotometrically (Holmgren and Pernow 1959)

pO_2 was measured with an oxygen electrode (Beckman Spinco Division) in

TABLE 3. The error for a single determination in various blood analyses, expressed as th standard deviation (SD) for single determination and the corresponding coefficient of variation. Th calculations are based on duplicate analyses on the same blood samples.

	Range	SD	Coefficient of variation	n

combination with a Beckman model 160 physiological gas analyzer The electrode was mounted in an open cuvette described by Holmgren (1965)

pH pCO and standard bicarbonate were measured with the microtechnique described by Siggaard Andersen (1963)

Carbon dioxide content of blood and for RQ determinations also the oxygen content, was determined according to Peters and van Slyke (1932)

Hemoglobin concentration was analyzed by the cyanmethemoglobin technique (Drabkin and Austin 1935) using a reagent and standard from Hycel Inc. USA.

Hematocrit was determined and corrected for trapped plasma (1.3 %) according to Garby and Vuille (1961) using a high speed, micro-capillary hematocrit centrifuge (Wifug Automatic 102—11)

Indocyanine green concentrations were measured spectrophotometrically in serum obtained after clotting and centrifugation of 2 ml blood samples. The analyses were made at 805 mμ using a Beckman B spectrophotometer A calibration curve was made for each subject with readings at 4 and 8 mg/l

Definitions

a = *arterial concentration* v = *deep venous concentration*

Fractional uptake of ^{14}C *L(+)-lactate* (F_{pl}) was calculated as the (a—v) difference of labelled lactate at relative steady state as a fraction of the arterial concentration of labelled lactate. Values given are means of at least 2 observations.

Uptake of lactate (synonym, extraction of lactate) was computed as the product of F_{pl} and the total concentration of lactate in arterial blood.

Rate of lactate uptake was calculated as the product of lactate uptake and muscle blood flow ($\dot{Q}_m$)

Net uptake and *net release of lactate* are defined as the magnitude of respectively a positive and a negative (a—v) difference of lactate.

Rate of net uptake and *rate of net release of lactate* were calculated as the product of net uptake and $\dot{Q}_m$ and of net release and $\dot{Q}_m$ respectively

Fractional oxidation of ^{14}C*-L(+)-lactate* was calculated as the (v—a) difference of $^{14}CO_2$ at steady state during the infusions as a fraction of the (a—v) difference of ^{14}C-L(+) lactate

CHAPTER III B

Blood Flow Determination

The procedure described by Hagenfeldt and Wahren (1968) for the study of human muscle metabolism during exercise has been used in the present study It is based on blood flow determination during forearm exercise by means of an indicator dilution technique with continuous infusion of the dye (indocyanine green) using an infusion rate of the dye solution of approximately 34 ml/min (Wahren 1966) the relatively high infusion rate being necessary for the achievement of complete mixing of blood and dye solution. Some modifications of the above procedure were required for the present study For determination of the blood flow it is necessary to calculate the concentration of recirculating dye. For infusion periods up to 2 min the concentration of recirculating dye may be considered with acceptable approximation to rise linearly with time (Wahren 1966) In metabolic studies, however it is often necessary to use longer infusion periods in order to obtain a constant (a—v) difference of the studied substance. A more exact model is then required for calculation of the concentration of recirculating dye.

This study was carried out in order to investigate how the concentration of recirculating dye can best be calculated for long infusion periods (6—7 min) and whether a somewhat lower rate of infusion than 34 ml/min could be used without affecting the mixing between the arterial blood and the infused solution.

Procedure and Experimental

A Recirculation

The investigation was made on two subjects who carried out a rhythmic forearm exercise with both arms at an intensity of 10 kpm/min. Through a catheter in the right brachial artery the dye solution (see Wahren 1966) was infused at a rate of 30 ml/min, corresponding to roughly 0.9 mg of dye per minute for 6—7 min. Blood samples were collected from the left brachial artery at 15-second intervals during and up to 1 min after the infusion for determination of the concentration of recirculating dye. Two infusions were made on each subject with an interval of about 40 min.

B Mixing of dye and blood

During the infusion of dye duplicate samples were drawn from the radial artery and deep forearm vein of 7 subjects on 15 occasions for determination of the concentration of dye. The samples from the artery and vein were drawn simultaneously

Calculations

The dye used, indocyanine green is eliminated from plasma at a rate proportional to the plasma concentration (Caesar *et al* 1961) As the rate of administration of dye is constant, the following approximate model can be set up for calculation of the concentration of recirculating dye The following symbols are used

t = time (sec)
a = quantity of dye infused per unit of time
Q = the plasma volume over which the dye is distributed
Y = quantity of dye in Q
C = the concentration of dye in plasma (mg/l) (C_1 C_2 and C_∞ are the concentrations of dye in plasma at times t_1 t_2 and infinity respectively)
k_1 k_2, k_3 and K = arbitrary constants

$$dY/dt = a - k \quad C \tag{1}$$

Under the assumption that $C = Y/Q$ the equation can be written

$$dY/dt + Y \quad k/Q = a \tag{2}$$

The general solution of this equation is

$$Y - a \quad Q/k = K \quad e^{-\quad k/Q} \tag{3}$$

which may also be written

$$C = a/k \quad + (K/Q) \quad e^{-\quad k/Q} \tag{4}$$

This expression yields

$$C_1 = C_2 (1 - k_3 \quad e^{-k_3 \quad t_1}) / (1 - \quad k_3 \quad e^{\quad k_3 \quad t_2}) \tag{5}$$

This relation can be used for calculation of the recirculating dye (C_1) at time t_1 when the corresponding concentration (C_2) is known at another time (t_2) The equation may also be written

$$C = C_\infty \quad (1 - k_3 \quad e^{-k_3 \quad t}) \tag{6}$$

or

$$1 - C/C_\infty = k_3 \quad e^{\quad k} \tag{7}$$

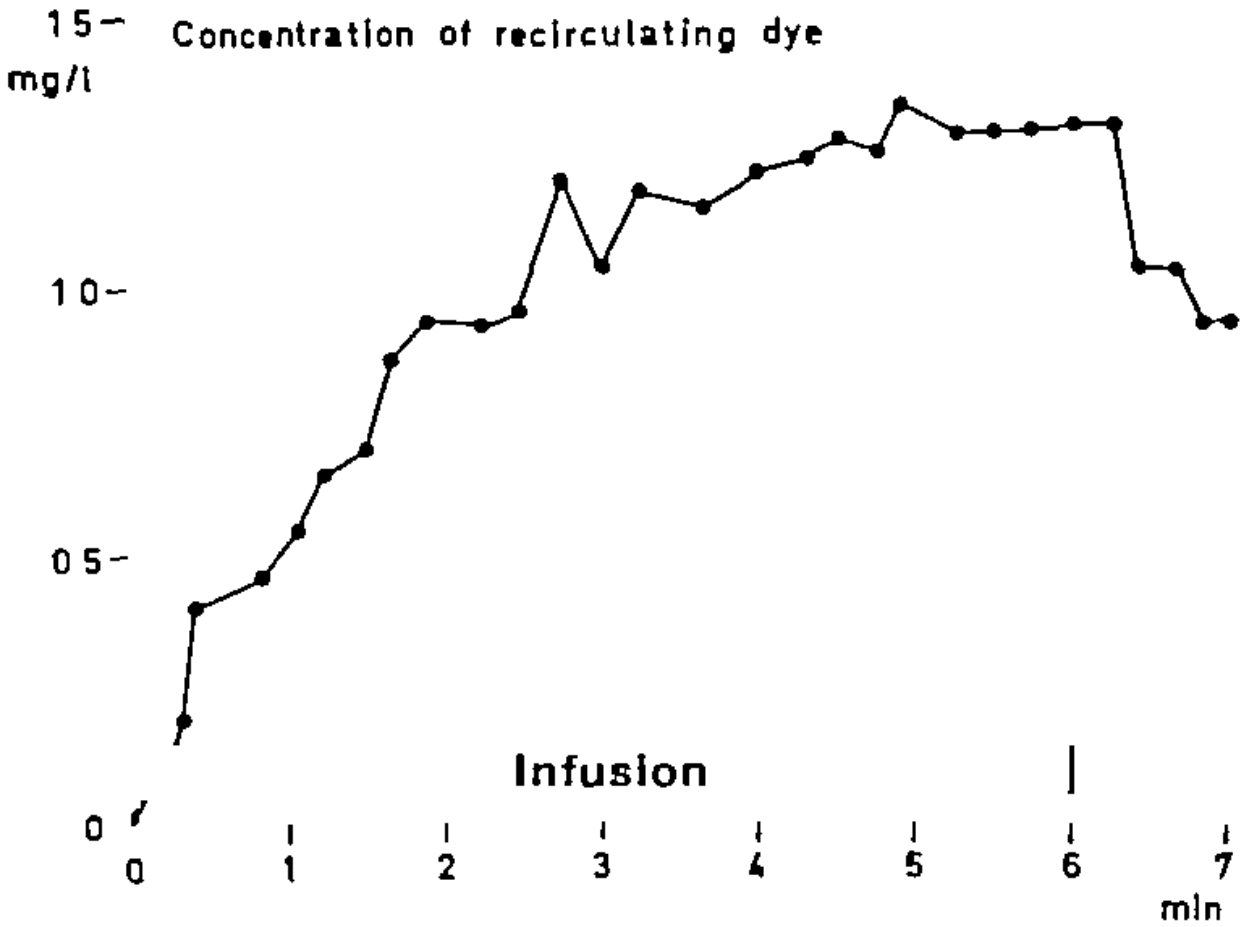

Fig 6 Concentration of recirculating dye during and after infusion of 0.9 mg/min of dye in one subject. Dye concentration determined in blood samples from the contralateral brachial artery during forearm exercise (10 kpm/min)

which makes it possible to determine empirically the arbitrary constants k_2 and k_3. For this purpose the concentrations of recirculating dye in the brachial artery was plotted for each of the four infusion periods, as function of the time, and C_∞ was estimated. For each infusion period the coefficient of correlation was calculated for the regression $^{e}\log (1-C/C_\infty) = {}^{e}\log k_2 - k_3\ t$ with $^{e}\log (1-C/C_\infty)$ as dependent variable both for the estimated value of C_∞ and for some slightly larger and smaller values. The values which corresponded to the found four regressions with optimal coefficient of correlation were lumped together and the constants $^{e}\log k_2$ and k_3 were calculated (Fig 7)

Results

A. (Fig 6 and 7) A typical course of the increase of concentration of recirculating dye is illustrated in Fig 6. The mean concentration of recirculating dye at the end of the infusions was 1.50 mg/l (range 1.35—1 65 mg/l) The mean value for C_∞ at optimal correlation was 1 65 mg/l (range 1 42—1.80

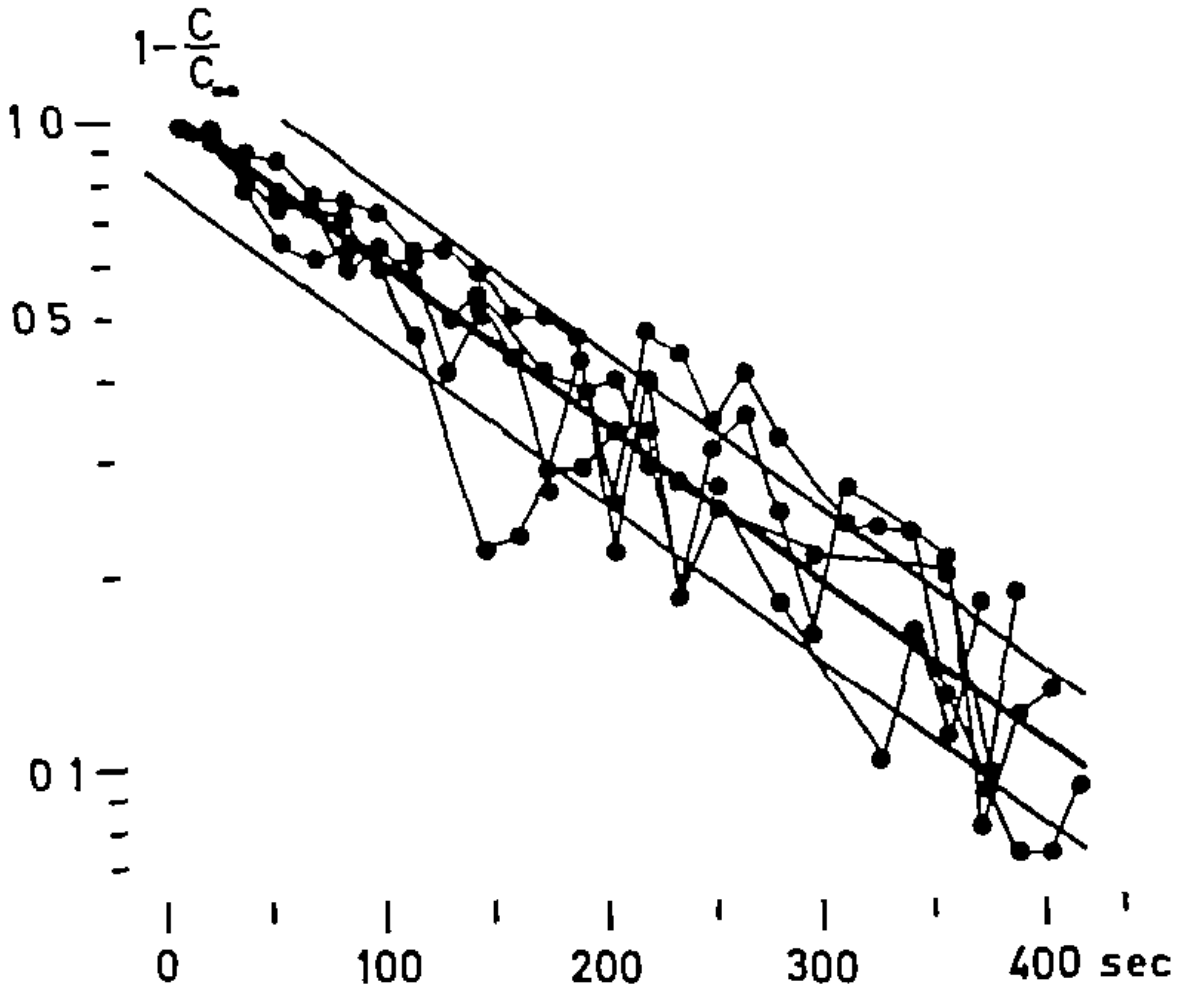

Fig 7 1—C/C$_\infty$ determined from 4 experiments, plotted semilogarithmically against time. For further explanation see text. The regression ($1 - C/C_\infty = 1\,09$ $^{-0.006}$ t $r = 0\,92$) ± 1 SD is shown. This figure can be used for calculation of the concentration of recirculating dye (C_1) at time t_1 if the concentration is known (C_0) at time t_0 $C_1 = ((1-y)/(1-y_0))$ C_0 where y is the ordinate ($1 - C/C_\infty$)

mg/l) The calculated mean values of the constants were $k_2 = 1\,09$ and $k_3 = 0\,0058$ sec The coefficient of correlation for the linear regression was $-0\,97^{***}$ The concentration of recirculating dye during infusion can be calculated by means of the expression

$$C_1 = C_0\,(3\,37 - e^{1.3\ \ 0.0058}\ )\,/\,(3\,37 - e^{1.3\,-\,0.0058\ t_1})$$

which is obtained from equation (5) after extension. Fig 7 can be used for the same purpose

B. The mean infusion rate was 30 ml/min (n = 15) with a lowest value of 29 6 ml/min. The coefficient of variation for a single determination of dye concentration was 3.9 per cent. F the ratio between the total intraindividual

variance for the 15 sets of 4 dye concentration values obtained on each occasion and the variance for a single determination was 1 27 ($p>0.05$) indicating uniform mixing of dye and blood.

Discussion

In the approximate mathematical model that has been set up it is assumed that the concentration of dye at a given moment is Y/Q, it being presumed that the dye is immediately distributed uniformly in the volume Q This approximation should be of subordinate importance apart from the first minute of the infusion period since the time taken for distribution of the dye in the plasma volume is short in relation to the time for the rise of concentration of the recirculating dye. Furthermore the arbitrary constants in the mathematical model have been determined empirically so that the formula set up for calculation of the concentration of the recirculating dye has been adapted to the prevailing experimental conditions.

The *mean value for the shortest recirculation time calculated from the relation* $\log (1-C/C_{\infty}) = 0.085 - 0\,0058\ t$ is about 15 sec. This agrees fairly well with earlier findings that the dye starts to appear in measurable quantities in the contralateral brachial artery 20—40 sec after the start of the infusions (Wahren 1966)

The concentration of recirculating dye constitutes only a small part of the total dye concentration in the forearm even after long periods of infusion. Small errors in the calculation of recirculating dye will thus have only a minimal influence on the blood flow calculation.

In the present experimental arrangement with long infusion periods the infusion rate was 30 ml/min. This rate is somewhat lower than the 34 ml/min recommended by Wahren (1966) The results show however that the infusion rate used produced an adequate mixture of infusion solution and blood.

CHAPTER III C

Uptake, Release and Metabolism of Lactate at Normal Arterial Lactate Concentration

Animal experimental studies (Omachi and Lifson 1956, Stainsby and Welch 1966) and to some extent studies on humans (Freyschuss and Strandell 1967) have given evidence that working skeletal muscle not only produces lactate but under certain conditions may take up lactate. One of the objects of the present study was by means of isotope technique, to investigate whether an uptake simultaneously with a net release of lactate takes place in human working skeletal muscle. It was also intended to quantitate the uptake if any and to determine the extent to which the lactate uptake was oxidized to CO_2. As the rate of net release of lactate from the forearm muscle varies during prolonged exercise, it was considered of interest to make these measurements both after 10 min of exercise when the rate is maximal, and after 40 min, when it has reached a lower and practically constant level (Wahren and Hagenfeldt 1968)

Subjects

The results presented in this chapter are based on data from 16 male volunteers aged 21—26 years. Five were students the others were firemen. All subjects had had regular physical training and health controls and were in good health at the time of the investigation. Arm dimensions of the subjects are given in Table 4

Procedure

The experiments were performed in the morning The subjects were fasting for at least 12 hours prior to the study

The study was arranged in two different series.

TABLE 4 Arm dimensions of the subjects in series 1 and 2

	n	Mean ± SD
Forearm volume, ml	15	1230 ± 190
Skinfold thickness, mm	15	3 9 ± 0.5

Isometric strength, kp	9	59.9 ± 7 5

Series 1 (n=10)

The experimental design is described in Chapter III.A and Fig. 4

Series 2 (n=5)

A discrepancy was found in series 1 between the amount of radioactivity which at steady state was taken up as ^{14}C-L(+) lactate and the radioactivity recovered as $^{14}CO_2$ and other ^{14}C-labelled metabolites. This discrepancy was tentatively assumed to be due to an incorporation of radioactivity into metabolites with a slow turnover rate. The studies in series 2 were undertaken to investigate whether this assumption was supported by the appearance of a slow phase in the release of $^{14}CO_2$ from the forearm muscles after infusion of ^{14}C-L(+) lactate.

For the right arm the same catheterization procedure was used as in series 1. In four of the experiments a catheter was also inserted into a deep forearm vein of the left arm. The subjects performed identical exercise with both arms using *two hand ergometers. Only one infusion was given starting after about 7* min of exercise (range 7—9 min). Blood samples were drawn from the deep vein of the contralateral arm. With this exception the procedure was identical with that in series 1 up to 12 min after the end of the infusion. For the rest of the exercise period arterial and venous blood samples were drawn every 5—10 min for analyses of lactate, ^{14}C-L(+)-lactate and $^{14}CO_2$ concentrations. No recording of the movements of the ergometer handle was performed in this series.

Special calculations in series 2

The $^{14}CO_2$ released after infusion of labelled lactate could be assumed to originate not only from oxidation of C-L(+)-lactate taken up during the infusions but possibly also from oxidation in the forearm muscles of recirculating ^{4}C-labelled substrates taken up during and after the infusions.

The latter component was probably of minor significance during the first period after the infusions, but it could possibly be of significance when the $^{14}CO_2$ release had reached a low level. The $^{14}CO_2$ release from oxidation of recirculating ^{14}C-labelled metabolites (U) was assumed to be a function of time ($U=f_U(t)$) and identical in both arms since the volunteers were performing exercise of the same intensity with both arms. The release of $^{1}CO_2$ originating from oxidation of ^{14}C-L(+)-lactate taken up during the infusion (Y) was also assumed to be a function of time ($Y=f_Y(t)$) and equal in both arms in proportion to the (a—v) difference of ^{14}C-L(+)-lactate at steady state during the infusion.

$$Y_l = Y_r \ ((a-v)_l{}^{14}\text{C-La}) / ((a-v)\ {}^{14}\text{C-La}) \quad (1)$$

r = right, l = left, La = L(+) lactate

The measured $^{14}CO_2$ release from either of the arms (Z) was a function of time ($Z = f_z\ (t)$) and was assumed to be the sum of $^{14}CO_2$ originating from oxidation of ^{14}C-L(+) lactate taken up during the infusions and recirculating ^{14}C-labelled substrates taken up after the infusions.

$$Z_r = U + Y \quad (2)$$

$$Z_l = U + Y_l \quad (3)$$

The following expression for Y can be calculated after combination and substitution in equations 1—3

$$Y = (Z_r - Z_l)\ ((a-v)\ {}^{1}\text{C-La}) / [((a-v)_r{}^{1}\text{C-La}) - ((a-v)_l\ \text{C-La})]$$

The arterial concentration of ^{14}C-L(+) lactate in the left arm was not measured during the infusions. However the mean arterial ^{14}C-L(+)-lactate concentration in the left arm during the last 4 min of the infusions could be calculated to be approximately 3/4 of the arterial concentration immediately after the end of the infusions. In these calculations it was assumed that the arterial concentration of ^{14}C-L(+)-lactate rose according to the equation $\square - \square\ (1 - e^{bt})$ where t denotes time in minutes and b is a constant. This assumption was supported by results from a complementary study including two experiments, from which b could be calculated to be about 0 1

Y revealed a biphasic course when plotted semilogarithmically against time. This function was fitted to a biexponential course and the quantity of $^{1}CO_2$ released was calculated after separate integration of the two phases.

Results

The results from the first period of infusion (infusion 1) after about 10 min of exercise comprise data from series 1 and 2 (n = 15) The results from the second period of infusion in series 1 (infusion 2) after about 40 min of exercise, are based on 9 experiments. One of the experiments in series 1 had to be interrupted after the first period of infusion owing to a technical mishap

Muscle blood flow and oxygen uptake (Table 5)

The calculated *muscle blood flow* was slightly greater ($p < 0.01$) after 40 min than after 10 min of exercise. It was positively correlated ($r = 0.5^{2**}$) to the variability in exercise pattern, for definition see legend of Fig 5 No significant difference existed in respect of *oxygen uptake* between 10 and 40 min.

TABLE 5 Data btained t normal arterial concentration of total lactate on uptake, release and fractional oxidation of lactat the brachial artery blood flow and the metabolism of oxygen, CO_2 nd pyruvate in the forearm after boot 10 min and 40 min of exercise p denotes the probability that the difference between 10 and 40 min of exercise was caused by random factors. The $p > 0.05$ values are omitted. a = rterial, v = deep venous concentrations, $\dot{Q}_{O_2}$ = forearm muscle oxygen uptake $\dot{Q}_{CO_2}$ = forearm muscle production of CO_2. Fig. 8. Uptake of C-L(+)-lactat during infusion expressed as fraction of the arterial concentration of C-L(+)-lactate. Individual values from infusion 1 nd 2 s normal arterial concentration of total lactat are given.

Release of lactate and pyruvate (Table 5)

The lactate concentration in the arterial blood was the same on both occasions of observation. The *net r lease of lactate* was 1.6 ± 1.0 and 0.4 ± 0.3 mmoles/l after 10 and 40 min of exercise respectively. The difference was significant ($p < 0.01$). This means that the *rate of net release of lactate* from the forearm muscles diminished ($p < 0.05$) during the exercise period. For *pyruvate* no significant differences were measured between 10 and 40 min as regards arterial concentration or rate of release.

Uptake of lactate (Fig. 8, 9, Table 5)

The uptake of ^{14}C-L(+) lactate was initially high during the infusions but fell successively and reached a constant level after about 4 min of infusion on both occasions. The *fractional uptake of* ^{14}C *L(+)-lactate* was similar ($p > 0.05$) in infusions 1 and 2 (0.32 ± 0.06 and 0.30 ± 0.07 respectively). No significant difference existed between 10 and 40 min of exercise as regards *uptake of lactate* and *rate of lactate uptake* in forearm muscle. Both were positively correlated to the arterial lactate concentration ($r = 0.68^{**}$ and $r = 0.57^{**}$ respectively). Within the limited range of variation for the arterial lactate concentration there was no significant deviation from a linear relation.

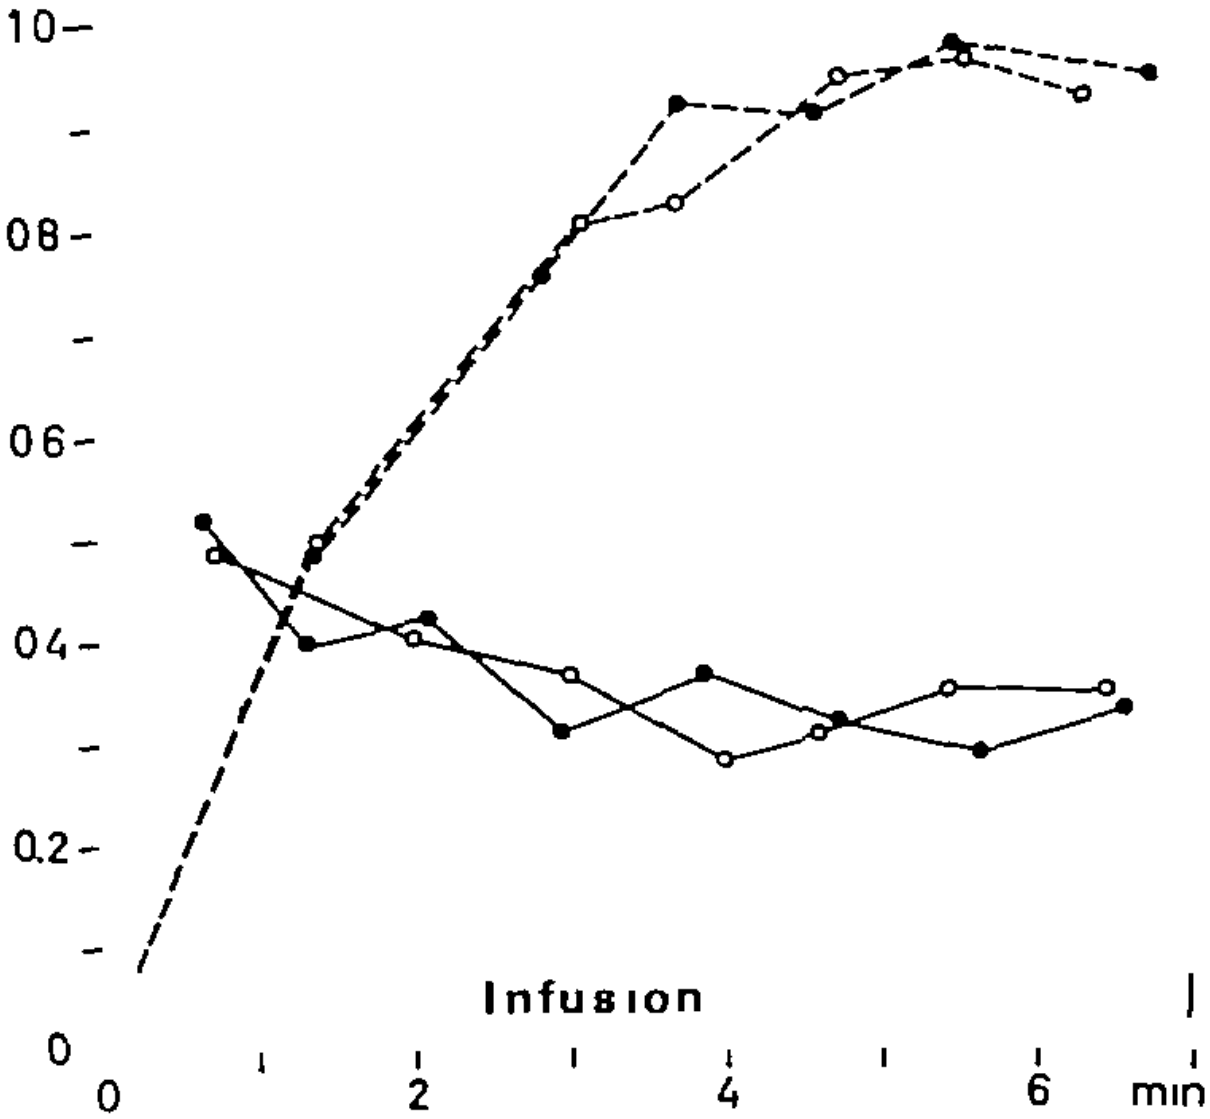

Fig 9. Uptake of ^{14}C-L(+)-lactate during infusion expressed as fraction of the arterial concentration of ^{14}C-L(+)-lactat (○—○, ●—●) and release of $^{14}CO_2$, calculated as fraction of the release t steady state during the infusion period (○---○, ● --●) Mean values from infusion 1 (○—○, ○- -○) and infusion 2 (●—● ●--●) at normal arterial concentration of total lactate are given. This figure shows that the uptake of ^{14}C-L(+) -lactate and the production of CO_2 normally reached constant level during the infusions.

No significant correlation existed in this material between uptake and net release of lactate.

Release of ^{14}CO during infusion (Fig 9 10 Table 5)

The (v—a) difference of CO_2 rose rapidly at the beginning of the infusions and reached a constant level after an average of about 5 min of infusion. The conditions were essentially similar in infusions 1 and 2. The fractional oxidation of C-L(+) lactate was 0.38 ± 0.16 and 0.52 ± 0.19 in infusions 1 and 2 respectively

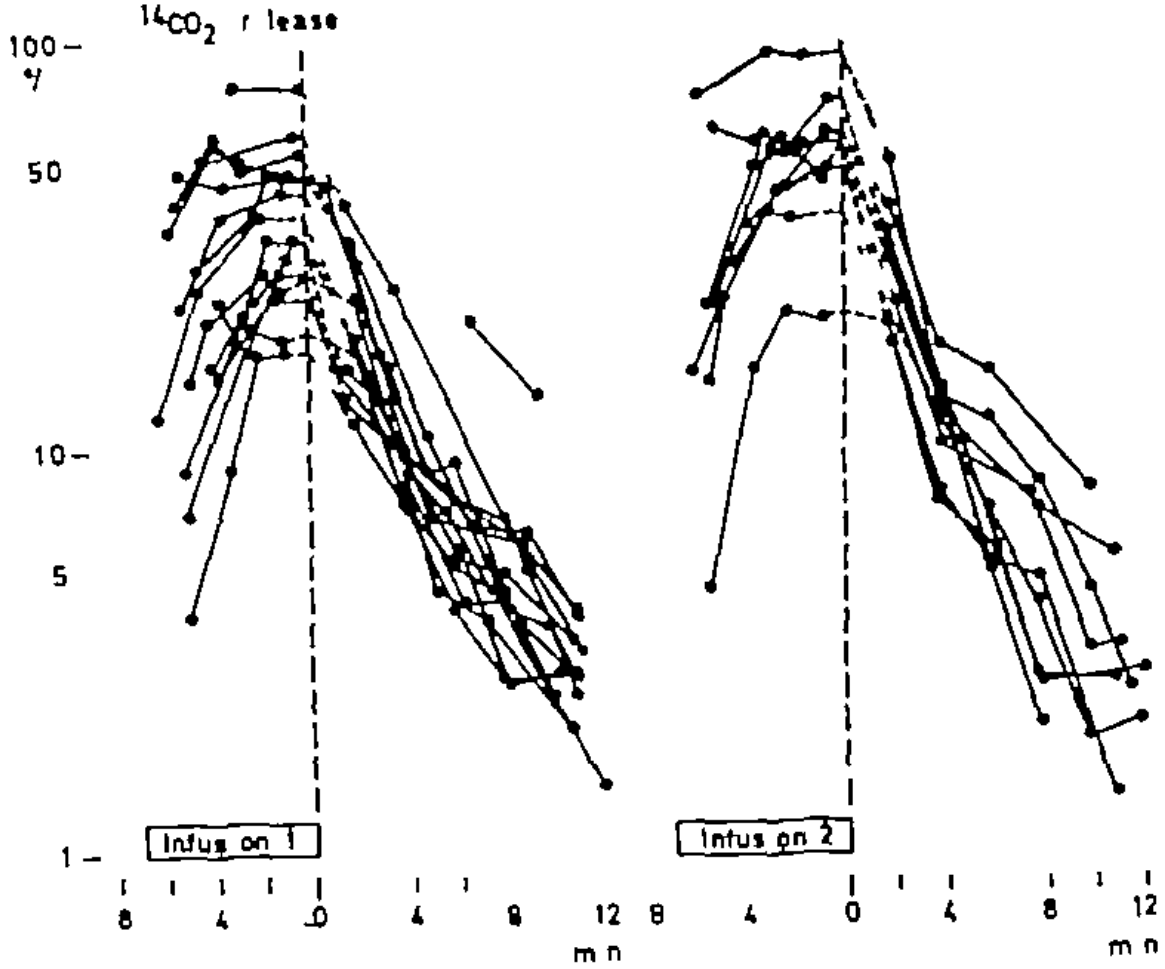

Fig. 10 Semilogarithmic representation of release of CO_2 during and after infusion ex pressed as fraction of the uptake of C-L(+)-lactat t steady stat during infusion Individual lues from infusions 1 nd 2 at normal arterial co centration of total lactat re gi en The calculated fractional oxidation is plotted on the y-axis and joined to the surrounding bser tions by broken lines.

Radioactivity in perchloric acid extract and fat extract of blood

The total content of radioactivity as well as the concentration of ^{14}C-L(+) lactate in a perchloric acid extract (PCA extract) were measured in four of the experiments at the end of and about 1 and 10 min after the infusions. No difference between infusions 1 and 2 was observable as regards the proportion of the total radioactivity in the PCA extracts recovered as ^{14}C-L(+) lactate the results from the two infusions have therefore been combined. During infusion all radioactivity in the PCA extracts in arterial blood was in the form of ^{14}C-L(+)-lactate In venous blood, however other ^{14}C-labelled substances than ^{14}C-L(+) lactate also existed constituting 5—10 % of the total radioactivity in the extract and about 20 % of the simultaneous uptake of ^{14}C-

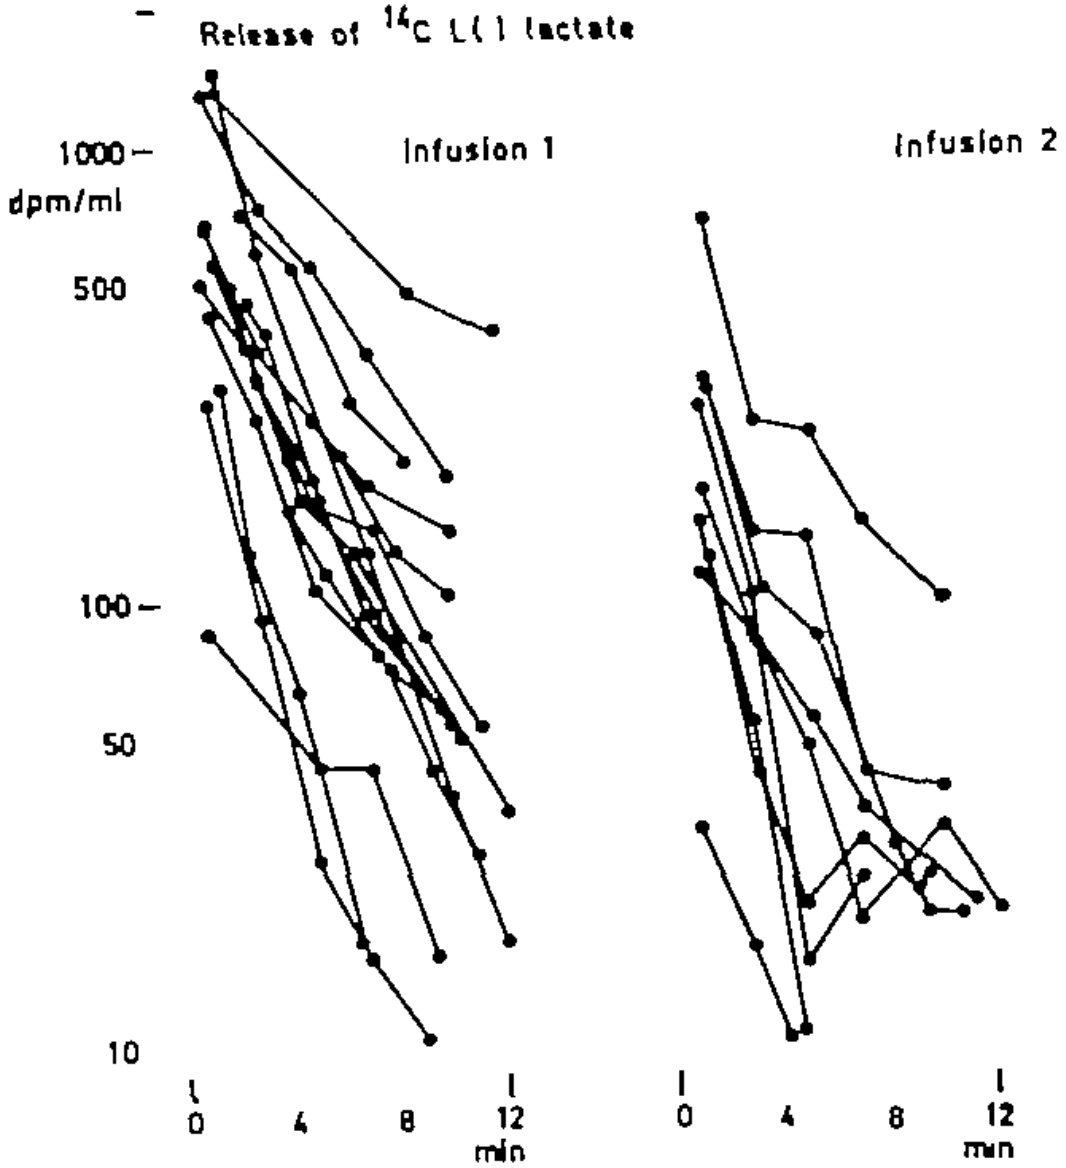

Fig 11. Semilogarithmic representation of release of ^{14}C-L(+)-lactate after infusion. I dividual values from infusions 1 and 2 t normal arterial concentration of total lactate are given.

L(+)-lactate. This finding indicates that about 20 % of the radioactivity from the ^{14}C-L(+) lactate extracted was released in the form of other ^{14}C-labelled metabolites.

One and ten minutes after the infusions ^{14}C-L(+) lactate constituted only about 60 and 50 % respectively of the total content of ^{14}C in PCA extract of arterial blood. The corresponding values for the venous blood were about 10 % higher indicating an uptake of other ^{14}C-labelled PCA-extractable metabolites than ^{14}C-L(+) lactate.

No significant incorporation of C in fat-extractable (Dole and Meinertz 1960) substances in arterial and venous blood was measured (one experiment)

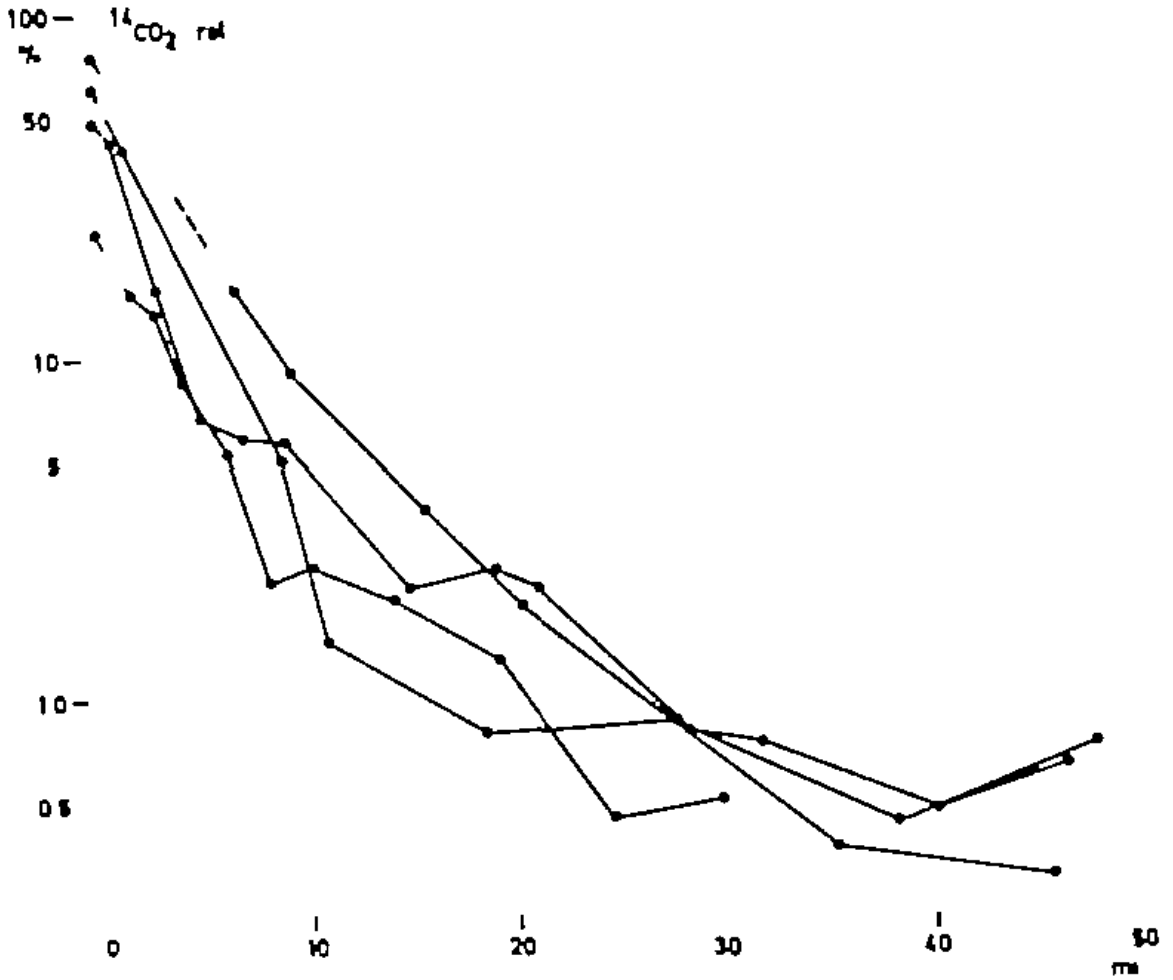

Fig 12 Semilogarithmic representation of release of $^{14}CO_2$ after infusion from the ^{14}C-L (+) lactate ven p by forearm muscle during the infusions. Y_{rf}((a—v) ^{14}C-La)) for the four mples experiments in series 2 are given for explanation see text. The calculated fractional oxidation of the ^{14}C-L(+)-lactat extracted during infusion is plotted and joined to the curves by broken lines.

Rel ase f $^{14}CO_2$ and ^{14}C L(+)-lactate after the infusions of ^{14}C L(+)-lactate (Fig 10 11 12, 13)

The release of CO_2 from the forearm muscles 0—12 min after an infusion of ^{14}C-L(+)-lactate revealed no clearly distinguishable multiphase course when plotted semilogarithmically against time for either of the infusion periods (Fig 10) Within the prolonged observation period in series 2, however the release of $^{14}CO_2$ from the ^{14}C-L(+) lactate taken up by the forearm muscles during the infusions (Y) exhibited a least biphasic course in semilogarithmic plotting against time (Fig 12) The appearance of at least one slow phase supported the assumption that a part of the ^{14}C from the extracted ^{14}C-L(+)-lactate was incorporated into metabolites with a slow turnover rate The quantity of

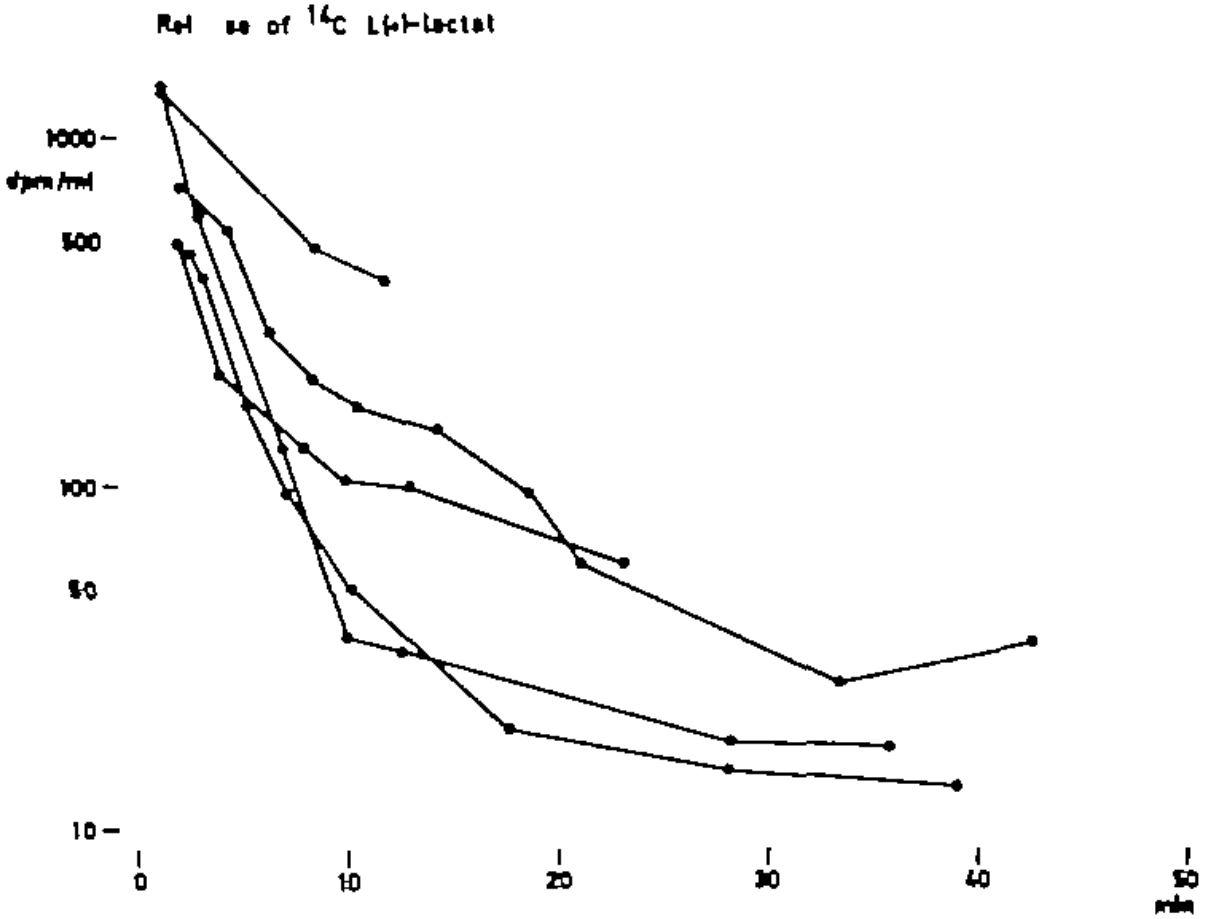

Fig 13 Semilogarithmic representation of release of ^{14}C-L(+)-lactate after infusion. Values from series 2.

$^{14}CO_2$ released corresponding to the slower phase amounted to about 70 % of the ^{14}C-L(+)-lactate taken up by the muscles during the infusion. The latter was calculated as the product of the (a—v) difference of ^{14}C-L(+) lactate at steady state during infusion, the forearm muscle blood flow and the infusion time.

The release of ^{14}C-L(+)-lactate after the infusions exhibited mainly the same course as that of $^{14}CO_2$ and there was no obvious difference in the elimination rate. However in contrast to the conditions for $^{14}CO_2$ there was no (v—a) difference of ^{14}C-L(+) lactate over the left forearm.

Discussion

The forearm as experimental model

In man the forearm muscle offers many advantages for quantitative studies of substrate uptake and utilization. The arterial blood supply of the forearm normally takes place through a single dominating artery the flow of which

can be determined during exercise (Wahren 1966) The part of the flow which goes to the muscles during exercise can also be determined indirectly with sufficient accuracy Furthermore practically pure muscle vein blood can be obtained from deep veins of the forearm (Coles *et al* 1958 Idbohrn and Wahren 1964) after percutaneous catheterization of these veins. Fick s principle can only be applied on the assumption that the sampled venous blood is representative of the entire area to which the blood flow determination related (Zierler 1961) That this may be considered to be the case as regards the oxygen content in the deep venous blood was shown by Wahren (1966) Whether the same applies to lactate and other metabolites is not known As the turnover of lactate is not necessarily associated with oxidative metabolism, a condition shown to be applicable to oxygen cannot unreservedly be extended also to lactate The quantitative calculations concerning lactate turnover in this study in which the blood flow is a variable must for this reason be regarded as approximate

The results as regards blood flow and oxygen uptake during lengthy exercise are entirely in agreement with earlier observations by Wahren and Hagenfeldt (1968) The reason why the forearm blood flow is greater after 40 than after 10 min of exercise is not fully clear but it is of importance for the calculations of rate of uptake and release of metabolites in forearm muscle that the increase in forearm blood flow is not caused by an increased cutaneous blood flow In fact, in a study using ^{133}Xe clearance technique it was shown that no changes of significance took place in the cutaneous blood flow during a 60 min forearm exercise (Jorfeldt and Wahren 1970)

Under the prevailing experimental conditions another type of variation in the forearm blood flow was noted namely random variations during the infusions and thereby at constant rate of infusion, also in the arterial concentration and in the fractional uptake of ^{1} C-L(+) lactate. But nor should this type of variation either have influenced the calculated uptake and release of lactate, inasmuch as the calculations are mean values of at least two determinations.

Release and uptake of lactate

Under the prevailing experimental conditions there was a considerable net release of lactate from forearm muscle The rate of net release was greater after 10 than after 40 min of exercise These results are fully in agreement with earlier observations (Wahren and Hagenfeldt 1968)

The fact that the (a—v) difference of ^{14}C-L(+) lactate attained a constant level during the infusions shows that there is a continuous uptake in muscle of lactate from the blood During the first part of the infusion periods the (a—v) difference of ^{14}C-L(+) lactate fell successively which together with a de-

creasing (v—a) difference after the infusions, suggests that an exchange of lactate takes place between blood and muscle.

Metabolism of lactate taken up

Within 1—2 min after the start of an infusion of ^{14}C-L(+) lactate into the brachial artery a considerable release of $^{14}CO_2$ was measured. This shows that a rapid oxidation of the ^{14}C-L(+)-lactate taken up from the blood occurs in forearm muscle during exercise. At the end of the infusions this oxidation was in equilibrium with the uptake, as is evident from the fact that a constant (a—v) difference was attained in respect both of ^{14}C-L(+) lactate and of $^{14}CO_2$.

After 10 or 40 min of exercise only 38 and 52 % respectively of the radioactivity of the ^{14}C-L(+) lactate extracted was recovered as $^{14}CO_2$. There must therefore be also other metabolic routes for the lactate extracted than by direct oxidation to carbon dioxide. Thus 70 per cent of the labelled carbon from ^{14}C-L(+) lactate was recovered as other PCA-extractable metabolites. No definite release of fat-extractable ^{14}C-labelled metabolites was observed. The remaining discrepancy between uptake of labelled lactate and release of labelled metabolites therefrom can be explained by the fact that, in the studied area in the forearm, a metabolism of ^{14}C-L(+) lactate took place, with incorporation of ^{14}C in one or more metabolite pools with slow turnover. This assumption is supported by the results from series 2, in which the $^{14}CO_2$ release after the infusions from the labelled lactate taken up during the infusions exhibited a least biexponential course. It is possible that the rapid phase is caused by ^{14}C-L(+) lactate, which via pyruvate, is directly oxidized in the tricarboxylic acid cycle, and the slower phase by oxidation of ^{14}C-labelled metabolites from pools with slower turnover.

About 40 % of the radioactivity of the ^{14}C-L(+) lactate extracted during the first infusion period was calculated to have been incorporated into such pools of metabolites with slow turnover rate. However, the ^{14}C recovered as $^{14}CO_2$ corresponding to the slow phase of the $^{14}CO_2$ release after the infusions was only approximately 20 %. The fate of the remaining 20 % of the ^{14}C is unclear. It cannot be excluded however that there was another slow phase of the $^{14}CO_2$ elimination which was not detected.

The experiments and their results offer no means of directly assessing which metabolites were labelled with ^{14}C from the ^{14}C-L(+) lactate extracted. Incorporation of ^{14}C in glycogen and a muscular triglyceride pool may be regarded as conceivable possibilities. This presupposes an exchange of ^{14}C upstream in the glycolysis, either through a reversal of the pyruvate kinase reaction or through the dicarboxylic acid shuttle. The first alternative seems to be relevant for skeletal muscle (Lardy and Ziegler 1945, Krimsky 1959, Utter

1959) but muscle seems to lack the enzymatic requirements for the latter alternative (Utter 1959 Salas *et al* 1964) The possibility of labelling of ^{14}C in skeletal muscle glycogen from ^{14}C-pyruvate and ^{14}C-L(+) lactate has been demonstrated in animal experiments (Hlatt *et al.* 1958 Koeppe *et al.* 1964) Enzymatic conditions exist for ^{14}C-labelling of the glycerol fraction of the triglycerides. Hagenfeldt and Wahren (1968) have suggested that some esterification of FFA in forearm muscle probably takes place during exercise and that oxidation of glycerol occurs in muscle.

The significance of white and of red muscle fibres

It should be observed that the results are summation values from the various units within the part of the forearm muscle which is drained by the catheterized deep forearm vein The bulk of the contraction work during this type of exercise is performed by the flexor muscles while other muscle groups probably perform static work for fixation of the forearm. Under the prevailing conditions the part of the forearm muscle concerned is probably fairly heterogeneous, not only between but also within the individual muscles and uptake of lactate fractional oxidation of extracted ^{14}C-L(+) lactate and net release of lactate may presumably shift between the units. Of interest in this connection is the simultaneous occurrence of red and white muscle fibres within an individual muscle The white fibres and certain glycolytically active red fibres are activated chiefly at the start of submaximal exercise (Kugelberg and Edström 1968, Grimby and Hannerz 1968) This may explain the considerable net release of lactate at the start of the exercise period. The greater part of the lactate uptake and the oxidation of the extracted lactate however probably take place in red muscle fibres which are adapted for a more significant oxidative metabolism (Keul, Doll and Keppler 1969) The possible significance of red and white muscle fibres is discussed in greater detail in Chapter IV

CHAPTER III D

Uptake, Release and Metabolism of Lactate at Elevated Arterial Lactate Concentration

At high arterial concentrations of lactate there may be a net uptake of lactate in exercising muscle (Stainsby and Welch 1966 Freyschuss and Strandell 1967) The present study was performed in order to determine to what extent the uptake, release and fractional oxidation of lactate in forearm muscle are influenced by the arterial concentration of total lactate.

Subjects

The results in this chapter are based on data from six volunteers aged 21—27 years. They were all healthy firemen who had gone through regulated health checks. Arm dimensions of the subjects are given in Table 6.

Procedure

The studies were made in the morning after the subjects had fasted for at least 12 hours. The right forearm was used in all cases. Catheterization was done in the same way as in the studies reported in Chapter III-C. Roughly 30 min before the start of exercise an infusion of unlabelled hyperosmotic sodium lactate was commenced through a catheter placed with the tip in the upper vena cava (see Chapter III A) Before the infusion a priming dose of about 15 mmoles was given, and thereafter about 3.5 mmoles/min was infused until the end of exercise. Unless otherwise stated, the procedure during the exercise and for the calculations was identical to that described for series 1 in Chapter III-C.

Control studies

Three preliminary experiments with constant intravenous infusion of sodium lactate after a priming dose showed that a constant arterial lactate level had been reached after about 30 min. This is in agreement with earlier studies (Fiorentini and Faini 1967) In the subsequent experiments with ^{14}C-L(+)

and fractional oxidation of lactate, the brachial artery blood flow and the metabolism of exercise. The probability that the difference between infusions 1 and 2 (p_{1-2}) and between rated arterial concentration of total lactate was caused by random factors is given. The $\dot{Q}_{O_2}$ = forearm muscle oxygen uptake $\dot{Q}_{CO_2}$ = forearm muscl production of CO_2. For

lactate, therefore, the exercise period was not started until after 30 min of Lv lactate infusion.

Two control experiments were made in order to see whether the rising bicarbonate concentration following on the combustion of the sodium lactate in the body (Schwartz 1962) affected the release, uptake and fractional oxida

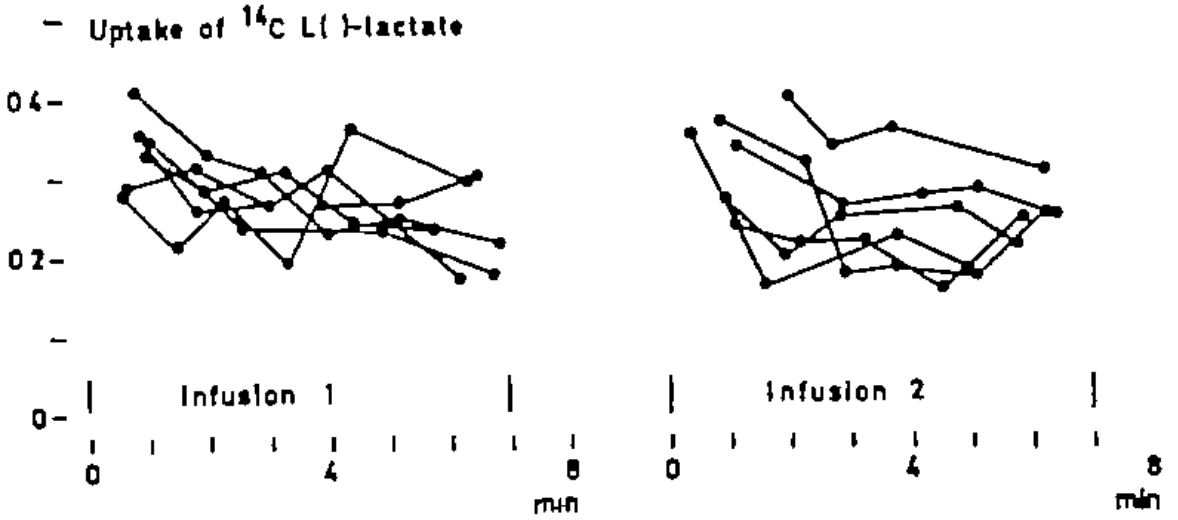

Fig 14 Uptake of ^{14}C-L(+) lactat during infusion expressed as fraction of th arterial concentration of ^{14}C-L(+) lactat I dividual values from infusions 1 and 2 at increased arterial concentration of total lactate re gi ven.

tion of lactate in forearm muscle during exercise as at diffusion equilibrium the ratio between intra and extracellular concentrations of lactate and bicar bonate may be assumed to be the same (Jacobs 1940 Granholm *et al.* 1968) Two identical experiments were made on each of two subjects with 1 hour s interval. Apart from the intravenous lactate infusion, each experiment was identical to the first half of the experiments in series 1 During the period of rest between the tv o experiments sodium bicarbonate was infused intravenously (roughly 100 meq) The infusion was adjusted so that in the second exer cise period the subjects had roughly the same bicarbonate concentration in plasma as in the experiments with infusion of sodium lactate (mean value for standard bicarbonate 30 0 and 29 0 meq/l respectively) The results showed no obvious difference between the two periods of exercise in respect of rate of net release of lactate (mean 0 29 and 0 25 mmoles/min, respectively) fractional uptake of ^{14}C-L(+) lactate (mean 31 and 36 % respectively) and fractional oxidation of ^{14}C-L(+) lactate (mean 53 and 55 % respectively)

Results

All statistical comparisons between 10 min of exercise (infusion 1) and 40 min (infusion 2) are based on intraindividual comparisons of the respective varia bles. In the comparisons between results obtained at normal (Chapter III-C) and elevated arterial lactate concentration the results for oxygen consumption and fractional uptake of ^{14}C-L(+) lactate from 10 and 40 min of exercise have been combined since no significant difference existed between the two in fusions in any of the investigations.

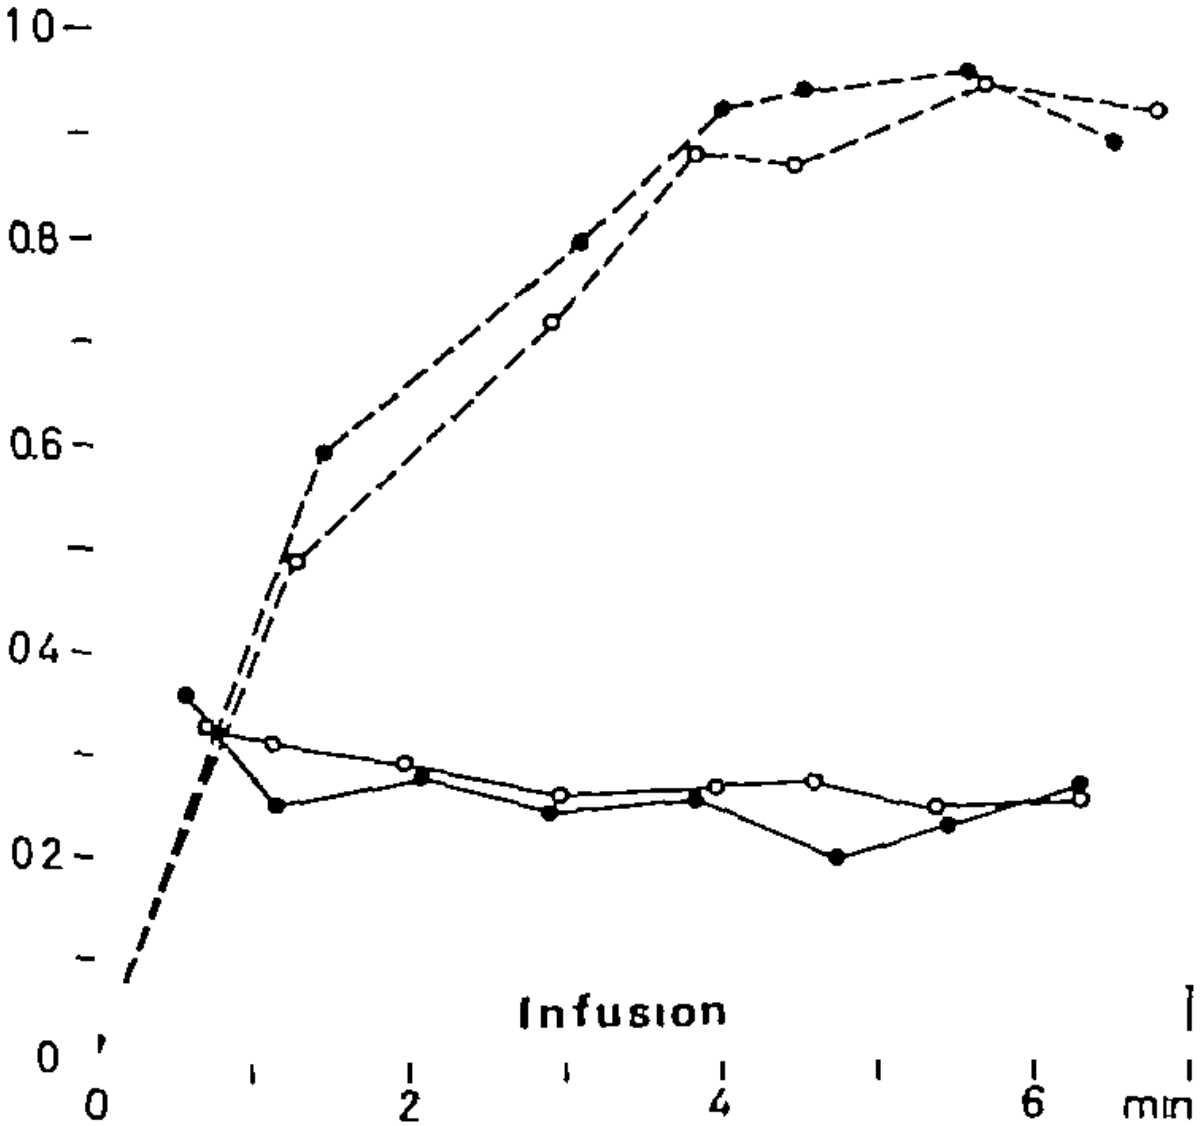

Fig. 15. Uptake of ^{14}C-L(+)-lactate during infusion, expressed as fraction of the arterial concentration of C-L(+)-lactate (○—○, ●—●) and release of $^{14}CO_2$, calculated as fraction of the release at steady stat during the infusion period (○- -○, ●—●) Mean values from infusion 1 (○—○ ○- -○) and infusion 2 (●—● ●--●) t increased arterial concentration of total lactate are given. This figure shows that the uptake of ^{14}C-L(+)-lactate and the production of $^{14}CO_2$ normally reached constant level during the infusions.

Muscle blood flow and oxygen uptake (Table 7)

No significant difference existed between 10 and 40 min as regards the calculated *muscle blood flow* Combining the results from 10 and 40 min, the calculated muscle blood flow was negatively correlated ($r = -0.75^{**}$) to the arterial hemoglobin concentration. In this series no correlation was found between the muscl blood flow and the variability in exercise pattern. The oxygen (a—v) difference was less ($p<0.05$) at 40 than at 10 min. The difference between the 10th and 40th minute as regards *oxygen consumption* in forearm muscle was, however not significant. The oxygen consumption in forearm

mu s le was significantly lower ($p<0.01$) in these experiments than at normal rterial lactate concentration.

Releas f lactate and pyruvate (Table 7)

The lactate concentration in the arterial blood was the same (3.4±0.5 mmoles/l) after 10 and 40 min exercise. The *rate of net release of lactate* was not significantly different at 10 as compared to 40 min of exercise. In two cases in which the arterial lactate concentration was greater than 4 mmoles/l a net uptake of lactate was recorded (1 after 10 min and 1 after 40 min). After 10 min of exercise both the net release and the rate of net release of lactate were lower ($p<0.05$) in this series than in the studies at normal arterial lactate concentration. No significant difference on the other hand existed in these respects after 40 min of exercise. After about 55 min of exercise a *net uptake of*

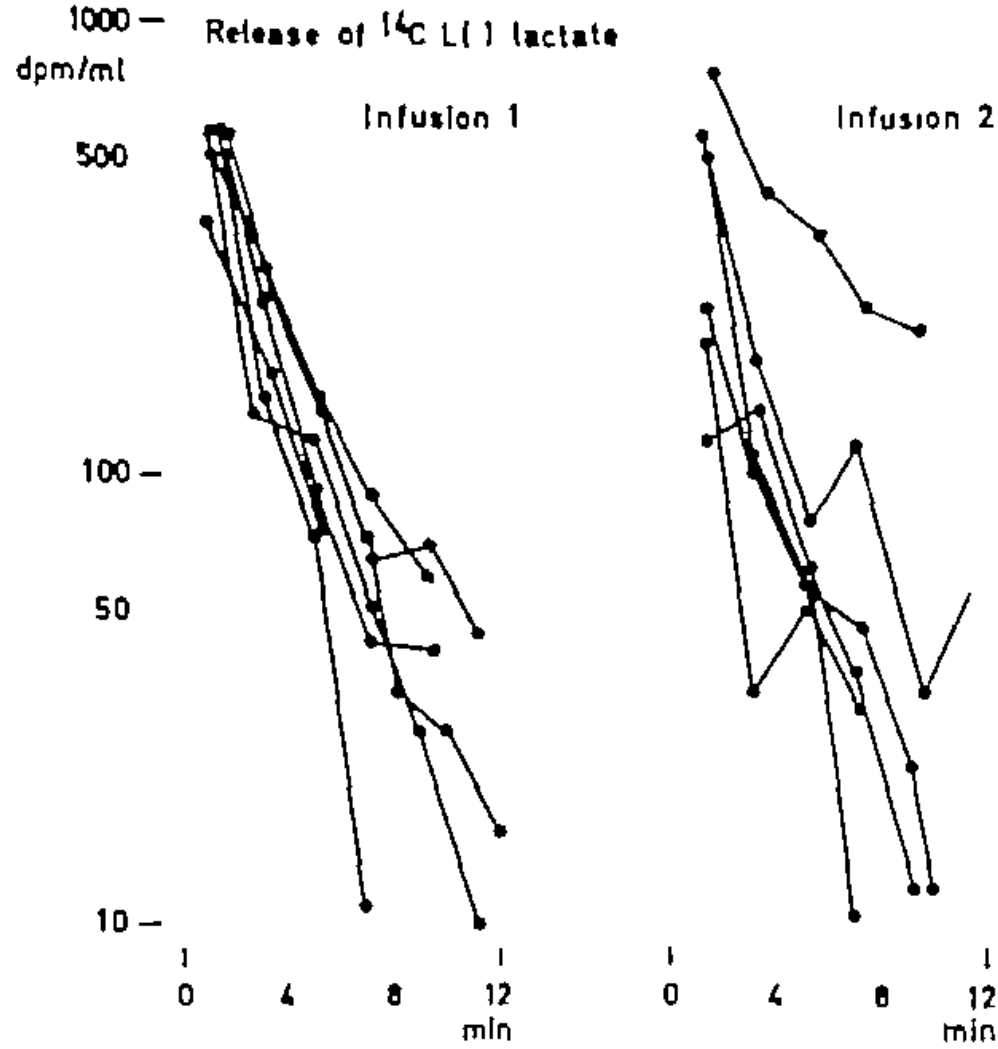

Fig 17 Semilogarithmic representation of release of C-L(+)-lactate after infusion. Individual values from infusions 1 and 2 t elevated arterial concentration of total lactate are given.

lactate (mean 0 09 ± 0 16 mmoles/l) was measured in all subjects. For pyruvate a net uptake was measured in two cases after 10 min and in two further cases after 40 min.

Uptake of lactate (Fig 14 15 Table 7)

In this series, as in the study at normal arterial lactate concentration, the *fractional uptake of* ^{1} *C I (+)-lactate* reached a constant level after about 4 min of infusion both in infusion 1 and in infusion 2. The fractional uptake of ^{14}C-L(+) lactate was the same in both infusions but significantly lower ($p < 0.01$) than at normal arterial lactate concentration. No significant difference between 10 and 40 min of exercise existed in respect of *uptake of lactate* or *rate of lactate uptake*. Both variables were positively correlated to the arterial

lactate concentration and the muscle blood flow there was an apparently linear relation ($r = 0.92^{***}$ $n = 36$) (Fig 19) The maximal rate of lactate uptake calculated from the y-intercept was 0 65 mmoles/min, which corresponds to approx. 0 08 mmoles $\times$ min $^{-1} \times 100$ ml $^{-1}$ muscle This value was calculated for an estimated muscle fraction of 0 6 of the forearm volume (Abramson and Ferris 1940 Cooper Edholm and Mottram 1955)

The fractional oxidation of the extracted lactate was negatively correlated ($r = -0.65^{***}$ $n = 36$) to the fractional uptake of ^{14}C-L(+) lactate The net release of lactate from forearm muscle was positively correlated ($r = 0.55^{**}$ $n = 36$) to the oxygen uptake

Discussion

For assessing the metabolic effects in forearm muscle of the artificially elevated arterial lactate concentration it must be noted that a high arterial lactate concentration probably affects the supply of other blood-borne substrates to the muscles. Issekutz *et al.* (1965) in experiments on dogs showed that an infusion of sodium lactate of the same relative magnitude as in this study results in a pronounced lowering of the plasma concentration of FFA and in a reduction of the rate of oxidation of FFA and glucose in plasma. In contrast to these findings Svedmyr (1966) found in man a slight elevation of the plasma concentration of FFA on infusion of sodium lactate The rate of infusion used by him, however produced a slightly less pronounced rise of blood lactate than in the present study The abovementioned factors however have presumably been of subordinate importance in the present experiments, as the same RQ was measured at ordinary and elevated lactate concentration after 40 min of exercise It is noted, however that the methodological errors in the RQ determinations are of such magnitude that minor deviations between the relative proportions of the various substrates in the total oxidation cannot be detected. The lower oxygen consumption at elevated arterial lactate concentration may possibly be interpreted as a sign that the carbohydrate oxidation constituted a greater proportion of the oxidative metabolism since the energy recovered per mole oxygen is somewhat greater in carbohydrate oxidation than *in fat oxidation*.

The results permit no conclusions concerning the mechanism underlying the lower net production of lactate in forearm muscle at elevated arterial lactate concentration. The following explanations, however may be conceivable

1) In muscle fibres with a net production of lactate the intracellular lactate concentration must rise in step with the arterial in order that an outward directed diffusion gradient may be maintained The high intracellular lactate

concentration which thus arises may conceivably inhibit the formation of lactate through one or more feedback processes.

2) Red muscle fibres, which appear to have the morphological and enzymatic prerequisites for utilization of exogenous lactate (see Discussion in Chapter IV) take up a quantity of lactate which in analogy with the myocardium (Goodale, Olson and Hackel 1959) is related to the arterial lactate concentration

The latter alternative appears to be the most probable explanation of the net uptake of lactate recorded after 55 min of exercise

The rate of lactate uptake rose with increased supply of lactate to the muscles. The curvilinear relation between these variables may indicate the existence of saturation kinetics. Whether the rate limitation is caused by a limited rate of transport for lactate through the cell membrane or a limited rate of metabolism of the extracted lactate cannot be definitely decided solely on the basis of the present results. Other investigations of the difference of concentration of lactate between skeletal muscle and blood in dog (Karlsson, Personal communication) and of the lactate transport conditions in hypothermal myocardium (Kübler *et al.* 1966) suggest that the rate of lactate transport through the cell membrane is restricted. Nor solely on the basis of the present results, can one draw any definite conclusions concerning the negative regression of the fractional oxidation of extracted lactate on the fractional lactate uptake. A conceivable mechanism is that, in the tricarboxylic acid cycle, the rate of direct oxidation of ^{14}C-L(+)-lactate taken up was mainly constant and that the surplus ^{14}C-L(+) lactate extracted was metabolized by other means. Further investigations are required, however to cast more light on these conditions.

CHAPTER IV

General Discussion

The use of labelled lactate enables a study to be made of the metabolism and turnover of lactate in the body as a whole and in individual organs and tissues. The rate of turnover of lactat is high however and incorporation of the label into other metabolites occurs rapidly It is therefore necessary in studies of this type to make use of a specific method of analysis for labelled lactate. The method described in this study has proved well adapted for studying the lactate turnover in forearm muscle during exercise. The recovery obtained by this method is not affected by th total lactate concentration in blood within physiological limits and the method hould therefore be usable also in turnover rate studies during physical exercise or in conditions of pathologically elevated lactate concentr tion. The necessity of a specific method of analysis for these studies is illustrated by the results reported in Chapter III-C. During a 5—10 min period of infusion of L(+)-lactate-1 ^{14}C into the brachial artery it was found that about 10 % of the radioactivity in the venous blood coming from the working muscles was incorporated into other non-volatile metabolites than labelled lactate Immediately after the infusion the corresponding value for arterial blood was about 50 %. In the light of the foregoing statements the assumption that all radioactivity in the blood after infusion of ^{14}C-L(+) lactate ith the exception of ^{14}CO consists of ^{14}C-L(+) lactate (Drury Wick and Morita 1955) must be regarded as an approximation.

The results of this study show that an exchange of lactate betwern the blood and skeletal muscle during exercise takes place in both directions and that the exogenous lactate is partly catabolized in muscle, inter alia to CO_2. These in vivo studies on man confirm earlier results from animal experiments (Drury and Wick 1956 Omachi and Lifson 1956) The net release of lactate from forearm muscle falls successively during prolonged exercise, whereas the lactate uptake appears to be independent of the length of the exercise period but dependent on the arterial lactate concentration. A possible explanation of this circumstance may be that the individual muscles are made up of red and white fibres which have different metabolic patterns (for survey see Keul Doll and Keppler 1969) The white fibres have a large content of glycogen and high activity of glycolytic enzymes. Their LDH is of M type, which has a high pyruvate to-lactate reducing activity even at high pyruvate concentrations (Daw

son, Goodfriend and Kaplan 1964) These fibres are thus adapted for resynthesizing their ATP to a large extent through glycolysis, with consequent production of lactate. The red fibres on the other hand are adapted for resynthesizing ATP chiefly through oxidative metabolism. They have an abundant capillary network, high myoglobin content, numerous mitochondria and high activities of the enzymes which are essential for complete oxidation of carbohydrates and free fatty acids. Their LDH is of H type, i.e. the same type as in heart muscle. This LDH is inhibited by pyruvate, thus favouring oxidation of the pyruvate in the tricarboxylic acid cycle (Dawson Goodfriend and Kaplan 1964)

In a study of the anterior tibial muscle of the rat Kugelberg and Edström (1968) were able to distinguish, apart from white fibres (A fibres) two types of red fibres (B and C fibres) According to these authors there are no pronounced differences in glycogen content between A B and C fibres. On the other hand they found a difference in glycogen breakdown on stimulation, the breakdown being very rapid in A fibres, rapid in B and apparently non-existent in C fibres. The B fibres thus have a significant anaerobic as well as aerobic metabolism and from this aspect are an intermediate form between A and C fibres. The same authors showed that a motor unit consists of only one kind of fibres, phasic units of white fibres, tonic units of red fibres. The recruitment of the motor units varies with time. In a study of the anterior tibial muscle of man Grimby and Hannerz (1968) found that, on rapid contraction of a resting muscle, a group of motor units (A units) is initially activated but on continued contraction is quickly relieved by another group (B units) On rapid contraction of a muscle which has recently been active, a direct activation of B units takes place. On prolonged isometric contraction these authors saw in some cases an activation of an additional unit (C unit)

These circumstances offer a conceivable explanation of the process of lactate release from the muscle during exercise. The very early release of lactate from the forearm muscles on changing from total rest to exercise (Pernow and Wahren 1962) may possibly be due to activation of A fibres. On continued intermittent exercise at submaximal level these fibres are probably not activated. But if the work intensity exceeds a given level, a reactivation of A fibres may conceivably take place. In such case this may contribute to the rapid rise of blood lactate at work intensities exceeding 75 % of maximum (Hermansen and Saltin 1966) and to the marked rise of lactate production in forearm muscle when the work intensity is increased from 5 to 10 kpm/min (Wahren 1966) The marked lowering of the rate of net release during prolonged exercise as found by Wahren and Hagenfeldt (1968) and verified in the present study may possibly be explained by a successive emptying of the glycogen con

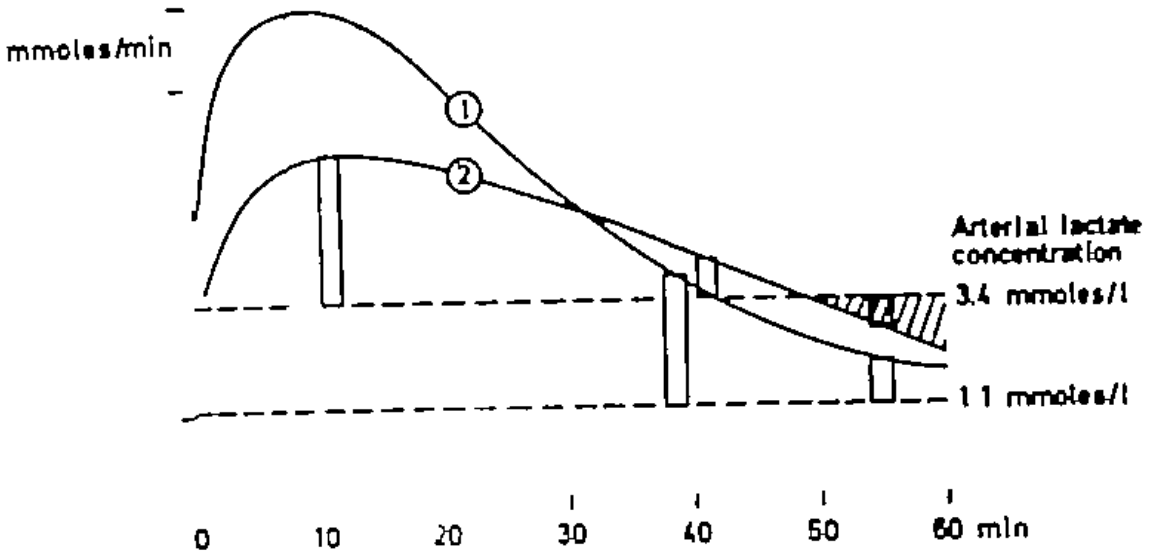

Fig 20 Schematic representation of rates of lactate uptake (— — —) net release (open brackets) or net uptake (shaded area and bracket) and calculated total production (——) during exercise at normal (1) and elevated (2) arterial concentrations of total lactate.

tent of the glycolytic fibres (cf Saltin and Hermansen 1967) and/or non activation of these fibres with successive changeover to C fibre activity The immediate oxidation of the lactate taken up in forearm muscle during exercise probably takes place mostly in red fibres. This assumption is confirmed by results of in vitro experiments in non-stimulated muscle which showed that the quantity of lactate 1 ^{14}C recovered as $^{14}CO_2$ was greater for red than for white muscle (Bär and Blanchaer 1965) Furthermore the LDH in the red fibres is better adapted for oxidation of lactate to pyruvate than the LDH in the white fibres. It may be assumed that in some of the red fibres, in conformity with the condition in the heart muscle (Goodale Olson and Hackel 1959 Keul *et al* 1965) a net uptake of lactate takes place which is related to the arterial lactate concentration. Whether the part of the ^{14}C-L(+) lactate uptake which is not immediately oxidized is metabolized preferentially in red or white fibres cannot be decided. In vitro studies indicate that the incorporation of ^{14}C in glycogen from DL-Lactate 1 C is equal in red and white muscle (Bär and Blanchaer 1965) These circumstances suggest that the relation between release and uptake of lactate differs in the different types of fibres. Some uptake of lactate, as determined in this study may however take place in all cells with an intracellular lactate turnover

A conceivable interpretation of the findings of simultaneous uptake and release of lactate in forearm muscle is illustrated in Fig 20 At a normal arterial lactate concentration (curve 1 Fig 20) the rate of production is greater than

the rate of uptake, so that a net release of lactate is recorded during the entire period of exercise. The successively diminishing rate of net release during the exercise reflects a reduced lactate production. At a higher arterial lactate concentration (curve 2, Fig 20) the rate of lactate uptake is increased. In this case, too the rate of production is greater than the rate of uptake during the greater part of the exercise period, so that a net release of lactate is recorded. At the end of the exercise period however the rate of lactate production within the forearm has fallen to so low a level that it is less than the rate of uptake and therefore a net uptake is recorded.

The fact that it would seem that a rapid exchange of lactate can take place across the cell membrane, and that the histological picture shows a close contact between red and white fibres (Kugelberg and Edström 1968) makes it possible that lactate released by white fibres can be partially taken up and oxidized by red fibres.

The rate of lactate uptake was better correlated to the product of the arterial lactate concentration and the muscle blood flow than to the arterial lactate concentration alone A possible explanation of this circumstance may be that a larger blood flow implies a larger open capillary surface and therefore more favourable conditions for uptake of lactate. This finding fits in with earlier investigations by Rämmal and Ström (1949) and Freyschuss and Strandell (1967) who at elevated blood lactate level, showed that the lactate utilization in the body was more rapid and the calculated rate of uptake of lactate in the legs greater respectively when the subjects were performing light leg exercise than at rest. The rapid exchange of lactate found between blood and skeletal muscle and the fact that under certain conditions a net uptake of lactate occurs in working skeletal muscle indicate that the skeletal musculature, which represents about 40 % of the body weight (Andres, Cader and Zierler 1956) may have a quantitative significance for the lactate catabolism in the body

CHAPTER V

Summary

The uptake and release of lactate in forearm muscle has been studied in young healthy volunteers at different times during prolonged exercise at both normal and artificially elevated arterial lactate concentration. *L(+) lactate-1 ^{14}C* has been used as tracer substance. An enzymatic method for determination of ^{14}C-L(+) lactate has been evolved.

1 *Method of analysis*

The lactate in a perchloric acid extract of blood is oxidized to pyruvate by using LDH and with NAD as proton acceptor. Hydrazine sulphate binds the pyruvate produced. After adjustment of the pH and addition of phenylhydrazine hydrochloride and pyruvate as carrier the pyruvate is precipitated as phenylhydrazone, washed, filtered off and the radioactivity counted in a liquid scintillation counter. A blank is analysed in an identical way but without LDH and NAD. The difference in radioactivity is considered to originate from *L(+)-lactate* since the *LDH* used is specific for that stereo-isomer. The recovery is 85.2 ± 4.0 (mean ± SD) and the coefficient of variation 2.8 % and 7.2 % at more than or less than 1000 dpm/ml blood respectively.

2. *Metabolic studies*

The subjects performed during 60 min a rhythmic, isotonic forearm exercise on a hand ergometer at a work intensity of 10 kpm/min and with one contraction per sec. Six subjects were given an intravenous infusion of sodium lactate, whereby an arterial lactate concentration of about 3.5 mmoles/l was obtained during the entire investigation. The forearm blood flow was determined by indicator dilution technique with continuous infusion of dye, which also contained the radioactive lactate.

The net release of lactate was higher after 10 min of exercise than after 40 min. If the exercise was performed at an elevated arterial lactate concentration the net release was lower and at the end of the period of exercise, changed to a net uptake. Simultaneously with the net release there was an uptake of lactate in forearm muscle. The uptake was the same at 10 and 40 min and amounted to 31 and 23 % respectively of the arterial lactate at normal and elevated arterial lactate concentration. The results indicate that a rapid ex

change of lactate takes place in both directions between blood and muscle. Only 30—50 % of the ^{14}C-L(+) lactate taken up in the muscles underwent immediate oxidation to $^{14}CO_2$. About 20 % was released from the muscle in the form of other metabolites. The release of $^{14}CO_2$ after the infusion of ^{14}C-L(+) lactate exhibited a biexponential course, which indicates that the remainder of the lactate uptake was incorporated into pools with slow turnover. The rate of lactate uptake has been best correlated to the lactate inflow into the muscle expressed as the product of blood flow and arterial lactate concentration, and the relation indicates a saturation kinetics mechanism for the uptake of lactate.

Acknowledgements

First of all I wish to express my gratitude to my teacher Associate Professor Bengt Pernow M.D for stimulating discussions and constructive criticism of the planning of the experiments and in the preparation of the manuscript, and for all other ways in which he facilitated this investigation.

I also wish to express my deep gratitude to

Assistant Professor John Wahren. M D for stimulating discussions and constructive criticism in the preparation of the manuscript, and whose previous work in this field has been of guidance

the entire staff at the Department of Clinical Physiology for their generous and skilful assistance in the collection, analysis and presentation of the data

Associate Professor Rolf Blomstrand, M.D for generous supply of laboratory resources and for valuable discussion of different chemical problems

Assistant Professor Lars Hagenfeldt, M.D for performing the gas radiochromatographic analyses

Assistant Professor Gunnar Carlberger M.D for valuable help with problems concerned with the liquid scintillation technique

Mr John Hogg who kindly translated the text.

Last but not least I wish to thank all the volunteers who willingly underwent the sometimes unpleasant experiments

The study has been supported by grants from Karolinska Institutet, which are gratefully acknowledged.

I INTRODUCTION

It is generally accepted that the brain is one of the tissues of the body which is most sensitive to a deficiency of its blood supply (for review see Mollwain 1966) This is due to the fact that the tissue has a high resting energy consumption and relatively low reserves of substrates and of high energy compounds Under normal circumstances the tissue utilizes glucose as the main substrate and the high energy consumption requires that the glucose is fully oxidated. Thus when oxygen is deficient the energy yield from glucolysis is insufficient both for the function of the tissue and for the maintenance of its structural integrity The tissue reserves of substrate (glucose and glycogen) and of high energy compounds (phosphocreatine and ATP) are sufficient to support function for only a few minutes and a complete interruption of the circulation will very quickly lead to irreversible tissue changes If the circulation is impaired but not abolished survival will be prolonged but the increased glucolysis and the ensuing lactacidosis will by itself represent a threat to the tissue

The brain possesses efficient mechanisms which adjust its blood supply relative to the needs of the tissue The blood flow is determined primarily by two factors i.e. the driving perfusion pressure and the vascular resistance An increased metabolic demand may through locally situated regulatory mechanisms, elicit a vasodilation which results in an appropriate cerebral blood flow A more dramatic vasodilatation however may occur in situations which are accompanied by decreased perfusion pressures In these situations it will depend upon the efficiency of the flow regulation if the brain may be saved from hypoxic injury

Variations in the cerebrospinal fluid (CSF) pressure – a commonly occurring phenomenon in intracranial diseases (see Lundberg 1960) – represent a potential threat to the cerebral circulation primarily and to the energy metabolism of the tissue secondarily While a decrease in CSF pressure has been said to provoke various vascular changes (arteriolar constriction local arterial vasospasms dilation of subarachnoid veins) and clinically been considered of importance ("intracranial hypotension syndrome" see Schaltenbrand 1940 Sarteschi 1951 Shenkin and Fimeson 1958) its effect on cerebral blood flow (CBF) has not been evaluated experimentally A considerable interest however has been focused on the effect of an increase in CSF pressure on CBF In such a situation the cerebral perfusion pressure is decreased pari passu with the increase

of pressure in the collapsible subarachnoidal veins occurring simultaneously to the increase in the CSF pressure and maintenance of the cerebral blood flow becomes dependent upon dilatation of the resistance vessels There is a great number of studies of the effect of an increased intracranial pressure on cerebral blood flow and cerebral function (for review see Paper I Langfitt 1968 Zwetnow 1966)

The clinical studies performed have indicated that the cerebral vessels can autoregulate when the intracranial pressure is increased but the quantitative data obtained have been somewhat conflicting Thus Kety et al (1948) showed that in patients with brain tumors the cerebral blood flow decreased when the intracranial pressure exceeded about 450 mm H_2O On the other hand Ryder et al, (1951) as well as Greenfield and Tindall (1965) showed that cerebrospinal fluid pressure could be increased acutely to 1000 mm H_2O before clinical symtoms appeared or before the cerebral blood flow decreased. The differences in results between these studies may be due both to the duration of the intracranial hypertension and to the nature of the processes leading to the hypertension since these may well interfere with the normal regulation of the CBF

It is to be expected that the quantitative relations between the intracranial pressure and the cerebral blood flow can be better evaluated in animal experiments There are a number of qualitative and semiquantitative studies showing that cerebral vasodilation occurs when the cerebrospinal fluid pressure is increased (Wolff and Forbes 1928 Wolff and Blumgart 1929 Fog 1934 Ludwigs and Wiemers 1953 see also Heiskanen 1964 and Langfitt 1968 for review) and it has also been shown that restitution of a normal CSF pressure is followed by a shortlasting increase of the flow above the control values ("reactive hyperemia" see Noell and Schneider 1948) However in spite of information of this type from a number of studies quantitative data have been lacking defining the level of CSF pressure which leads to a decrease of flow and no study has been made of the effects of intracranial pressure upon the cerebral energy metabolism

The present study is an attempt to assess quantitatively the influence of an increased CSF pressure on the cerebral blood flow both during and after the hypertension (Papers I and II) as well as on the energy metabolism of the tissue The latter was studied by analysing lactate pyruvate and bicarbonate concentrations in brain tissue (Papers IV and V) and in CSF (Paper III) as well as the tissue concentrations of phosphocreatine ATP ADP and AMP (Papers IV and V) The results of the studies will be presented by considering first the relation between the CSF pressure and the cerebral blood flow and then the relation between the CSF pressure and the cerebral energy metabolism

II THE EFFECTS OF INCREASED CSF PRESSURE ON CEREBRAL BLOOD FLOW

The influence of experimental increases in the CSF pressure on the cerebral blood flow (CBF) of dogs was studied in Papers I and II which also contain details of different experimental procedures and techniques CBF measurements were also carried out in several experiments in papers III and IV and served the purpose of defining the cerebral circulatory state of the animals in which chemical analyses were made of cerebral energy metabolism

a Methodological considerations

With the method used for increasing the CSF pressure (P_{CSF}) a generalized increase of the intracranial pressure (ICP) was produced as shown in Paper I This generalized increase in pressure may be of importance when evaluating the effects on flow since it has been found (Langfitt et al, 1965 Huber et al 1965 Baldy-Moulinier and Frerebeau 1968 Easton and Pálvölgyi 1968) that if the method used for increasing the pressure gives rise to local pressure effects autoregulation may be absent (see below) or deficient The method also allows the intracranial pressure to be almost instantaneously raised and to be accurately controlled even during longlasting experiments However since an increased CSF pressure usually leads to an increased absorption of CSF (see Davson 1967 Andersson and Löfgren 1965) there will be a flow of artificial CSF over the convexities of the hemispheres allowing a diffusion of ions into the intercellular spaces of the brain (Rall Oppelt and Patlak 1962 Fencl Miller and Pappenheimer 1966) It was thus possible that vascular or metabolic effects would be elicited by the artificial CSF per se if it differed in composition from that of the native CSF However in all instances the potassium magnesium calcium and bicarbonate concentrations of the artificial CSF were very close to those of dog CSF in the control state Moreover control experiments with infusion of dextrane blood or CSF from a donor dog into the cisterna magna did not significantly influence the reactive hyperemia elicited by increased intracranial pressure under otherwise comparable conditions (Paper II)

The CBF method used (Lassen et al. 1963 see also Höggendal et al 1965) is based on the tissue clearance of an inert gas – xenon^{133} or krypton^{85} – injected into the vertebral artery The method requires only moderate surgical preparation and no blood sampling thus restricting the traumatic influence on the cerebral vascular bed to a minimum It allows repeated measurements at intervals of 10 – 15 min to be made but since it requires a steady state with regard to flow during this period rapid changes in flow are difficult to assess quantitatively

The CBF values varied from animal to animal probably chiefly due to a biological scatter In the particular animal however a virtual constancy in flow was found when induced CSF pressure levels of different heights were kept unchanged for hours Thus using each animal as its own control the study of CBF under the defined steady state conditions of pressure and flow was considered fully possible (for accuracy of flow method see Höggendal 1965)

In all experiments CBF was estimated from the fast component of the clearance curve The values thus represent cortical flow mainly (Lassen et al 1963 Höggendal et al 1965) In addition total cerebral blood flow was also calculated in all cases by means of the height–over–area method (see Höedt-Rasmussen et al, 1966) The main emphasis was placed on the results obtained with the first mentioned method but the conclusions drawn from these data were usually not much different from those based on total CBF determinations

b Summary of main results

The main task of Paper I was to study the cerebral blood flow when the CSF pressure was raised stepwise from –15 mm Hg to +150 mm Hg The cerebral blood flow was consistently found to remain virtually unchanged until a CSF pressure of about 100 mm Hg was reached corresponding to a cerebral perfusion pressure (for definition see above) of 30–50 mm Hg At pressures above 100 mm Hg however the CBF fell progressively approaching flow values as low as 10 – 20 ml/100 g/min If at such low flow values the cerebrospinal fluid pressure was raised still further a rapid fall in systemic pressure usually occurred and the animals succumbed The well-known vasoactive influence of hypercapnia and hypocapnia on CBF was demonstrated to be present even at high intracranial pressure Even when the cerebral perfusion pressures were lowered down to 20 – 30 mm Hg the vasodilatory effect of CO_2 still seemed to operate A compensatory blood pressure rise (Cushing effect) was ob–

served when the CBF pressure exceeded 100 mm Hg The main object of the experiments described in Paper II was to give a quantitative description of the reactive cerebral hyperemia elicited when an elevated cerebrospinal fluid pressure was brought back to normal The cerebral hyperemia usually ensued upon periods of induced cerebrospinal fluid pressure exceeding about 50 mm Hg corresponding to a cerebral perfusion pressure of 70–80 mm Hg as well as upon periods of reduced cerebral blood flow In some cases however a hyperemia was also seen without a prior flow reduction. An impressive feature of the hyperemia was its long duration in some experiments lasting for several hours Reversibility of the hyperemia was the rule though the time before the overshoot in flow was restored to normal varied greatly

c Discussion

The results of Paper I clearly indicate two mechanisms which operate to maintain the CBF at increased CSF pressures as well as their relative efficiency Obviously the changes in cerebrovascular resistance play the main part operating efficiently as long as the cerebral perfusion pressure exceeds a level of 30–50 mm Hg Later studies with a serio–angiographical x-ray technique (Alba et al 1967) have confirmed these results

The second flow-compensating mechanism – the increase in systemic pressure (the Cushing effect see Cushing 1901) – was called into action at CSF pressures exceeding about 100 mm Hg when there was already a measurable decrease in CBF No overlapping seemed to occur between the two flow-compensating mechanisms An exhaustion of the autoregulatory mechanism seemed to be a prerequisite for the Cushing effect to appear Moreover it was evident that while the cerebral vasodilatation very effectively kept the CBF up the Cushing effect was never able to restore it to normal only to diminish the degree of flow reduction. Evidence is accumulating that ischemia or hypoxia in the brain stem is the factor eliciting the Cushing effect (see Sagawa 1967 and paper V) If so the present results make it probable that the blood flow in the brain stem decreases simultaneously with the flow in the grey matter areas of the cerebral hemispheres The Cushing effect appearing in this situation may thus be taken as a clearcut and ominous sign of a general ischemia of the brain

It may seem odd that the cerebral blood flow was kept virtually unchanged up to CSF pressures around 100 mm Hg in our experiments while rather

small rises in CSF pressures brought about by intracranial expansive lesions tend to reduce the CBF both in clinical cases (Kety et al 1948 Easton and Pálvölgyi 1968) and in animal experiments (Huber et al 1965 Langfitt et al. 1965) It would thus seem that a decreased flow may result from an intracranial expansivity as such or from regional increases in the intracranial pressure which only to a moderate extent affect the cerebrospinal fluid pressure Another explanation might be that a long-lasting CSF pressure of moderate height might have special effects not seen in acute situations Decreases in the flow values were however not observed in our experiments when constant levels of increased CSF pressure were induced and kept for periods up to 6 hours

It may here be emphasized that reduced CBF at high CSF pressures not necessarily means maximal vasodilatation. Thus experiments where CSF pressure was raised in hypercapnic animals suggested that CO_2 could dilate the vessels further in a situation when maximal vasodilatation was assumed to be attained due to the markedly reduced perfusion pressure (20–30 mm Hg) This finding, which has later been confirmed (Ekström Jodal et al 1969) suggests that the vasodilatory mechanisms during autoregulation and during CO_2 administration are different.

In Paper II an attempt was made to perform a closer study of the increase in cerebral blood flow which followed when the increased CSF pressure was brought back to normal The existence of a reactive hyperemia after periods of increased CSF pressure was anticipated by earlier workers (Wolff and Forbes 1928) and it was qualitatively studied by Noell and Schneider (1948) and by Ludwigs and Wiemers (1953) A more systematical study of this phenomenon has however so far been lacking

The main features of the cerebral hyperemia (schematically outlined in fig 1) followed essentially the same general pattern as has been observed in other tissues or body organs (see Barcroft 1963 Greenfield 1963 Gregg and Fisher 1963)

The cerebral hyperemia was usually reversible although in contrast to hyperemias in most other tissues it sometimes took several hours to bring the flow back to normal The first blood flow value measured during the hyperemia was always the largest one and this could amount to 5 – 6 times the control flow value Usually the blood flow measured prior to the hyperemia was diminished compared to the control value, but a measurable hyperemia was occasionally seen without a preceding reduction of CBF The flow debt was usually overpaid

It should be pointed out that the calculated vascular resistances during the last phase of the intracranial hypertension and during the first minutes of

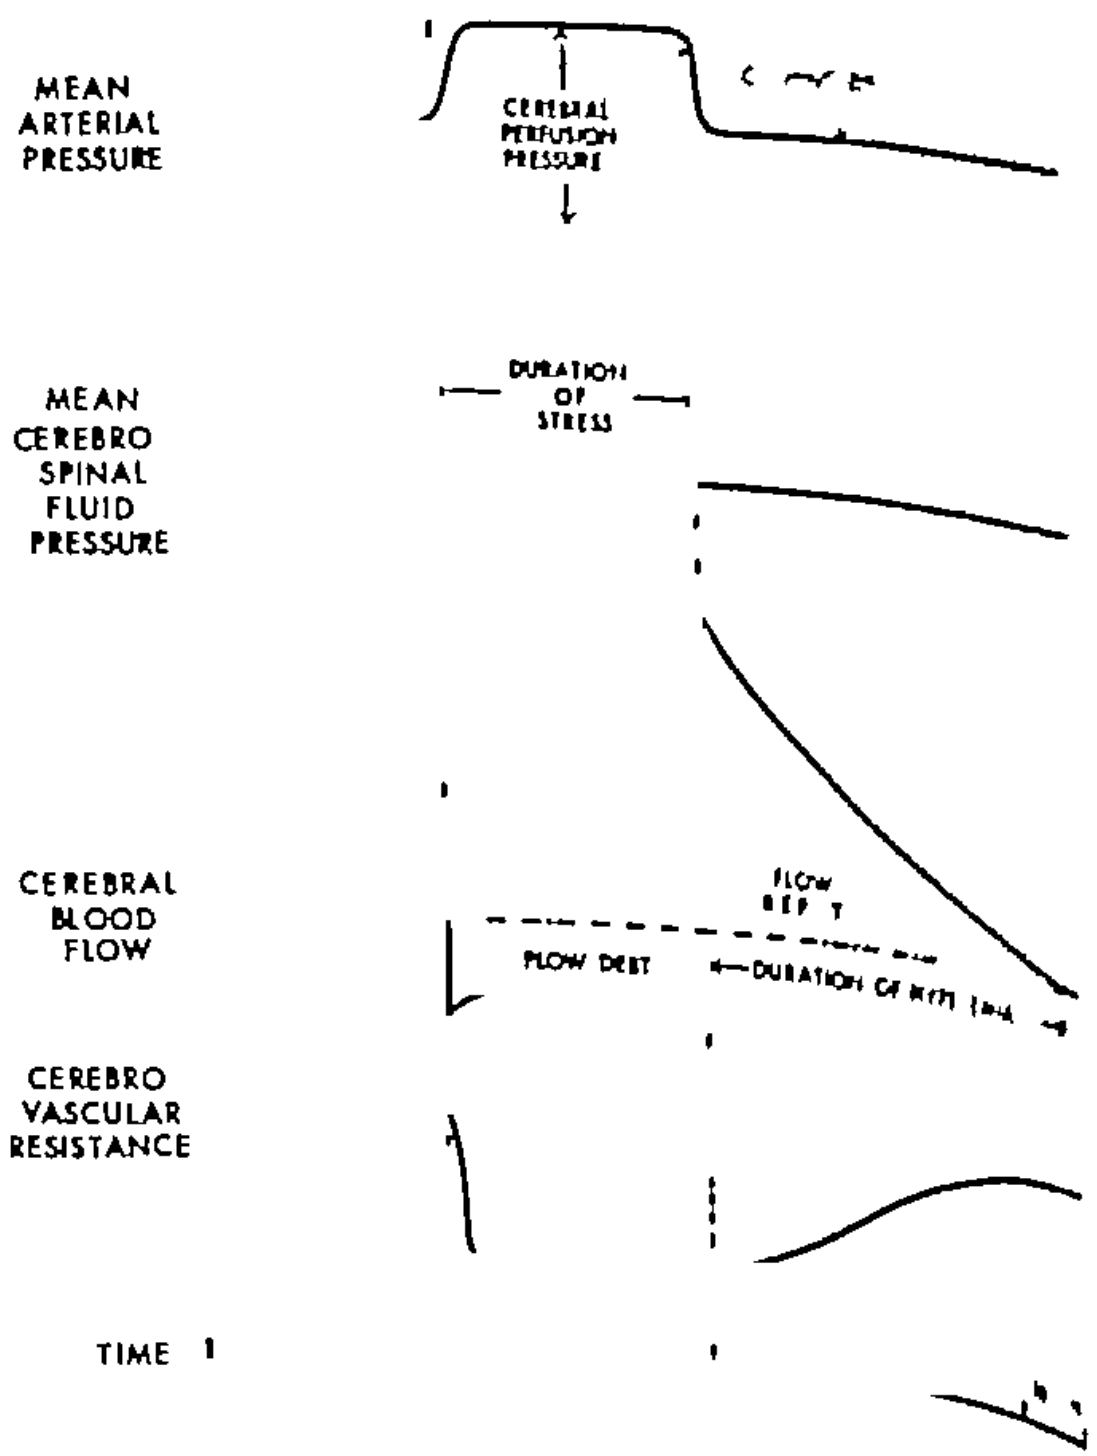

Fig 1 Schematical description of the changes in the pertinent hemodynamic parameters during an induced square wave increase in CSF pressure (For details see text)

the hyperemia respectively differed very little Thus the vascular resistance calculated for the period immediately preceeding the normalization of pressure determined the peak value of the hyperemia which subsided concurrently with the increase of the resistance caused by the gradual constriction of the resistance vessels While the changes in vascular diameter occurring after small variations in cerebral perfusion pressure have been reported to occur quite rapidly i e within a few minutes a slow regulation of the vascular resistance appears to be responsible for the prolonged hyperemia An overshoot of flow - a reactive hyperemia in its strict sense - must always be assumed to follow a period of reduced cerebral perfusion pressure even if this reduction is very shortlasting However after shortlasting and moderate reductions of the cerebral perfusion pressure the hyperemia may vanish so quickly that it cannot be adequately measured with steady state flow methods (see e g Kjällquist Siesjö and Zwetnow 1969) Such a hyperemia may merely reflect the preceeding dilatation of the vessels and has presumably a pathophysiological implication which is different from the longlasting hyperemia usually seen after prolonged and marked reductions of the cerebral perfusion pressure It would thus appear most logical to assess the hyperemia in terms of its duration which in most situations would give important information on the severity of the disturbance of tissue metabolism (see Lassen 1966) The long-lasting and slowly subsiding cerebral hyperemia is probably closely related to the phenomenon of cerebral vasoparalysis which may be produced experimentally in animals using intracranial expanding lesions or repeated impacts to the skull (Langfitt 1968)

III THE EFFECTS OF INCREASED CSF PRESSURE ON THE CEREBRAL ENERGY METABOLISM

The object of the experiments described in Paper III IV and V was to study the effects of increased intracranial pressure on the energy metabolism of the tissue as reflected in the tissue concentrations of phosphocreatine ATP ADP AMP lactate pyruvate and bicarbonate and in the CSF concentrations of lactate pyruvate and bicarbonate The importance of these parameters in the energy metabolism of the tissue will be evident from the following arguments

a Biochemical background

As mentioned in the introduction the tissue can only obtain an adequate amount of high energy compounds by oxidating glucose to CO_2 and water The necessary amount of ATP is obtained when the electrons obtained from the oxidation of pyruvate are passed along the electron transport chain to be finally accepted by oxygen In a hypoxic situation irrespective of its cause a series of characteristic biochemical events will follow Thus when less oxygen is available to accept the electrons the various redox systems will shift toward their reduced states At a certain degree of reduction the phosphorylation of ADP will slow down and there will be a tendency for the ATP concentration to decrease However due to the operation of the creatine phosphokinase reaction the ATP levels will be maintained at the expense of the phosphocreatine concentrations The ATP concentrations can also be upheld through the myokinase reaction but this will lead to an increase also in the AMP concentrations Consequently it is to be expected that a moderate hypoxic condition will be accompanied by decreased phosphocreatine concentrations and increased AMP concentrations However it is possible that a certain degree of reduction of the electron carrier systems can occur before there are any measurable changes in the concentrations of the phosphorylated compounds In such a case a chemical diagnosis of tissue hypoxia will depend on methods which can detect a change in the oxidation-reduction state of the carriers A convenient method of measuring such a change is to analyze the components of a system which exists in a steady state relationship with a carrier system such as the $NADH/NAD^+$

couple Of such systems the lactate/pyruvate system lends itself best to analyses and this system also has the advantage that its components are diffusible through cell membranes Accordingly an increase in the lactate/pyruvate ratio of the cytoplasm will be transmitted to the extracellular fluid (Huckabee 1958 Hohorst Kreuz and Bücher 1959 Hohorst 1960 Siesjö Kjällquist and Zwetnow 1968) When evaluating the redox state from lactate/pyruvate ratios it must be kept in mind though that these ratios depend not only on the cytoplasmatic NADH/NAD^+ ratio but also on the hydrogen ion activity according to the relation

$$\frac{NADH}{NAD^+} = \frac{Lactate}{Pyruvate} \frac{K}{(H^+)}$$

A decrease in the pH of the system will thus by itself tend to increase the lactate/pyruvate ratio A proper evaluation of the NADH/NAD^+ ratio requires knowledge both of the intracellular lactate/pyruvate ratio and of the intracellular pH However it is not certain that such a calculation will reveal a moderate increase of the NADH/NAD^+ ratio due to inevitable variations in the calculated values It could thus be desirable to evaluate the redox state from the lactate and pyruvate concentrations alone This can be done qualitatively since there are many reasons to believe that a decrease in the intracellular pH by itself increases the lactate/pyruvate ratio and decreases the lactate concentration (Leusen Lacroix and Deemester 1957 Granholm and Siesjö 1969 Kjällquist Nardini and Siesjö 1969) Thus if there is an increase in the lactate/pyruvate ratio and a concomitant increase in the lactate concentration a true rise in the NADH/NAD^+ ratio is probably present

b Methodological considerations

In the experiments in which the influence of the increased CSF pressure on the CSF lactate pyruvate and bicarbonate concentrations was studied the infusion of an artificial CSF made it difficult to study the changes in the native CSF The distortion of the true lactate pyruvate and bicarbonate concentrations should be grossly proportional to the amount of CSF infused and thus both to the level of intracranial pressure and to the duration of the pressure period The error was minimized by calculating the admixture of artificial CSF to the samples from the dilution of added C^{14}-inulin. However since the outflux of lactate pyruvate bicarbonate and inulin from the CSF system will probably not be equal the procedure

will only give approximate concentrations whereas the true lactate/pyruvate ratios can be assumed to be unaffected In order to ascertain that changes in the lactate and pyruvate concentrations calculated represented true events they were verified by decreasing the cerebral perfusion pressure by means of controlled arterial bleeding both in the present experiments (Paper III) and in other experiments from the laboratory (Siesjö and Zwetnow 1970)

When evaluating the CSF results it must also be remembered that changes in the tissue concentrations of lactate pyruvate and bicarbonate will be reflected in the bulk CSF sampled from the large cavities with an inevitable lag Thus a transient increase in the lactic acid production in the tissue will show a delayed rise in the large cavity CSF fluid and the CSF may show an increased lactate concentration and an increased lactate/pyruvate ratio at a time when the tissue values are again approaching the normal ones (c f Kaasik Nilsson and Siesjö 1970b) When interpreting changes in the CSF concentrations of these ions it may be helpful to remember that the rate of free diffusion of e.g. bicarbonate ions in the intercellular channels is such that 50 per cent of a step change should be transmitted 10 mm in 10 min (Pappenheimer et al. 1965) and that 0 4 per cent of the CSF is renewed every minute (see Davson 1967)

The determination of tissue concentrations of bicarbonate lactate pyruvate ATP ADP AMP and phosphocreatine were performed with previously described titrimetric and enzymatic techniques (Pontén and Siesjö 1964 Hohorst Kreutz and Bücher 1959 Lowry et al. 1964) In all experiments the tissue was frozen in situ with a method described by Pontén 1966 (see also Granholm et al. 1968) and the tissue was extracted for the enzymatic analyses using the method described by Lowry et al 1964 This method yields optimal concentrations for the labile tissue phosphates with minimal autolysis (for discussion see Nilsson and Siesjö 1970) It should be remarked though that the AMP concentrations reported in Paper IV are slightly too high due to a contamination of the NADH with AMP (Lowry et al. 1964)

c Summary of the main results

In Paper III it was shown that increments in CSF pressure leading to cerebral perfusion pressure reductions to 40 mm Hg or lower and to a decrease in CBF and thus ultimately to a measurable reactive hyperemia also led to long-lasting and usually marked increases in the lactate concentrations and the lactate/pyruvate ratios as well as to

decreases in the bicarbonate concentration of the cerebrospinal fluid. Similar changes though to a less degree were usually observed also after such small increments in CSF pressure which did not seemingly alter CBF Reduction of the cerebral perfusion pressure brought about by controlled bleeding produced in essence the same metabolical findings

In Paper IV the influence of a 15 min reduction of the cerebral perfusion pressure to 30 – 35 mm Hg on labile metabolites and on bicarbonate concentrations of brain tissue were studied There were variable but usually marked increases in the tissue lactate and pyruvate concentrations as well as in the lactate/pyruvate ratios corresponding decreases in the bicarbonate concentrations and marked decreases in the ATP and the phosphocreatine concentrations Resting values for all metabolites measured were not approached until 30 – 90 min after restitution of a normal perfusion pressure CBF measured in some of the animals generally showed reduced values during the period of increased CSF pressure and a reactive hyperemia upon restoration of the CSF pressure to normal The duration of the hyperemia grossly coincided with the disturbance of the energy metabolites

In Paper V the cerebrospinal fluid pressure was progressively raised in rats and studies were made of energy metabolites and of bicarbonate in parts of the tissue designated as supratentorial parts cerebral hemispheres cerebellum and the brain stem No significant changes in phosphocreatine ATP ADP or AMP concentrations and no marked changes in the lactate concentrations were found until the induced intracranial hypertension had decreased the cerebral perfusion pressure to about 30 mm Hg There was a small increase in the lactate concentrations and in the lactate/pyruvate ratio of supratentorial structures and of the cerebellum but not of the brain stem at perfusion pressures which were presumably within the CBF autoregulation range (50 – 100 mm Hg) From the measured total CO_2 contents and from the arterial CO_2 tensions "intracellular pH" and the intracellular bicarbonate concentrations were calculated These figures showed that there was no significant non-respiratory acidosis in the intracellular space until the cerebral perfusion pressure had been reduced below 30 mm Hg

d Discussion of results

The results of Paper III showed that any increase in the CSF pressure which decreased the cerebral perfusion pressure to 40 mm Hg or lower gave rise to marked and longlasting increases in the CSF lactate/pyruvate ratios and in the lactate concentrations as well as to an approximately stoichiometrical decrease in the bicarbonate concentrations The CSF changes were longlasting and could persist for hours after the CSF pressure had been normalized It was also apparent that the reactive hyperemia was unrelated to the extracellular lactacidosis since in some experiments the latter was found to outlast the hyperemia by hours The fact that the CSF lactacidosis sometimes could persist for such long periods makes it entirely unprobable that the lactacidosis of the tissue proper had vanished (see above) and it was thus apparent that a persisting extracellular lactacidosis was compatible with a normal flow Thus even if we assume that the reactive hyperemia is partly caused by the metabolic consequences of the tissue hypoxia it was clear that the flow could return to normal in spite of a remaining extracellular lactacidosis

An unexpected finding was that the typical changes in the CSF lactate pyruvate and bicarbonate concentration were usually seen also after such moderate increases in the P_{CSF} which gave a CPP still within the autoregulation range. These findings were tentatively interpreted as being caused by a transient decrease in flow when the P_{CSF} was increased (see Ludwigs and Wiemers 1953) but a definite answer required tissue analyses (see below)

The longlasting lactacidosis and the longlasting increase in the lactate/ /pyruvate ratio in the CSF recorded after an increase in the ICP (Paper III) could evidently either be due to a slow clearing of lactate from the bulk CSF or to a longlasting disturbance of the oxidative metabolism of the tissue In order to study this problem tissue analyses were carried out at various periods after a 15 min reduction of the CPP to 30 - 35 mm Hg (Paper IV) Although this lowering of the CPP was chosen to give a reproducible reduction of the CBF the results were sufficiently variable to suggest that even these low pressures were just at the limits of the autoregulatory ability of the cerebral circulation. However the main finding of the experiments was the longlasting changes in the metabolites studied Thus it was apparent that the decrease in the CPP gave rise to a cellular lactacidosis which did not subside until 1 - 1 5 hours after the CSF pressure had been brought back to normal There was also a strikingly slow rephosphorylation of ATP and phosphocreatine These results strongly indicate that the oxidative metabolism of the tissue was disturbed for long periods after the normalization of the ICP Thus it has been shown that the tissue phosphates were restituted within 2-5 min after a period

of asphyxia with equally large or larger metabolic changes (Kaasik Nilsson and Siesjö 1970a) The slow restitution of the tissue metabolism after a decrease in the cerebral perfusion pressure may thus be due either to a damage to enzymatic systems involved in the oxidative metabolism or to temporary occlusion of certain capillary channels

The gross correlation of the restitution of flow and energy metabolites respectively would seem to have a bearing on the local control of the cerebral circulation Generally local control of the circulation has been attributed to different factors (myogenic activity acid metabolites adenine nucleotides extra- and intracellular pH increased osmolarity potassium ions and many others see Mellander and Johansson 1968) The extent to which these factors contribute to the reactive hyperemia is not known in detail.

As mentioned above a marked and long-lasting hyperemia ensued when the cerebral perfusion pressure was decreased to such values which gave marked reductions in flow (paper II) Such reductions in perfusion pressure were usually accompanied also by marked changes in the lactate and pyruvate concentrations of both CSF and tissue (Papers III and IV) suggesting that a pronounced hyperemia was elicited only in those cases in which there was a definite disturbance of the oxidative metabolism of the tissue This fact and the gross agreement between the duration of the hyperemia and the duration of the metabolic changes in Paper IV makes it tempting to assume that the longlasting vasodilatation during the reactive hyperemia had a metabolic cause However in our experiments as well as in those of Ekström-Jodal et al, (1969) a reactive hyperemia could also be found without a previous flow reduction and it can even occur at increased flow levels where metabolic changes could hardly be expected to occur (Ekström-Jodal et al, 1969) At this point it thus seems as if both metabolic and myogenic factors may be responsible for the hyperemic response after periods of increased CSF pressure (see Folkow 1962 1964)

In order to study the possible occurrence of minor metabolic changes at moderate increments in CSF pressure (see discussion of Paper III above) a series of experiments were carried out in rats with reductions of the cerebral perfusion pressure within the autoregulatory range established in the dog experiments The CSF pressure was increased in the same manner as in the dog experiments by infusing artificial CSF into the cisterna magna The results were consistent with the findings reported in papers I III and IV in the main points (see also Kjällquist et al 1969 and Siesjö and Zwetnow 1970) Thus although the cerebral perfusion pressure could be reduced to about 30 mm Hg before there were any measurable changes in the tissue concentrations of phosphocreatine ATP

ADP and AMP the lactate concentrations and the lactate/pyruvate ratios were increased at much higher CPP values

In an attempt to evaluate the effect of moderate increases in CSF pressure on different parts of the central nervous system the cerebellum the brain stem and the cerebral hemispheres were analyzed separately Lowering of the CPP to 50 - 100 mm Hg resulted in increased lactate concentrations as well as increased lactate/pyruvate ratios for all structures studied except for the brain stem The resistance of the brain stem to minor CPP reductions is compatible with the clinical reports in which the brain stem survives situations leading to the cell death in supratentorial structures

In order to substantiate that the CSF pressure effects are in reality an effect of CPP reduction and in order to make it possible to evaluate both CSF and tissue changes in a large series of experiments the cerebral perfusion pressure was reduced in rats by means of controlled bleeding so as to yield mean arterial pressures of 30 - 160 mm Hg (Siesjö and Zwetnow 1970) This series of experiments confirmed the results reported above Thus the cerebral perfusion pressure could be reduced to about 40 mm Hg before there were any measurable changes in the tissue concentrations of phosphocreatine ATP ADP and AMP However the lactate concentrations and the lactate/pyruvate ratio in both the extracellular and intracellular spaces appeared to increase continuously when the CPP was lowered within the pressure range mentioned

The increase of lactate concentrations and of the lactate/pyruvate ratios in both rat studies (Paper V and Siesjö and Zwetnow 1970) suggest that a moderate reduction of the cerebral perfusion pressure may lead to minor degrees of reductions in the NADH/NAD^+ system long before there are any changes in the phosphocreatine and the AMP concentrations It is thus possible that the lactate/pyruvate system may be suitable for analyses of minor degrees of tissue hypoxia provided that no altered transfer of the lactate or pyruvate ions between blood and tissue occurs Moreover it must be stressed that as long as the tissue concentrations of phosphocreatine and AMP are not significantly changed the oxidative metabolism of the cerebral tissue cannot be considered to be appreciably disturbed and such a condition could be compatible with normal values of globally measured CBF and $CMRO_2$

The results of the present series of experiments have a bearing on the mechanism regulating the cerebrovascular resistance at reduced perfusion pressures It has been assumed that the extracellular pH of the brain is one of the main factors responsible for the dilatation of the cerebral resistance vessels (see symposium ed. by Ingvar et al. 1968 and Paper III) In view of the present results it appears very improbable

that the extracellular pH could be an important factor regulating the CVR at moderate variations of the CPP Thus since the reduction of the CPP to e g 40 mm Hg in Paper V was associated with an increase in the intracellular lactate concentration of about 0 5 - 1 0 mmole per kg of intracellular water and since a corresponding increase could be expected in the extracellular lactate concentration the CSF bicarbonate should decrease by maximally 1 mEq/kg. At constant CO_2 tension such a decrease in bicarbonate should lead to a decrease in the extracellular pH of about 0 01 units It is thus probable that the dilatation of the cerebral vessels at reduced CPP values is due to other factors It is possible that the myogenic theory which has been proposed by many previous workers (Folkow 1962) can better explain cerebral autoregulation (Ekström-Jodal et al 1969)

IV GENERAL SUMMARY

The present thesis describes a series of experiments which were devised to study the effects of an increased cerebrospinal fluid pressure on the circulation and the oxidative metabolism of the brain. The rationale behind the experimental approach was that a generalized increase in the cerebrospinal fluid pressure will exert its effects on the tissue mainly by decreasing the effective perfusion pressure and that an adequate tissue blood flow can only be upheld at a lower perfusion pressure if the resistance vessels of the tissue dilate, i.e. if autoregulation is present. There had previously been a number of qualitative or semiquantitative studies indicating that the cerebral blood flow showed autoregulation if the cerebral perfusion pressure was decreased due to a decreased blood pressure or to an increased CSF pressure. However, there was very little information about the range of CSF pressures which can be induced without significant decreases in blood flow, and very little was known about the quantitative aspects of the reactive hyperemia which can be elicited by a decreased tissue perfusion. It was thus the intention to study the range of CSF pressures compatible with an efficient autoregulation, as well as the circulatory changes caused by a marked decrease in the perfusion pressure. When those results were obtained an attempt was made to define the effect of a markedly decreased perfusion pressure upon the oxidative metabolism of the tissue, as this is reflected in the tissue and CSF lactate and pyruvate concentrations, and in the tissue concentrations of phosphocreatine, ATP, ADP and AMP. These measurements gave an unexpected side result in that changes in the CSF lactate and pyruvate concentrations were observed even if the cerebral blood flow was not significantly lowered. This result prompted a separate investigation of possible metabolic changes in the tissue at perfusion pressures which had previously been found to be within the autoregulatory range.

The experiments were carried out on dogs and rats. The dogs were used to study the cerebral circulation with the tissue clearance method for a radioactive inert gas, to study changes in the CSF lactate, pyruvate and bicarbonate concentrations, and to study metabolic changes in the brain after a marked reduction in perfusion pressure. For the last study, and in order to facilitate experiments on a large series of animals, rats under nitrous oxide anesthesia were used.

The main results of the circulatory studies was the finding of an efficient

autoregulation over a wide range of CSF pressures and the finding of a very marked and often longlasting reactive hyperemia after a pronounced decrease in the cerebral perfusion pressure Thus the cerebral blood flow did not change appreciably if the CSF pressure was varied from about -15 to about 100 mm Hg i.e if the cerebral perfusion pressure varied between about 140 and about 30 - 50 mm Hg At these lower pressures the cerebral blood flow started to decrease and there occurred a concomitant increase in the mean arterial blood pressure ("Cushing effect") However the Cushing effect was not sufficient to restore the blood flow to normal. Control experiments showed that a lowering of the perfusion pressure to about 30 mm Hg did not give any marked decrease in the oxygen consumption of the tissue At these low pressures an increase in flow was induced by hypercapnia indicating that the dilatation of the vessels during autoregulation and during hypercapnia occurs by separate mechanisms

In general there was a fair correlation between the decrease in flow during a period of increased CSF pressure and the magnitude and duration of reactive hyperemia after the restoration of normal CSF pressure However the coupling was not obligatory in that a reactive hyperemia could be seen to follow upon an intracranial hypertension which was not accompanied by a decreased flow The peak flows during the period of reactive hyperemia could amount to 500 - 600 per cent of the control values and the hyperemia could last for 2 - 3 hours or more It is concluded that although a shortlasting hyperemia must be assumed to follow upon any reduction of the perfusion pressure however moderate it may be the longlasting and pronounced hyperemias must be assumed to be the result of a serious disturbance of the tissue metabolism

When the increase in the CSF pressure gave rise to decrease in flow there were marked and often very longlasting increases in the CSF lactate concentrations and in the lactate/pyruvate ratios and corresponding decreases in the CSF bicarbonate concentrations These changes were interpreted to reflect an increased anaerobic metabolism of the tissue and thus a disturbed oxidative metabolism In some instances after pronounced or repeated reductions of the perfusion pressure the lactacidosis of the CSF could persist for many hours However it was found that the cerebral blood flow could return to normal in spite of a persisting acidosis and it was thus not possible to relate the hyperemia to the extracellular acidosis

In order to study if the longlasting increases of the CSF lactate pyruvate and bicarbonate concentrations were due to a slow clearing of lactate from the relatively stagnant CSF pools or to a persisting lactacidosis in the tissue proper the tissue concentrations of lactate pyruvate bicarbonate phosphocreatine ATP ADP and AMP were measured at

various times during and after a 15 min decrease in the perfusion pressure to 30 – 35 mm Hg These experiments showed that the tissue lactate pyruvate and bicarbonate concentrations did not normalize until 60 – 90 min after that the perfusion pressure had been brought back to control values Further since the rephosphorylation of ATP and phosphocreatine was equally slow it was concluded that the circulatory alteration induced gave rise to a damage to the oxidative systems or to a state with persisting focal underperfusion

An unexpected finding was that decreases in the perfusion pressure to values still within the range of autoregulation could give rise to increases in the CSF lactate concentration and lactate/pyruvate ratio In order to study if these changes were the result of transient decreases in flow or if they represented persisting tissue events metabolic studies were done on rat brains after the CSF pressure had been increased to various levels It was found that the perfusion pressure could be decreased to about 30 mm Hg before the tissue concentrations of phosphocreatine ATP ADP and AMP were affected but that moderate lactate and pyruvate changes occurred at much higher perfusion pressures It was concluded that the results confirmed the previous findings that the oxidative metabolism of the tissue is not grossly changed until the perfusion pressure falls to values around 30 mm Hg but also that the lactate/ /pyruvate changes probably reflect minor degrees of tissue hypoxia possibly of focal nature If this interpretation is correct the results definitely indicate that the tissue lactate/pyruvate ratio is a more sensitive indicator of tissue hypoxia than e g the phosphocreatine or AMP concentrations

V LIST OF ABBREVIATIONS USED

ADP	adenosine diphosphate
AMP	adenosine monophosphate
ATP	adenosine triphosphate
CBF	cerebral blood flow
$CMRO_2$	cerebral metabolic rate of oxygen
CPP	cerebral perfusion pressure
CSF	cerebrospinal fluid
NAD^+	nicotine amide adenine dinucleotide (oxidated form)
NADH	nicotine amide adenine dinucleotide (*reduced form*)
P_{CSF}	cerebrospinal fluid pressure

ACKNOWLEDGEMENTS

These investigations have been carried out at the Department of Clinical Physiology and the Department of Neurosurgery University of Gothenburg and at the Brain Research Laboratory E-blocket University Hospital Lund Sweden

My sincere gratitude is presented to my clinical colleagues as well as to the nurses and the administrative staff for their kind help which made it possible for me to carry out the time-consuming experiments

In particular I wish to express my deep gratitude to:

My chief Professor Gösta Norlén for enabling me to carry out this investigation and for his never-failing encouragement interest patience and support throughout the work.

Professor Arne Carlsten and Docent Bo K. Siesjö for having generously placed the facilities of their experimental laboratories to the benefit of the investigations and for valuable theoretical and practical help

Professor Nils Lundberg for his kind and encouraging support through several years

Professor Björn Folkow and Professor Stefan Mellander for their never-failing readiness to discuss arising problems and to give valuable advice

Docent Ingemar Petersén and Docent Urban Pontén for helpful criticism and valuable suggestions

My collaborators Docent Egil Häggendal Docent Åke Kjällquist Assistant Professor Nils Johan Nilsson Dr Jan Lögren and Docent Bo K. Siesjö for their generous cooperation and constructive criticism

Miss Lena Danielsson Mrs Gun Larsson and Miss Maj-Lis Österlund for skillful assistance with the animal preparations Miss Christina Andersson Mrs Barbro Asplund Miss Ingrid Fellert Miss Gunilla Gidö Mrs Karin Hansson and Mrs Gertie Johansson for conscientious assistance with time-consuming chemical analyses

Miss Kerstin Andersson and Mrs Maj-Britt Collin for careful preparation of the manuscripts and help in many ways

The staff of the University Medical Library in Gothenburg for their amiable efficiency

The investigation was supported by grants from the Medical Faculty University of Gothenburg Göteborgs Läkaresällskap Rådman and fru Ernst Collianders Stiftelse R Halvorsens Minnesfond the Swedish Medical Research Council and the Swedish Bank Tercentary Fund

INTRODUCTION

1.1 *General remarks*

The biogenic amines have, since their isolation and identification in the first two or three decades of this century attracted the attention of a great number of workers (see Gudernatsch, 1951). The remarkable pharmacological actions of some of these natural tissue constituents were soon recognized and led to the assumption that the biogenic amines were physiologically significant. For some of these compounds, such as acetylcholine and the catecholamines, their putative physiological significance was early linked with transmitter function, which as a consequence, for long has been the most prominent functional role ascribed to biogenic amines.

Amines are the result of decarboxylation of L-α-amino acids. All amino acid decarboxylases seem to be stereospecific, attacking only the L form of the substrate. It can be assumed that the number of biogenic amines is very large: every amino acid may give rise to at least one amine and in several cases the resulting primary amine undergoes secondary reactions. As a matter of fact, a great number of different amines were early isolated from biological material. Nervous tissue, to name one example, contains a wide variety of amines (see Perry Hansen Fourlas and Lido 1965; Seiler and Wiechmann 1965; Nakajima, Wolfram and Clark, 1967; Perry Hansen and MacDougall, 1967), most of which are still unidentified (see Seiler and Wiechmann 1965). In spite of this multiplicity interest was primarily focused upon a fairly small group of biogenic amines,* which included histamine, acetylcholine, 5-hydroxytryptamine (5-HT) and the catecholamines (adrenaline, noradrenaline and dopamine). This was a natural consequence of their powerful pharmacological effects, which permitted their quantitation through simple bioassay procedures. The interest in this particular group of compounds has led to an overwhelming wealth of intriguing information, which in turn has resulted in a number of provocative and attractive theories as to their functional roles.

Research on biogenic amines is based on certain fundamental assumptions. The first and most important of these assumptions pertains to the physiological significance of biogenic amines such as histamine, 5-HT and the catecholamines. It is generally assumed that these compounds play an important role in the regulation of both neuronal and extra-neuronal functions. The possibility that in some tissues they may be merely waste products is seldom, if ever, considered. Another perhaps even more questionable idea often intimated in the literature, can be formulated as follows: The physiological functions of biogenic amines are reflected in their pharmalogical effects, *i.e.* the p

---

* Other biogenic amines have been disregarded to such extent that the term amines" now appears to be reserved for acetylcholine, histamine 5-hydroxytrypt catecholamines, a terminology which appears difficult to justify

cological effects of these compounds are sometimes regarded as extrapolations of their physiological actions. According to this view amines without strong pharmacological effects are less likely to be of physiological significance. This is not necessarily correct since there may not always be a relation between the pharmacological activity of biogenic amines and their physiological roles. A third assumption can be formulated as follows The observation of a high concentration of an amine in a tissue may be taken as an indication of a particularly important role for that amine in that particular tissue. This is a questionable assumption, since there may be no relation whatsoever between the concentration of a tissue component and its physiological importance. A low tissue level of a particular amine does not exclude its rapid formation and rapid turn-over neither does it exclude the possibility of a very important physiological role for that compound.

Although it is evident that the various assumptions in this field of research should not be uncritically accepted, there are good reasons to acknowledge the assertion that some biogenic amines do have physiologically important functions. The fundamental assumption that we have deliberately selected to form the basis of our investigation is that certain cells actively produce and store amines not only because they affect other cell systems but because the amine is somehow significant to the function of the cell itself

While earlier work emphasized the participation of biogenic amines in neuronal transmission, current studies tend to get more and more involved with the extra neuronal functions of these compounds (for a review see FALCK and OWMAN 1968) This re-orientation was greatly assisted by recent methodological advances in the histochemistry of biogenic amines. The fluorescence microscopic method developed by FALCK and HILLARP (FALCK and TORP 1961 FALCK, 1962 FALCK, HILLARP THIELE and TORP 1962) for the histochemical detection of 5-HT and the catecholamines has caused a major break through in research on biogenic amines in general and in our understanding of non-neuronal amine mechanisms in particular

This treatise attempts to survey recent observations on the cytochemistry of gastric amine-producing cells and to confront these observations with the vast amount of data available in the literature and in so doing try to put recent results in a proper perspective It has been our deliberate intention to integrate observations on the formation and functions of a variety of amines such as histamine dopamine and 5-hydroxytryptamine Since many of the biogenic amines appear to be functionally related—possibly also functionally interdependent—it is becoming increasingly evident that compartmentalization" in this area of research is to be avoided.

1.2. *Current concepts on the physiological role of histamine 5-HT and catecholamines*

Histamine In the mammalian organism, the basophils of the blood (GRAHAM LOWRY WHEELWRIGHT LEDUC and PARROTT, 1955 COOK and MITCHELL, 1957 ROBERMAN, 1962)

and the mast cells of the tissues (Riley 1953a and b Riley and West 1953 Carr, Riley West Head and Straub, 1954) regularly contain histamine. The distribution of histamine in most tissues parallels the distribution of mast cells, and it is now well established that the major portion of the amine is contained in these cells (Riley 1959) Agents such as Compound 48/80 which act as histamine-depleting drugs, do so through liberating mast-cell-histamine (Riley 1953a) However also non-mast-cell localizations of tissue histamine have been established For example, histamine is found in the brain predominantly in the hypothalamic region (Harris, Jacobsohn and Kahlson, 1952 Adam 1961 Garlick 1964 Adam and Hyde, 1966) where mast cells are scare, if present at all and the histamine content of the rat stomach is very high in spit of the fact that in this species gastric mast cells are few (Mota, Beraldo Ferri and Junqueira, 1956) Gastric histamine in the rat can thus be assumed to reside in another cell system. This assumption has received confirmation through the recent histochemical demonstration of histamine in an epithelial cell system in the oxyntic gland area of the rat and mouse (Håkanson and Owman 1967 Håkanson Owman and Sjöberg, 1967 Thureson, 1967) These histamine-containing cells are morphologically very similar to the enterochromaffin cells of the pyloric gland area, and have been referred to as enterochromaffin-like (Håkanson and Owman 1967 see also Håkanson, Lilja and Owman, 1967)

Very early mast cell histamine was proposed as one of the mediators of the allergic reaction (see review by Rocha e Silva, 1955) This concept initiated much experimental work directed towards alleviating the symptoms of allergy through antihistaminic agents. In many respects, this concept has since proved inadequate and histamine is now regarded as only one of many mediators of the allergic response (see Telford and West 1963)

During the last decade, interest has been focused on the role of non-mast-cell histamine mainly as a result of investigations by Schayer (1960a and b 196) and by Kahlson and co-workers (see reviews by Kahlson 1962 by Kahlson and Rosengren 1968) The latter authors showed that some tissues of the foetal rat and foetal mouse are very active in forming histamine and that the amine formed is rapidly eliminated from the foetus (Kahlson, Rosengren and White, 1960 Rosengren, 1963 see Rosengren, 1966) This and further observations of a similar nature on other rapidly growing tissues of the rat (Kahlson, Nilsson Rosengren and Zetterqvist 1960 Håkanson 1961 Kahlson and Rosengren, 1963) was interpreted as indicating growth-promoting function of histamine. Although this may be the case in the rat and mouse, it does not appear to be general phenomenon since in other species rapidly growing tissues fail to develop increased histidine decarboxylase activity (Mackay Reid and Shuttleworth 1961; Kahlswaran and West 1963 Mitchell, 1963 Håkanson, 1966b Rosengren, 1966)*

Kahlson and co-workers also studied the formation and turn-over of histamine in th rat stomach and suggested from their results that histamine is the final common mediator of gastric secretion (Kahlson, Rosengren, Svaetichin and Thunberg, 1964; Kahlson Rosengren and Thureson, 1967) Their main supporting evidence was the observation that injection of gastrin or the intake of food cause a loss of gastric histamine and a concomitant increase in gastric histidine decarboxylase activity This was interpreted as an indication of self-regulating feed-back mechanism with the reaction product, histamine acting as the enzyme repressor This concept will be further discussed in section 3 10.

Schayer has suggested role for histamine in the control of microcirculatory homeostasis (Schayer, 1962) He observed an activation of the histidine decarboxylase activity of tissues such as muscle and skin following treatment with a variety of stressful stimuli. These findings hav been used to develop theories on microcirculatory control function for newly formed histamine. It has been suggested that "intrinsic histamine is formed at rates commensurate with tissue requirements for blood and that histamine is the principal regulator of the microcirculatory system.

Histamine and other amines, such as 5-HT and the catecholamines, are also believed to play role in the acute inflammatory response and in tissu repair (Spector and Willoughby 1964 Lahiri and Sanyal, 1967)

---

* Recent observations by Jänne (1967) Smith and Jänne (1967) and Russell and Snyder (1968, 1969) of remarkably high activity of ornithine decarboxylase in certain types of rapidly growing tissues suggest that, apart from histamine other amines may play part in the process of growth and tissue repair

In the light of the recent histochemical demonstration of histamine in the enterochromaffin-like cells of the rat stomach (Håkanson and Owman 1967 Håkanson, Owman and Sjöberg, 1967) the role of histamine in the function of these cells has attracted some interest. This particular aspect of the possible physiological function of histamine will be one of the main subjects of the present treatise.

Histamine in tissues may arise from two sources. One is by uptake of histamine absorbed from the intestines. The other is by *decarboxylation of histidine in the tissues. Histamine* formation in mammalian tissues may be catalyzed by at least two histamine-forming enzymes. One is believed to be identical with DOPA decarboxylase (EC 4 1 1.26)* also referred to as non-specific aromatic amino acid decarboxylase (Lovenberg, Weissbach and Udenfriend, 196) Another enzyme appears to be specific and is probably of greater physiological significance as a catalyst of histamine formation *in vivo* (Garbut Rosenquist and Rosenquist, 1961 Weissbach, Lovenberg and Udenfriend, 1961) The enzyme is generally referred to as mammalian histidine decarboxylase or specific* histidine decarboxylase (EC 4 1 1.22) Th specific histamine forming enzyme, which is identified by its very characteristic kinetic properties (Håkanson 1963 1964 1966b, 1967a and b) has been found in a limited number of tissues. Foetal rat liver hamster placenta and murine mastocytoma are rich sources of this enzyme (Garbut Rosenquist and Rosenquist 1961, B ichalier, 1962 Håkanson 1963 1967b Auerbach and Noll, 1966) Considerable activity has been demonstrated also in murine gastric mucosa, in red bone marrow and in various transplantable tumours of the rat (Håkanson, 1964 1966b Håkanson and Owman 1966b Auerbach, Håkanson and Schauer, 1968) In many tissues the enzyme appears to be adaptive since the enzyme activity is subject to considerable variation (for details see sections 3 10. and 5 5) The marked adaptability of mammalian histidine decarboxylase may be of great physiological importance.

In certain species, thus histamine may result from enzymatic formation or from a combination of enzymatic formation and intestinal absorption. I other species, where conclusive evidence is lacking for histidine decarboxylase activity histamine may be absorbed from the intestines in sufficient quantities to supply all tissue stores (Waton 1963 1964 Duncan and Waton, 1969)

5-HT and cat cholesterase. 5-HT has widespread occurrence in tissues of both vertebrates and invertebrates (see Garattini and Valzelli, 1965) Histochemical methods have been very successful in establishing the cellular localization of 5-HT and the catecholamines (cf *e.g.* Falck and Owman, 1968) Their occurrence and functions in the central nervous system has ttracted particular attention (Brodie and Costa, 1962 Hillarp Dahlström and Fuxe, 1966 Dewhurst 1968a and b) With the exception of the pineal nerves (Owman, 1964a) 5-HT has an extra-neuronal localization in peripheral tissues of mammals. The major portion of the 5-HT in the body is found in the intestines (Bertaccini, 1960), where it is located in the enterochromaffin cells (see Pearse, 1966 Vialli, 1966) In addition, 5-HT occurs in particularly high amounts in certain endocrine organs (Erspamer, 1966 Falck and Owman, 1968) such as the thyroid of the sheep (Falck, Larsson von Mecklenburg, Rosengren and Svensson, 1964) the pancreatic islet cells of the guinea-pig, cat, dog, horse, duck, pigeon and pig (see Grobbelaar, 1968) the pineal gland of the mouse, rat (Quay and Halevy, 1962 Quay 1963 Bertler, Falck and Owman, 1964) and pig (Owman, 1964b) There is reason to believe that in some of these endocrine cells 5-HT and dopamine can be present concomitantly (Grobbelaar, 1968) or the cells may contain catecholamine but not 5-HT (Grobbelaar, 1968) It should be pointed out that the absence of 5-HT (or catecholamines) i some of these endocrine cells does not immediately exclude the possibility that other amines are produced and stored in them, and that these amines are capable of performing the same intracellular function. It is therefore difficult to discuss one biogenic amine independent from the other amines. The physiological function of the peripheral extra-neuronal amines is largely unknown. The 5-HT containing enterochromaffin cells of the digestive tract are believed to hav an endocrine function, which involves the secretion of some still

---

* In accordance with the nomenclature recommended by the Enzyme Commission f the International Union of Biochemistry these enzymes re referred to by the following systematic names DOPA decarboxylase 3,4-dihydroxy L-phenylalanine carboxy-lyase (EC 4 1 1.26) 5-HTP decarboxylase 5-hydroxy-L tryptophan carboxy lyase (EC 4 1 1 28) Histidine decarboxylase -histidine carboxy-lyase (EC 4 1 1.22)

unidentified polypeptide- or protein hormone(s). It has also been suggested that the gastric antipernicious principle (intrinsic factor) originates from these cells (Jacobsson 1939). Gastrointestinal 5-HT has also been associated with bowel motility (see Bülbring and Lin 1958, Haverback and Davidson 1958); 5-HT released from preganglionic nerve endings in the myenteric plexus as a result of vagal stimulation, is believed to cause relaxation of the smooth muscles of the stomach (Bülbring and Gershon, 1966, 1967). From their localization, usually in the basal part of the intestinal and pyloric glands, it appears more likely that the 5-HT-containing enterochromaffin cells are involved in secretory mechanisms. There is no histochemical evidence indicating the presence of 5-HT in the myenteric plexus (Jacobowitz, 1965; Gabella and Costa, 1967; Norberg, 1967; Read and Burnstock, 1969) and the participation of 5-HT in regulation of bowel motility does not appear to be a likely hypothesis (Gershon 1968; see also Boullin 1964).

Recently Hägerdal (1967) detected dopamine in human gastric juice, and Håkanson, Owman, Sjöberg and Stenström (1970d) reported the presence of dopamine-containing enterochromaffin cells in the gastric mucosa of the cat and rabbit. It should be noted that dopamine in the digestive tract may have a cellular storage site other than the enterochromaffin cells. Thus, large amounts of dopamine have been demonstrated in mast cells of the digestive tract of ruminants (Falck, Nyström, Rosengren and Stenflo 1964). The role of gastrointestinal 5-HT and dopamine is entirely unknown; for a discussion of their possible function in enterochromaffin cells see section 3.10.

5-HT and dopamine result from decarboxylation of 5-hydroxytryptophan (5-HTP) and 3,4-dihydroxyphenylalanine (DOPA), respectively. These reactions are probably catalyzed by one and the same enzyme, which is sometimes referred to as aromatic amino acid decarboxylase (Lovenberg, Weissbach and Udenfriend, 1962), sometimes as DOPA/5-HTP decarboxylase. The formation of 5-HT and dopamine, however, is preceded by hydroxylation of tryptophan to 5-HTP and of tyrosine to DOPA. The initial hydroxylation of tyrosine and tryptophan is considered to be the rate-limiting step in the biosynthesis of dopamine and 5-HT because the decarboxylating enzyme is available in high concentration in most tissues. It is very doubtful whether DOPA or 5-HTP are normally present in the blood. Available data suggest that the formation of these amino acids takes place in the same cell that converts them into amines. Thus, the hydroxylation is the critical step determining not only the rate of amine formation but also the identity of the amine which is formed in the cell.

1.3 *Presentation of the subject*

The presence in the intestines of a cell system, which can be visualized by the chromaffin reaction and which contained "enteramine" has been recognized for a considerable time (see Erspamer, 1954a); the cells are named enterochromaffin cells, and "enteramine" has been identified as 5-HT (see Erspamer and Asero 1952b; Vialli 1966). The histochemical fluorescence method of Falck and Hillarp (Falck and Torp 1961; Falck, 1962; Falck, Hillarp, Thieme and Torp 1962) in combination with microspectrofluorometry has directly confirmed that the chromaffinity of these cells is due to their high 5-HT content (Vialli and Erspamer, 1969; Håkanson *et al.* 1970d), except at certain locations (*e.g.* the gastric mucosa of the cat and rabbit) where some of the enterochromaffin cells have been found to contain dopamine* (Håkanson *et al.*, 1970d). The parietal cell region of

* The dopamine-containing epithelial cells of the gastric mucosa have not been identified as chromaffin by strict histochemical criteria. Nevertheless, they are referred to as enterochromaffin because of their morphological resemblance to the conventional 5-HT-containing enterochromaffin cells, and because cells which contain dopamine in extremely large amounts, are capable of giving the chromaffin reaction (Falck, Hillarp and Torp 1959). For definition of the enterochromaffin cell see section 3.2.

the rat and mouse is lacking in enterochromaffin cells, but has recently been found to contain cells morphologically similar to enterochromaffin cells and referred to as "enterochromaffin-like" (HÅKANSON and OWMAN 1966b HÅKANSON LILJA and OWMAN 1967) These enterochromaffin-like cells have been found to produce and store histamine (HÅKANSON and OWMAN 1967 HÅKANSON OWMAN and SJÖBERG 1967 THUNBERG 1967) Both the enterochromaffin and the enterochromaffin-like cells are agyrophil (HÅKANSON and OWMAN 1969) but only the enterochromaffin cells give a positive argentaffin reaction. Apart from mast cells, the cellular storage site of gastric histamine, dopamine and 5-HT is the argyrophil cell system (HÅKANSON *et al.*, 1970d) Thus, any physiological function of these amines in the gastrointestinal tract appears to be closely related to the function of the enterochromaffin (argyrophil, argentaffin) and the morphologically similar "enterochromaffin-like" (argyrophil, non argentaffin) cells. Since 1938 these cells have been referred to as endocrine on the basis of their morphology (FEYRTER, 1938) They have many of the ultrastructural characteristics common for polypeptide and protein-secreting endocrine cells (SOLCIA, VASSALLO and SAMPIETRO 1967) but so far it has not yet been possible to identify the hormones produced in the cells (for a discussion see AURIA and HÅKANSON 1968a AURIA, HÅKANSON and OWMAN 1970)

The histological classification of these cells is historically based on their "chromaffinity" and their reactivity towards various silver stains. The chromaffin reaction detects biogenic amines, such as 5-HT and the catacholamines, by converting them into pigments through oxidation, or by reduction of the bichromate with a concomitant cytoplasmic deposition of chromium (for a discussion see HALE, 1958) The fluorescence microscopic method of FALCK and HILLARP introduced for the histochemical detection of these amines, is much more sensitive and specific. The term enterochromaffin, however is accepted for historical reasons and for want of a better name. The argentaffin reaction is a consequence of the presence of a reducing substance such as 5-HT (or dopamine) in the enterochromaffin cells the non-argentaffin, argyrophil cells are morphologically indistinguishable from the argentaffin cells, but they are devoid of 5 HT and dopamine and lack the ability to reduce ammoniacal silver salts. The difference in reactivity towards silver stains is widely used to classify the various types of gastrointestinal endocrine cells although this may mean overemphasizing one particular cytochemical characteristic of these cells. Conceivably the conventional classification of these endocrine cells into two types on the basis of their 5-HT content (reflected in their argentaffinity) may be an arbitrary and unjustified distinction with little bearing on the endocrine function of these cells, which presumably involves the formation and secretion of some polypeptide or protein hormone (for a discussion see section 3 9)

It is now generally recognized that all known gastrointestinal endocrine cells, which by conventional argyhophilic stains are morphologically indistinguish-

able, in reality comprise several different cell populations, distinguishable on the basis of differences in their cytochemistry (amine producing enzymes, amine-storing mechanisms) (HÅKANSON and OWMAN 1966b HÅKANSON LILJA and OWMAN 1967 1969 HÅKANSON and OWMAN 1967 AURIS HÅKANSON OWMAN and SPORRONG 1968 HÅKANSON and OWMAN 1969 HÅKANSON *et al.* 1970d) as well as in their ultrastructure (SOLCIA and SAMPIETRO 1965 SOLCIA, VASSALLO and SAMPIETRO 1967 CARVALHEIRA, WELSCH and PEARSE, 1968 PEARSE, 1968a CAPELLA SOLCIA and VASSALLO 1969 VASSALLO SOLCIA and CAPELLA, 1969 FORSSMAN ORCI PICTET RENOLD and ROUILLER, 1969) The truly important differences between these various cell types are of course related to their function (of which we know very little) and not related to the identity and characteristics of the amine stored (of which we know somewhat more) It is therefore not surprising that at present, interest is focused on the functions of these amine-storing endocrine cells as such rather than on the role of the amines which they contain (cf *e.g.* CAPELLA, SOLCIA and VASSALLO 1969 FORSSMAN ORCI PICTET RENOLD and ROUILLER 1969 PEARSE, 1969 VASSALLO SOLCIA and CAPELLA, 1969) However the identification of the endocrine mechanisms operating in these amine-producing endocrine cells requires a detailed knowledge of their regional and topographical distribution as well as of their distinguishing cytochemical features.

2. METHODOLOGY

2.1 *Chemical assay of amines and amino acid decarboxylases*

Most of the techniques used for the chemical determination of the amines and of the amine forming enzymes are widely used and hardly deserving of a detailed description. Details will be given only when modifications have been introduced or when problems of specificity have been the subject of controversy. Thus particular emphasis will be given to certain aspects of the assay of histamine and of histidine decarboxylase.

Amines

Histamine In earlier days, histamine was quantitated by its contractile effect on the atropinized guinea-pig ileum. This technique has now largely been abandoned for other methods. In 1959 Shore, Burkhalter and Cohn introduced a sensitive fluorometric assay for the determination of histamine, using o-phthaldialdehyde (OPT) as the reagent. Prior to its determination, histamine is extracted from tissues according to the following general procedure (details are given by Hakanson 1963). The tissue is homogenized in a cold 5 per cent solution of trichloroacetic acid and precipitated proteins are spun down. Aliquots of the clear supernatant is extracted with a 3:2 mixture of n-butanol and chloroform after alkalinization with sodium hydroxide and saturation with sodium chloride. The organic phase, which now contains the histamine, is washed once with salt-saturated 0.1 N sodium hydroxide and then extracted with 0.1 N hydrochloric acid in the presence of heptane. By this procedure histamine is transferred to the aqueous phase. Aliquots of the hydrochloric acid extract can be taken for fluorometric analysis, which involves condensation of histamine with OPT under alkaline conditions and subsequent stabilization and enhancement of the fluorescence by acidification. The fluorescence intensity is determined in an Aminco-Bowman spectrophotofluorometer (excitation at 350 mμ, emission maximum at 450 mμ). The now well-known non-specificity of OPT as a reagent for histamine (see Cohn and Shore, 1961; Carlini and Green 1963a and b; Krumdieck and Pfeiffer, 1966; Shelley and Juhlin 1966; Maickel and Miller, 1966; Michaelson 1967; Aures, Fleming and Hakanson 1968; Tustner and Wightman 1968) makes special precautions necessary: 1) The activation and fluorescence spectra are registered routinely. This is useful in establishing inadvertent contamination with *e.g.* spermidine (Michaelson 1967) as well as with certain as yet unidentified OPT reactive tissue components (the emission max. of the OPT-spermidine fluorophore is at about 400 mμ). 2) Fluorescence is read also before the final acidification step. A lower fluorescence intensity at this stage eliminates the possibility that histidine, arginine and agmatine (which emit more intense OPT induced fluorescence at alkaline pH) cause the OPT induced fluorescence. 3) In some cases hista-

mine has been chromatographically identified by *e.g.* gel (Sephadex) chromatography ion exchange chromatography (Kreiznер and Wilson 1961 Håkanson 1963) or a combination of gel chromatography and ion exchange chromotography (Aures Håkanson and Spolter, 1968) and paper or thin-layer chromatography (Aures Fleming and Håkanson 1968) Levine, Sato and Sjoerdsma (1965) investigated the specificity of the fluorometric method in the assay of gastric histamine and reported, that provided small amounts of tissue were tested no other compound interfered with the assay

5-HT All determinations of 5-HT are made on fresh material since 5-HT is rapidly destroyed upon storage. The tissue to be analyzed is homogenized in 0.1 N hydrochloric acid and precipitated proteins are spun down. Aliquots of the supernatant are extracted from an alkaline environment with *n*-butanol (Udenfriend Weissbach and Clark, 1955) or *n* heptanol (Mirolli, 1966) The final aqueous extract is assayed for 5-HT by the fluorescence (activating wavelength 295 mμ fluorescence max. at 550 mμ) induced by strong hydrochloric acid (Bodanski Pletscher, Brodie and Udenfriend, 1956) The specificity of the fluorescence is secured by subsequent quenching of the specific fluorescence with hydrogen peroxide (Contractor, 1964) or with potassium ferricyanide followed by ultraviolet irradiation (Andén and Magnusson 1967) to produce a more correct tissue blank. The identity of 5-HT can also be established by paper or thin-layer chromatography where aqueous or gaseous formaldehyde is used as the detection reagent (Shepherd West and Erspamer, 1953 Bell and Somerville, 1966 Håkanson Lombard des Gouttes and Owman 1967 Aures Björklund and Håkanson 1968 Aures, Fleming and Håkanson 1968 Björklund Falck and Håkanson 1969 1970a and b) The intense yellow fluorescence resulting from the reaction of 5-HT with formaldehyde, can be readily detected by illumination in ultraviolet light.

Catecholamines Dopamine, noradrenaline and adrenaline are determined fluorometrically after isolation by cation exchange chromography (Bertler, Carlsson and Rosengren 1958 Carlsson and Waldeck, 1958) The identity of the various catecholamines can be confirmed by paper or thin-layer chromatography followed by treatment with various gaseous or aqueous formaldehyde reagents, which result in intensely fluorescent condensation products (Bell and Somerville, 1966 Aures Björklund and Håkanson 1968 Aures Fleming and Håkanson 1968 Björklund Falck and Håkanson 1969 1970a and b)

Amino acid decarboxylases

In principle the activity of amino acid decarboxylases can be determined in two different ways 1) Estimation of the carbon dioxide produced during reaction with the amino acid substrate 2) Estimation of the amount of amine produced during the reaction.

The classical method for the study of amino acid decarboxylases is the manometric determination of the amount of CO_2 released during the reaction. Determination of the amine product became possible when spectrophotometric and fluorometric methods were introduced (Boodanski *et al.*, 1956 Waalkes and Udenfriend 1957 Carlsson and Waldeck, 1958 Hess and Udenfriend 1959 Shore, Burkhalter and Cohn 1959) The growing interest in the formation and function of biogenic amines has since stimulated the development of simple, rapid and sensitive radiometric methods for measuring very low activities of amino acid decarboxylases (Schayer, 1956a and b Weissbach Kino Sjoerdsma and Udenfriend 1959 Kobayashi, 1963 Snyder and Axelrod 1964 McCaman McCaman Hunt and Smith 1965 Häkanson 1966a) During the last decade, such techniques have become available in great variety Most of them are superior to conventional spectrophotometric and fluorometric techniques in sensitivity sometimes also in simplicity and versatility The general principle for assays of amino acid decarboxylases applies also with radiometric techniques The enzyme activity can be estimated by determining the amount of radiolabelled amine produced or by determining the amount of $^{14}CO_2$ released from carboxy-labelled substrates.

Aromatic L-amino acid decarboxylase This enzyme is widely distributed in the mammalian organism and for the assay of this enzyme classical manometric techniques are quite often satisfactory In studies on the more precise distribution of this enzyme in *e g* discrete areas of the brain or in tissue sections, more sensitive and accurate methods have to be employed. Both fluorometric and radiometric techniques have been successfully applied to studies on minute amounts of tissue (Kuntzman Shore, Bogdanski and Brodie, 1961 McCaman *et al* 1965 Häkanson 1966a Robins, Robins Crontinger, Moses Spencer and Hudgins 1967 Aures Häkanson and Schauer, 1968)

Fluorometric techniques utilize either the fluorescence of the native amine or that of some conjugation or condensation product of the amine for its quantitative estimation. For this reason, the amount of amine produced can be measured fluorometrically only after adequate separation from the amino acid substrate which usually interferes with the assay This can be done by ion exchange chromatography or by selective extraction of the amine with organic solvents It should be pointed out that in studies on tissue homogenates or crude tissue extracts the presence of large amounts of preformed amines in the tissue sometimes makes accurate fluorometric estimation of newly formed amines difficult In this respect radiometric techniques are superior

All available radiometric techniques, based on the determination of the amount of amine produced, employ modifications of the conventional methods for separation of the product from its precursor (Weissbach *et al.* 1959 Snyder and Axelrod 1964 McCaman *et al* 1965 Häkanson 1966a) Both ion exchange chromatography and solvent extraction procedures have been adapted successfully for the special requirements of radiometry As a rule radiometric techniques make even greater demands on accurate separation of

product from precursor that the fluorometric techniques and the separation procedures have had to be modified accordingly The final radioassay can be performed in a gas flow-counter or by liquid scintillation.

One technique employed in the first part of the present investigation involved incubation of tissue extracts or small pieces of tissues with small amounts of ^{14}C-DL DOPA (3 μg) in a total volume of one ml (0 1 M phosphate buffer pH 7 0) Incubation was stopped after one hour by the addition of 4 ml 0 4 N perchloric acid containing 10 μg nonradioactive dopamine as carrier After homogenization, the precipitate was spun down, and the supernatant was neutralized with 2 N potassium carbonate to a final pH of about 6.5 The perchlorate was spun down and the supernatant was passed through a Dowex 50 Na^+ column. Dopamine was retained on the column whereas DOPA could be eliminated by washing the column with 35 ml 0 06 M phosphate buffer pH 6 6 and with 10 ml re-distilled water Dopamine was quantitatively eluted with 10 ml N hydrochloric acid. The eluate was evaporated to dryness on a steam bath during which procedure the heat-labile catechol amines were destroyed. The dry residue was washed several times with acidified acetone, which resulted in a quantitative extraction of the radioactivity The acetone extracts were transferred to standard planchettes, one inch in diameter and evaporated to dryness for measurement of radioactivity (HÅKANSON 1966) The method has been found useful for the assay of DOPA decarboxylase in a variety of tissues (HÅKANSON and MÖLLER, 1963 HÅKANSON MÖLLER and STORMBY 1965 HÅKANSON and OWMAN 1965 1966a and b HÅKANSON LOMBARD DES GOUTTES and OWMAN 1967)

In more recent studies (AURES HÅKANSON and SCHAUER, 1968 AURES and HÅKANSON 1968b AURES DAVIDSON and HÅKANSON 1969) tissue extracts were incubated with ^{14}C-carboxy-labelled DL DOPA (8×10^{-4}M) pyridoxal 5 -phosphate (10^{-5} or 2×10^{-5}M) and glutathione (5×10^{-4}M) in a total volume of 0.5 ml or 0 05 ml phosphate buffer pH 6.9 for one hour The amount of ^{14}CO liberated in the reaction was determined by liquid scintillation after trapping in a suitable absorbent medium (for details on this procedure see the section on measurement of histidine decarboxylase activity) This latter technique is superior in convenience and versatility and has a similar degree of sensitivity compared with the first method.

L-Histidine decarboxylase Histamine formation can be determined fluorometrically or radiometrically These methods seem to be superior to the bioassay procedure developed by WATON (1956a) In this procedure the histamine content of tissue extracts is determined on the atropinized guinea pig ileum after incubation in the presence or absence of histidine. The difference in histamine content at the end of incubation is the measure of histamine formation. Fluorometric techniques were developed as a result of the observation of SHORE, BURKHALTER and COHN (1959) that histamine condenses with o-phthaldialdehyde (OPT) to form a highly fluorescent conjugate.

Since histidine forms a similar fluorophore with OPT adequate separation of histamine from its precursor is essential. Isolation of histamine can be obtained through ion exchange chromatography (Kremzner and Wilson 1961 Gan rot Rosengren and Rosengren 1961 Lovenberg Weissbach and Udenfriend 1962 Häkanson 1963) or through extraction with organic solvents (Shore, Burkhalter and Cohn 1959 Burkhalter, 1962 Anton and Sayre, 1969) The most widely used method is the one in which the incubation mixture is deproteinized with acid, made alkaline with sodium hydroxide and extracted with a mixture of n-butanol and chloroform (Burkhalter, 1962 Häkanson 1963) After extraction histamine is in the organic phase but the bulk of histidine remains in the aqueous phase After one washing with dilute sodium hydroxide which removes residual histidine, the organic solvent mixture is extracted with dilute hydrochloric acid, by which procedure histamine is transferred into the aqueous phase for subsequent fluorometric assay after condensation with OPT This method is not sufficiently sensitive to detect the very small amounts of histamine produced by most mammalian tissues. The sensitivity of the fluorometric method can be greatly increased if the histamine produced is instead purified by ion exchange chromatography and then concentrated before the assay (Häkanson 1963) However it is necessary to exercise some caution in the interpretation of data from experiments on tissue homogenates or crude tissue extracts, In many tissues the histamine content is fairly high and the histidine decarboxylase activity comparatively low This makes it extremely difficult to assess accurately the amount of newly formed histamine against a high tissue blank. An additional difficulty is the non-specificity of the reaction with OPT (see above) A large variety of compounds, of which spermidine may be the quantitatively most important, are known to react with OPT to form highly fluorescent condensation products. It may therefore be difficult to establish beyond doubt that the newly formed OPT reactive compound is in fact histamine although spectrofluorometric analysis of th fluorophore may assist in establishing the identity

Thus the fluorometric assay for histidine decarboxylase is well suited for studies on highly active and highly purified preparations of the enzyme but is *not satisfactory for studies on crude extracts with a high histamine content.* For this purpose radiometric techniques are to be preferred. Several methods have been described Schayer, Davis and Smiley (1955) introduced a technique in which the histidine used is labelled with ^{14}C in the 2 position of the imidazole ring and in which the resulting radioactive histamine is diluted with non-radioactive carrier and converted to the picrate salt, crystallized and counted at infinite thickness in a gas-flow counter An alternative method is to prepare the dibenzenesulfonyl or the p-iodobenzenesulfonyl derivative (Schayer, 1957 see also Kahlson Rosengren and Thunberg 1963) with the latter method the radioactivity can be measured by the liquid scintillation technique, which is more efficient than assay in the gas-flow counter Methods have also been described in which the radioactive histamine formed is separated

from the substrate by paper chromatography before counting (HÅKANSON 1966a SKIDMORE and WHITEHOUSE, 1966b) One such technique (HÅKANSON 1966a) involved incubation of tissue extracts or small pieces of tissue with small amounts of ^{14}C-L-histidine (2 µg) in a total volume of one ml (0 1 M phosphate buffer) After incubation for one hour trichloroacetic acid was added to give a final concentration of 5 per cent and a total volume of 3 ml. Non radioactive histamine dihydrochloride, 20—40 µg was added as carrier After homogenization the resulting precipitate was spun down and discarded. The supernatant was washed twice with four volumes of diethylether to remove the trichloroacetic acid, and then extracted with a mixture of n-butanol and chloroform (3.2) according to the procedure described in detail elsewhere (HÅKANSON 1966a) Since histamine is not separated entirely from contaminating ^{14}C-histidine by organic extraction, a further purification of the amine by paper chromatography was found to be necessary The extract was evaporated to dryness on a steam bath and histamine was extracted quantitatively from the dry residue with alkaline ethanol and applied to a filter paper for chromatography The routine solvent system used separates histidine and histamine very effectively The histamine-containing spot was visualized with ninhydrin. This portion of the chromatogram was cut out and eluted overnight with 5 ml of ethanol containing a few drops of ammonia per 25 ml. The ethanol extract was evaporated to dryness on planchettes for measurement of the radioactivity in a gas flow-counter The reproducibility and sensitivity of this assay procedure was adequate for the determination of the histidine decarboxylase activity of a number of tissues (HÅKANSON 1964 1966a and b HÅKANSON and OWMAN 1966b) SKIDMORE and WHITEHOUSE (1966b) described a method in which extracts were incubated with ^{14}C-labelled histidine small aliquots of the incubation mixture were taken for paper chromatography at frequent intervals during the incubation the radioactivity of the histamine-containing portion of the paper chromatogram was determined by liquid scintillation. A similar procedure involving paper chromatography and/or electrophoresis has been described by SOMERVILLE (1964) for the assay of aromatic amino acid decarboxylase.

The simplest method for measuring histidine decarboxylase activity is that in which histidine labelled with ^{14}C in the carboxyl group is used as substrate. The ^{14}CO released is trapped in a suitable absorbent medium and its radioactivity is then determined directly by liquid scintillation. Several modifications of the original procedure of KOBAYASHI (1963) have been described (AURES and CLARK, 1964 LEVINE and WATTS 1966 1967 LEINWEBER and WALKER, 1967 AURES, DAVIDSON and HÅKANSON 1969) and the method has been adopted by a great number of workers (AURES and CLARK, 1964 LEVINE and WATTS 1966 LEINWEBER and WALKER, 1967 SMITH and CONE, 1967 FISCHER and SNYDER, 1965b JOHNSON 1967 MAUDSLEY RADWAN and WEST 1967 RADWAN and WEST 1967 POWELL and KUMAR, 1968 SNYDER and EPPS 1968 SCHWARTZ, RÖNNBERG COHEN and VALETTE, 1969 HÅKANSON and LIEDBERG 1970a and b) The method currently in use in our laboratory employs

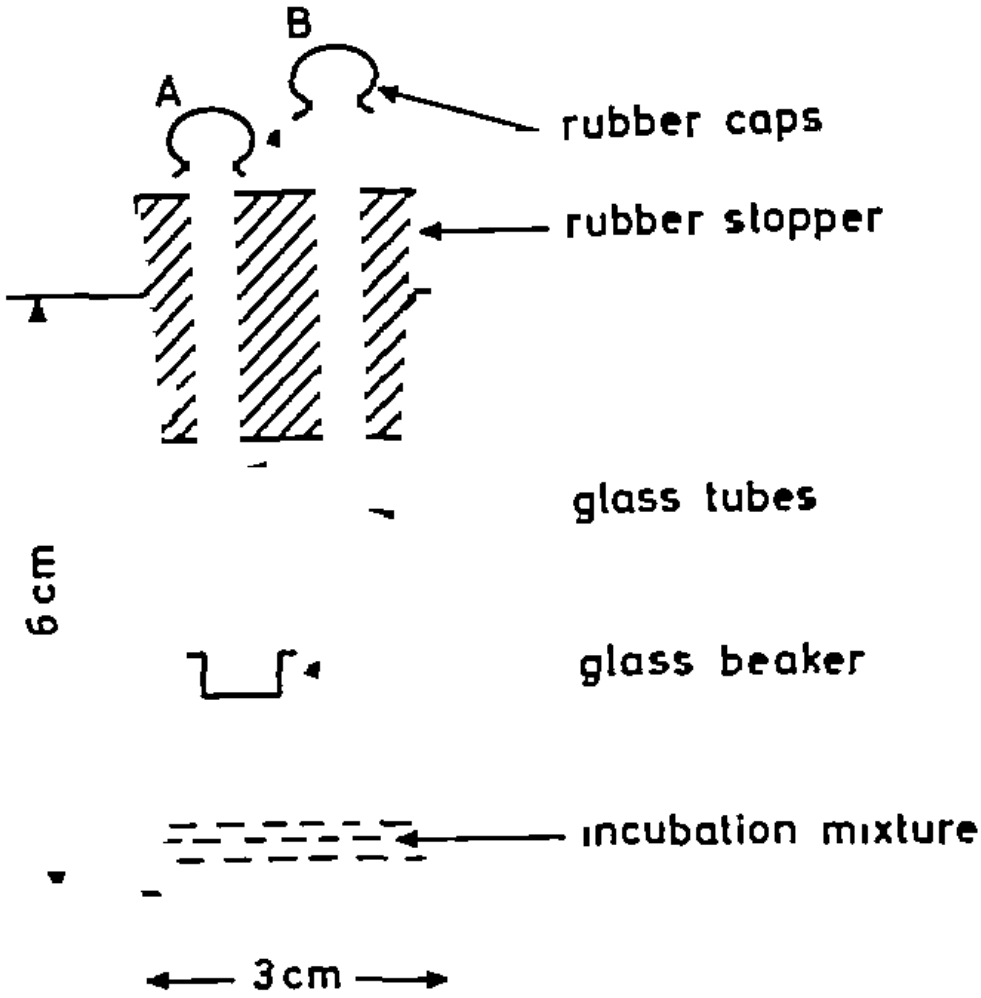

Fig. 1 Schematic drawing of the equipment used for radiometric determination of the amino acid decarboxylase activity

the technical set-up illustrated in fig. 1 Extracts are incubated with 1-^{14}C-L-histidine (4×10^{-4} or 4×10^{-5}M) pyridoxal 5 phosphate (10^{-5} or 2×10^{-5}M) and glutathione (5×10^{-4}M) at pH 6.9 in a total volume of 0.5 ml. The ^{14}CO produced in the reaction is released by acidification (0.5 ml 10 per cent trichloroacetic acid) and further expelled by the addition of sodium bicarbonate the samples are left in the mechanical shaker for another 30 min to permit all ^{14}CO to be trapped on a multifolded piece of filter paper (0.5×4 cm) previously moistened in NCS (Nuclear Chicago) or Digestin (New England Nuclear) The recovery of $^{14}CO_2$ released from ^{14}C-labelled sodium bicarbonate was between 95—100 % and the radioactivity registered was the same as when the isotope was added directly to the Bray (1960) liquid scintillation

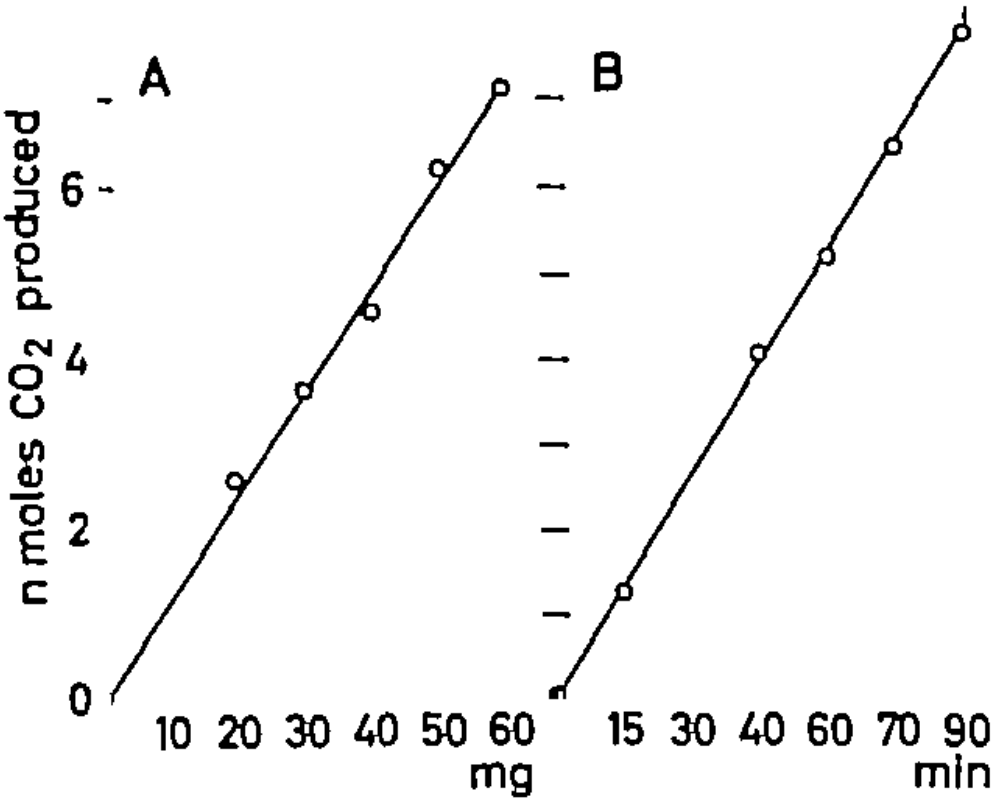

Fig. 2. Rate of histamine formation as dependent on enzyme concentration (A) and incubation time (B). The enzyme extract was incubated with 1-^{14}C-L-histidine (4×10^{-4}M 1,3 mc/mmol) pyridoxal-5-phosphate (10^{-5}M) and glutathione (5×10^{-4}M) in 0.1 M phosphate buffer at pH 6.9. Total incubation volume 0.5 ml. The extract was prepared by homogenization of the tissue (gastric mucosa of vagally denervated rats) high speed centrifugation and dialysis over-night (Håkanson and Liedberg, 1970). The concentration of the final extract corresponded to 200 mg tissue (wet weight) per ml. (A) Incubation time 60 min. (B) The amount of extract added corresponded to 50 mg tissue.

fluid.* The amount of ^{14}C-histidine routinely added to the incubation mixture corresponded to 250 000 cpm (instrumental values). Blanks were provided by incubating heated samples. Under these conditions the blank value never exceeded 100 cpm above background. The enzyme activity was rectilinear with time (up till 2 hr) and with the amount of enzyme (Fig. 2). This method has also been modified for assay of histidine decarboxylase (and DOPA decarboxylase) on a micro-scale (Fig. 3). This procedure permits the determination of enzyme activity in minute amounts of material such as histological sections. The incubation volume is approx. 50 µl (for details see Ahlman, Håkanson and Schauer, 1968; Ahlman, Davidson and Håkanson 1969).

---

* The high counting efficiency of this procedure confirms earlier observations of Wang and Jones (1959), Nunez and Jacquemin (1961), Bousquet and Christian (1960) and Lupien, Hinde and Beelmouet (1968).

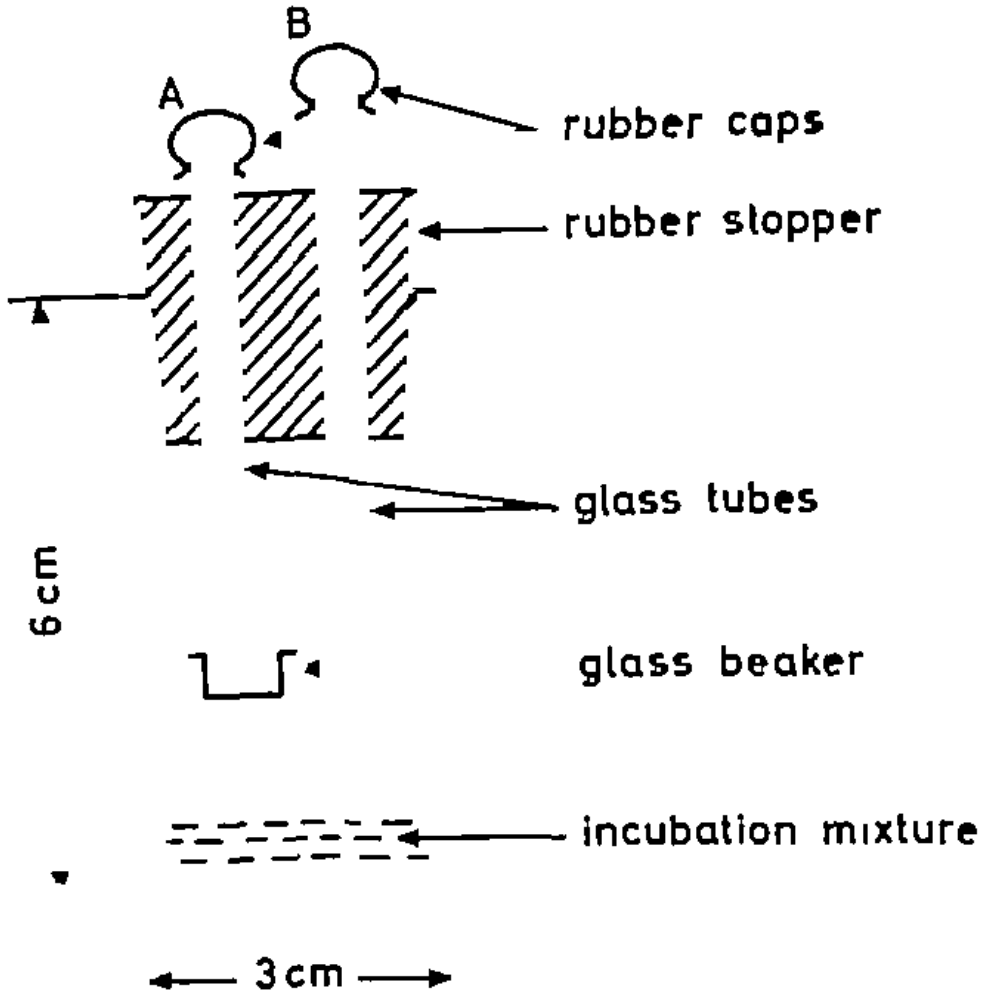

Fig. 1 Schematic drawing of the equipment used for radiometric determination of the amino acid decarboxylase activity

the technical set-up illustrated in fig 1 Extracts are incubated with 1-^{14}C-L-histidine (4×10^{-4} or 4×10^{-5}M) pyridoxal-5 phosphate (10^{-5} or 2×10^{-5}M) and glutathione (5×10^{-4}M) at pH 6.9 in a total volume of 0.5 ml. The $^{14}CO_2$ produced in the reaction is released by acidification (0.5 ml 10 per cent trichloroacetic acid) and further expelled by the addition of sodium bicarbonate the samples are left in the mechanical shaker for another 30 min to permit all $^{14}CO_2$ to be trapped on a multifolded piece of filter paper (0.5×4 cm) previously moistened in NCS (Nuclear Chicago) or Digestin (New England Nuclear) The recovery of $^{14}CO_2$ released from ^{14}C-labelled sodium bicarbonate was between 95—100 % and the radioactivity registered was the same as when the isotope was added directly to the BRAY (1960) liquid scintillation

1967 Graihn and Rosenoren 1968 Schayer, 1968 Levine and Noll, 1969) The method used for preparing the tissue specimen may be critical One widely used technique involves incubation of minced tissue samples. This makes impossible the exact assessment of enzyme activity since the enzyme is sensitive to changes in the concentration of various components in its environment (cf Burkhalter, 1965 Levine and Noll, 1969 for a general discussion see Reinter, 1959) The use of this method is defended on the grounds that in some cases one can detect decarboxylation of histidine in minced preparations or in cell suspensions but not in cell-free preparations (Schayer, 1956a) Generally however the initial step in preparing the tissue for assay is disruption of cells by homogenization. For studies on the kinetics of histamine formation further purification of the enzyme is essential since tissue homogenates may contain variable amounts of substrate, cofactor and endogenous inhibitors or activators. Levine and Watts (1966) recommended an initial purification also when studying physiological alterations of the enzyme activity in the rat stomach. Other workers have found this unnecessary (Kim, Ridley and Tuzel, 1968) Fluorometric methods for the study of amino acid decarboxylases are of limited usefulness. They are quite satisfactory with purified preparations from tissues rich in the enzyme but not very well suited for studies on crude tissue extracts which are rich in the amine and low in enzyme content. There are a number of instances where these methods have failed to detect histidine decarboxylase activity readily measured by radiometric methods. Radiometric techniques are superior since the tissue content of endogenous non-radioactive amine is of no consequence and since these methods have a very high sensitivity only limited by the specific radioactivity of the commercially available substrates. All radiometric techniques, in which the labelled amine product is measured, usually involves laborious separation procedures. Although as a rule these techniques have a high degree of sensitivity specificity and precision they all have the disadvantage of being somewhat tedious. The $^{14}CO_2$ techniques, on the other hand, have a similar sensitivity and offer the advantage of being very simple and versatile. Maudsley Radivan and West (1967) compared the method of Waton (1956a) with the radiometric techniques of Schayer (1956a and b 1957) and of Kobayashi (1963) The two radiometric methods were found to be more sensitive than the non radiometric one. In their opinion the method of Schayer was more sensitive than the $^{14}CO_2$ method because of a lower blank value. Graihn and Rosenoren (1968) criticized the ^{14}CO method on the grounds that addition of large amounts of adrenaline and ascorbic acid was found to cause the release of $^{14}CO_2$ from carboxy ^{14}C-labelled histidine. This reaction took place without a concurrent formation of histamine. From this observation they concluded that the ^{14}CO method "may not be trustworthy for the purpose of measuring the rate of histamine formation" The authors, furthermore, maintained that these decarboxylation reactions occur also when tissue is present in the incubation mixture, although in the only experiment they performed to test this assumption they found that

with the CO method adrenaline seemed to depress histamine formation in minced mouse and rat lungs" But even if spontaneous decarboxylation had occurred in the presence of tissue the error introduced by the lability of histidine (presumably not only carboxy ^{14}C-histidine) can be avoided by proper blanks. Moreover the problem is not that the $^{14}CO_2$ method gives too high values, but that it seems to give lower values for the histidine decarboxylase activity of most tissues (AURES DAVIDSON and HÅKANSON 1969) than those reported by KAHLSON and co-workers (cf KAHLSON *et al.* 1964) It should be noted that their results have been obtained using blanks provided by the addition of semicarbazide. MACKAY and SHEPHERD (1967) have pointed out that the use of carbonyl trapping agents such as semicarbazide may result in falsely low blank values. This may be critical in the assessment of enzyme activity in tissues with low enzyme content.

All ^{14}CO methods have quite correctly been criticized on the grounds that they may be non-specific, *i.e.* $^{14}CO_2$ may be released through break-down of the amino acid along other pathways than the one expected. It is thus advisable to verify results obtained with these methods by the parallel use of some other technique. It should be kept in mind, however that whereas the enzyme activity recorded with the $^{14}CO_2$-method may thus sometimes be too high, it is difficult to imagine a situation in which the enzyme activity registered is too low (unless carbon dioxide trapping systems exist in the extract, which can easily be tested by incubating the extract with known amounts of a ^{14}C-labelled carbonate salt) This is of importance in regard to *e.g.* histidine decarboxylase (EC 4 1 1.22) since its existence in many tissues has been disputed. A high histidine decarboxylase activity recorded with this technique may have to be verified by some other method, but there is no reason to doubt that unless CO fixation takes place in the extract the inability to register decarboxylase activity with the $^{14}CO_2$-method reflects a very low enzyme level. The use of carboxyl-labelled histidine moreover eliminates a potential error that is present in all methods in which histamine is detected as the product of the reaction, namely that some of the histamine formed may be destroyed or degraded during the incubation and thus escape detection by the assay procedure used.

The term HFC (abbreviation of histamine forming capacity) as a synonym for histidine decarboxylase activity has recently gained widespread use. HFC is defined as a new term to express the rate of histamine formation in minced tissue or cell suspensions incubated *in vitro* with small physiological concentrations of histidine at present measurable only isotopically (KAHLSON 1962) In such an assay the enzyme is not necessarily rate-limiting The HFC value depends on the amount of tissue, on the concentrations of endogenous histidine and pyridoxal-5 phosphate, and on the time of incubation. Therefore the quantitative assessment of HFC is possible only when the various conditions are strictly defined. But even so the HFC assay provides no information as to what type of catalyst is present in the tissue

being studied. For a detailed criticism of the conventional HFC assay see BURKHALTER (1965) and PEARLMAN and WATON (1966)

2.2. *Assay of the gastric antipernicious anaemia principle (intrinsic factor)*

The intrinsic factor (IF) is known to have a high vitamin B_{12}-binding capacity which can be quantitatively determined Tissue extracts were prepared by homogenization in 0 1 M sodium acetate-acetic acid buffer pH 3.5 After centrifugation in a refrigerated centrifuge at 10,000 x g for 10 min, small amounts of the supernatant were mixed with ^{57}Co-labelled cyanocobalamin (usually 20—40 000 cpm, instrumental values) Aliquots (0 05—0 2 ml) of the mixture were passed through a Sephadex G 25 column (length 200 mm, inner diameter 8 mm) The column was washed with 0 1 M phosphate buffer pH 7 0 Protein-bound vitamin B_{12} was excluded from the gel and appeared in the first 3 ml fraction after the void volume This fraction was collected and quantitated by gamma spectrometry Blank values were obtained by running a parallel separation of the same amount of free vitamin B_{12} and collecting the same fraction for quantitation. The blank value usually did not exceeded 100 cpm above background. Standards were provided by measuring the radioactivity of the aliquots before separation on the columns (HÅKANSON LINDSTRAND, NORDOREN and OWMAN 1969)

The capacity to bind vitamin B_{12} is a prerequisite for IF activity but IF may be only one of several vitamin B_{12}-binding proteins in the gastric mucosa. The possible existence of several binders was tested by column chromatography and paper electrophoresis. One ml of tissue extract was chromatographed on a Sephadex G 150 column (90 × 1.5 cm) equilibrated with 0.05 M sodium phosphate buffer pH 6 containing 0.2 M NaCl. The major vitamin B_{12}-containing fraction was further analyzed by chromatography on a diethylaminoethyl (DEAE) cellulose column (13 × 1.5 cm) Before application on the column the pooled vitamin B_{12}-containing protein fractions were concentrated in a dialysis bag against polyethyleneglycol. The concentrated fractions were then passed through a Sephadex G 25 column in order to change the buffer composition to 0.005 M phosphate buffer pH 7.5 which was desirable for the DEAE chromatography With the DEAE cellulose column, gradient elution was performed with phosphate buffer starting with a molarity of 0 005 and a pH of 7.5 whereafter the molarity was increased gradually to 0 05 and the pH shifted to 6.0. The fractions were analyzed for radioactivity

The major vitamin B_{12}-containing protein fractions obtained in the gel chromatography were also analyzed by paper electrophoresis in a 0 05 M Veronal buffer pH 8 6 (4 V/cm, 16 hrs.)

By definition IF is a protein which facilitates the intestinal absorption of vitamin B_{12}. The capacity of rat stomach vitamin B_{12}-binding proteins to perform this function was tested in rats in which the oxyntic gland area had been surgically removed. These animals failed to absorb ingested vitamin B_{12}. ^{58}Co-

labelled cyanocobalamin (with or without vitamin B_{12}-binding proteins) was given orally to the rats and the amount of radioactivity retained in the body was established by whole-body counting immediately after and 1 3 and 7 days after ingestion of the isotope (Hàkanson *et al* 1969)

2.3 *Fluorescence microscopy of biogenic amines*

5 HT and catecholamines The fluorescence of enterochromaffin cells in formalin fixed material (mammalian intestines) was described by Erős in 1932 the fact that the fluorescence was induced by the formalin was recognized and discussed by Feyrter in 1938. After the chromatographic identification of 5-HT extracted from intestinal mucosa (Erspamer and Asero 1952b) Shepherd West and Erspamer (1953) demonstrated in model experiments that formalin treatment of 5-HT on paper causes a strong yellow fluorescence in ultraviolet light. Barter and Pearse (1953) concluded that the fluorescence of the enterochromaffin cells seen after formalin fixation was due to the presence of 5-HT and caused by the condensation of 5-HT with formaldehyde. These authors further suggested that the fluorescent reaction product formed from 5-HT and formaldehyde was a β-carboline (Barter and Pearse, 1955)

The observation by Eränkö (1955) that noradrenaline-containing cells in the adrenal medulla showed a bright green fluorescence following fixation in aqueous formalin was the first report on the demonstration of catecholamines by fluorescence microscopy However because of diffusion of the amines from the cells into the fixation medium, the sensitivity of the technique was poor Thus, noradrenaline could not be demonstrated in adrenergic neurons, and it became necessary to reduce the diffusion artifacts.

Although many observations indicated that formaldehyde could react with certain biogenic amines forming highly fluorescent condensation products (see also Hess and Udenfriend, 1959) the procedure employing aqueous formaldehyde for the histochemical detection of 5-HT in enterochromaffin cells and catecholamines in adrenal medulla had a low sensitivity which in no way made it superior to other existing methods for the histochemical detection of 5-HT and catecholamines. Moreover the specificity of the formalin method was unexplored and the chemical mechanism underlying the reaction was poorly understood. At this point Falck and Hillarp developed the gaseous formaldehyde condensation technique which resulted in a break-through in the histochemistry of 5-HT and catecholamines (Falck and Torp 1961 Falck, 1962 Falck, Hillarp Thieme and Torp 1962) By adequate freeze-drying followed by treatment with formaldehyde gas they were able to devise a method, which would prove to have a sensitivity and reproducibility superior to all previous methods, and which for the first time permitted the demonstration of noradrenaline in nerve terminals (for a description of the procedure as currently used see Falck and Owman 1965 Corrodi and Jonsson 1967) The chemical mechanism of the reaction between formaldehyde and these biogenic monoami-

nes was elucidated by Corrodi, Hillarp and Jonsson in a series of communications (Corrodi and Hillarp 1963 1964 Corrodi Hillarp and Jonsson 1964 Corrodi and Jonsson 1965a and b 1966 Jonsson 1967a, b and c) which gave a solid theoretical basis for the practical application of the histochemical technique. Their studies provided a starting point for further investigations on the complex condensation reaction (Axelsson Björklund and Håkanson 1970) and also for perfecting the method to permit the histochemical detection of previously non-detectable amines, such as tryptamine (Björklund Falck and Håkanson 1968)

It could be established that the formation of the fluorophores takes place as a sequence of reactions, which involves an initial Pictet-Spengler condensation, followed by secondary dehydrogenation reactions (Fig 4) In the first step, the catecholamines and indolamines are transformed into tetrahydroisoquinolines and tetrahydro-β-carbolines, respectively these derivatives are believed to be non-fluorescent or only weakly fluorescent. In a second step the condensation products are oxidized (dehydrogenated) to strongly fluorescent end products, the catecholamine fluorophores emitting a green fluorescence (emission max. 480 mμ) and the 5-HT fluorophore a yellow fluorescence (emission max. 535 mμ) The dehydrogenation reactions are catalyzed by protein (see Jonsson 1967b) and seem to proceed particularly fast if the monoamines are enclosed in a solid matrix *e.g.* in freeze-dried tissues or in a protein film. This second step can be controlled to some extent by manipulation of the oxidizing capacity of the reaction milieu and this has been utilized to give higher sensitivity and specificity to the reaction (Björklund Falck and Håkanson 1968 1969) Many aspects of the various reactions involved are still poorly understood. Recently silica gel thin layers have been introduced as a model system for the condensation reaction (Aures, Björklund and Håkanson 1968 Aures Fleming and Håkanson 1968 Björklund, Falck and Håkanson 1970a) and this has aided in the further elucidation of the reaction sequence. With this technique, it has been established that the fluorophores resulting from formaldehyde condensation of the various indolamines and catecholamines are heterogenous and consist of a number of fluorophores with different fluorescence colours and fluorescence intensities (Axelsson Björklund and Håkanson 1970)

The histochemical method of Falck and Hillarp has enormously increased our knowledge of adrenergic and tryptaminergic structures, and it has also been used for the cytochemical and cytopharmacological characterization of numerous nervous and endocrine cell systems (see *e.g.* review by Hillarp Dahlström and Fuxe, 1966 Falck and Owman 1968)

Histamine Schauer and Werle (1959) were first to suggest a technique for the histochemical detection of histamine. This technique was based on the ability of histamine to form a precipitate with Reinecke salt. The histamine-Reineckat in the tissue could then be stained with diazotized sulfanilic acid. The specificity of the method has not been fully established but its sensitivity

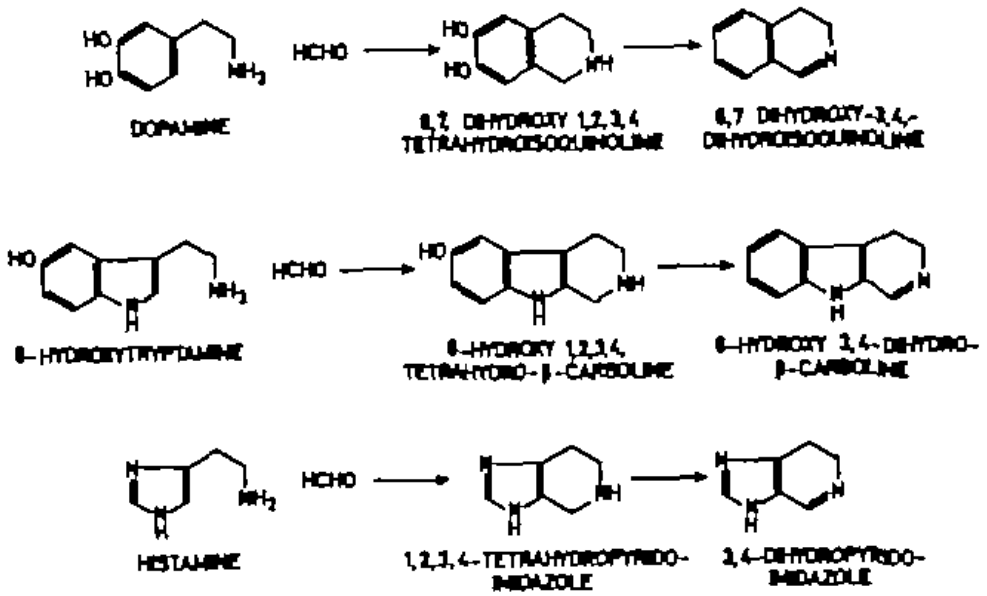

Fig 4 Proposed reaction scheme for the condensation of dopamine, 5-hydroxytryptamine and histamine with formaldehyde, and for the subsequent dehydrogenation of the condensation products. For dopamine and 5-hydroxytryptamine this sequence of reactions leads to highly fluorescent products. Histamine, however does not seem to yield fluorophores with formaldehyde, although it may condense along the route indicated.

appears to be adequate for the detection of mast cell histamine in spreads of rat mesentery The technique has not been widely used.

The treatment of freeze-dried tissues with paraformaldehyde vapour was suggested by Lagunoff Phillips and Benditt (1961) for the demonstration of mast cell histamine by fluorescence microscopy From observations on the fluorescence of solid histamine (pure crystals) after formaldehyde treatment, Lagunoff Phillips and Benditt suggested that the fluorescence exhibited by rat mast cells was due to histamine and caused by the formation of tetrahydropyridoimidazole (Fig 4) Also Van Orden (1966) studied the condensation of histamine with gaseous formaldehyde and claimed that fluorescence of fairly high intensity was observed after this reaction. Characterization of the fluorophore by microspectrofluorometry revealed excitation max. at 365 mμ and emission max. at 440 mμ the fluorophore was believed to be dihydropyridoimidazole (Fig 4) These results have not been confirmed in our laboratory It is possible that formaldehyde condenses with histamine (see Dale and Dudley 1921) but the resulting condensate seems to emit fluorescence of low intensity only (Björklund Håkanson and Sporrong unpublished observation) Moreover there is no evidence of formaldehyde induced fluorophore formation in tissues, which can be attributed to histamine-storing cells. The fluorescence observed by Lagunoff Phillips and Benditt (1961) in rat mast cells was probably not due to histamine but to 5 HT Dog mast cells which contain histamine but are devoid of 5-HT gave no fluorescence.

In 1966 JUHLIN and SHELLEY introduced another technique for the histochemical detection of histamine. They applied *o*-phthaldialdehyde (OPT) dissolved in xylene onto fresh cryostat sections, and, as a result, were able to demonstrate intense fluorescence in mast cells. The OPT method, as described by JUHLIN and SHELLEY did not reveal with certainty any other histamine-containing cell system besides mast cells. Independently two other groups had been working on the application of OPT as a histochemical detection reagent for histamine. By adequate freeze-drying, strictly anhydrous procedures and the use of gaseous OPT it could be shown that OPT induces fluorescence in mast cells (EHINGER and THUNBERG 1967 AUREN *et al.*, 1968 HÅKANSON OWMAN and SPORRONG 1968a HÅKANSON LILJA and OWMAN 1969 HÅKANSON OWMAN SJÖBERG and SPORRONG 1969) rabbit thrombocytes, basophil leucocytes (EHINGER and THUNBERG 1967) and also in several epithelial cell systems, such as the enterochromaffin-like cells of the rat and mouse stomach (EHINGER and THUNBERG, 1967 HÅKANSON and OWMAN 1967 HÅKANSON OWMAN and SJÖBERG 1967 THUNBERG 1967) rat pinealocytes (HÅKANSON LINDSTRAND OWMAN and TVERRING 1970c) pancreatic islet cells in the mouse, and certain unidentified cells in the pituitary (EHINGER, HÅKANSON OWMAN and SPORRONG 1968) * Unfortunately for unknown reasons the OPT method has been found unsatisfactory (high background fluorescence) in studies on brain (HÅKANSON OWMAN and SPORRONG unpublished observation) and the cellular localization of hypothalamic histamine is still unknown.

The enterochromaffin-like cells of murine gastric mucosa, on the other hand, have been extensively studied. The histochemical detection of histamine in epithelial cell systems is possible only with thoroughly dried tissue specimens (EHINGER and THUNBERG 1967 HÅKANSON and OWMAN 1967) Condensation with OPT however requires slight hydration, which unless carefully controlled, may cause diffusion of the fluorophore. Thus, to avoid diffusion artifacts either of the following two procedures is applied 1) Freeze-dried cryostat sections cut at temperatures below —30 C are exposed to OPT gas at room temperature for 1—2 min. This treatment is followed by gentle hydration under controlled conditions. As a consequence, an intense fluorescence appears in mast cells as well as in some epithelial cell systems (EHINGER and THUNBERG 1967 HÅKANSON and OWMAN 1967 THUNBERG, 1967) 2) Sections from freeze-dried, paraffin-embedded specimens are deparaffinized and then treated as under 1) with identical results (EHINGER, *et al.*, 1968) However since under certain conditions OPT reacts with a number of biogenic compounds, forming fluorophores with several, it may be argued that the specificity of this histochemical reagent is poor When properly

* In at least one of these cell systems (rat pineal) the fluorogenic compound has been shown to be different from histamine and from all other known OPT reactive compounds (Håkanson, Lindstrand, Owman and Tverring, 1970; see also the report by Ohman and Shelley 1968, on the OPT induced fluorescence in the retina)

performed, however the OPT method may well have a specificity similar to that of the formaldehyde method. With both these histochemical techniques the primary requisite is that the compound to be demonstrated should occur accumulated in sufficiently high concentrations at specific cellular sites. This requirement is sometimes fulfilled by biogenic amines, which often occur in special cells of limited distribution and often are stored in granular storage sites.

From model experiments it may be concluded that apart from histamine and histidine, other known OPT reactive biogenic compounds give poor fluorescence under the conditions used (Ehinger and Thunberg 1967) * Moreover those compounds that give an OPT induced fluorescence can be distinguished from histamine by the spectral characteristics of the resulting fluorophores (Ehinger and Thunberg 1967 Håkanson Juhlin Owman and Sporrong 1970a)

The specificity of the OPT technique as a method for detecting cellular histamine has to be verified chemically pharmacologically or otherwise in each individual case (see Ehinger and Thunberg 1967 Håkanson and Owman 1967 Håkanson Owman and Sjöberg 1967 Thunberg 1967 Håkanson *et al.* 1970a) One disadvantage here is that also the conventional chemical assay of histamine involves OPT as reagent which limits its usefulness as a means for identification of the OPT reactive tissue component. Another difficulty is the finding that the OPT induced fluorescence in tissues sections may appear in either a blue or yellow form (Ehinger and Thunberg 1967 Håkanson *et al.*, 1970a) Mast cells are usually yellow whereas fluorescing epithelial cells are blue. This is not due to inadvertent variations in experimental conditions, since the two flurophores may appear in one and the same tissue section. In recent studies using histamine on silica gel thin-layers and in protein droplets as models, it could be established that the OPT induced fluorescence changes in colour from blue to yellow as the concentration of histamine was increased This concentration-dependent red-shift has been studied by microspectrofluorometry (Håkanson *et al.*, 1970a) The blue fluorophore was maximally excited at 36 mμ and had its emission max. at 420—430 mμ the corresponding values for the yellow fluorophore was 405 mμ and 540—550 mμ (see also Ehinger and Thunberg 1967) Microspectrofluorometric analysis of OPT reactive gastric epithelial cells showed that the properties of their fluorophore were similar to those of the blue fluorophore in the model systems whereas the OPT-induced fluorophore of mast cells usually resembled the yellow fluorophore (Håkanson *et al.* 1970a) The difference in fluorescence colour between mast

* Indole compounds which under aqueous conditions and at extremely acid pH are known to form fluorophores with OPT (Maickel and Miller 1966) do not give any fluorescence under the conditions of the histochemical OPT technique. Spermidine, moreover which occurs in high concentrations in the central nervous system (Michaelson, 1967) does not seem to interfere with the histochemical detection of histamine in peripheral tissues (Ehinger and Thunberg, 1967 Håkanson and Owman, unpublished observations)

cells and certain gastric epithelial cells may reflect markedly different histamine concentrations in the two cell systems in analogy with the observations in the model experiments. From this assumption a new principle for the quantitation of intracellular histamine has been suggested according to which the emission maximum (and/or excitation maximum) can be used as a parameter of the histamine concentration (HÅKANSON *et al* 1970a)

2.4 *Conventional light microscopy*

Silver stains Silver impregnation has proved useful for the demonstration of cytoplasmic granules in certain epithelial cells. Such techniques can be divided in two main groups those in which no reducing agents are added (*e g* the FONTANA and MASSON HAMPERL techniques, cf PEARSE, 1960) and in which consequently endogenous compounds in the cytoplasm reduce the silver in an ammoniacal silver salt solution and those in which the silver salt is reduced by the addition of a reducing agent (BONIAN GRIMELIUS) the metallic silver forms precipitates, selectively impregnating the granules. In the first case the reacting cells are referred to as argentaffin in the second as argyrophil, although strictly both words have the same meaning To add to the confusion the term argentophil is sometimes used as a synonym for argyrophil There is a fundamental difference between the argentaffin and argyrophil reactions in that the former is brought about by the reducing capacity of a tissue component (such as 5-HT and catecholamines) and the latter by the addition of an extraneous reducer Argentaffin cells are usually also argyrophil, but argyrophil cells may very well be—and often are—non-argentaffin.

The argyrophil reaction, *i.e* the black to brown cytoplasmic granules seen on light microscopy corresponds on the ultrastructural level to secretory granules, to which the silver particles are localized. What chemical or physico-chemical factor that give rise to this formation of silver precipitates is unknown. All these techniques have been developed empirically

Mast cell stain Mast cells are recognized by their metachromasia after staining with toluidine blue in ethanol solution (cf ROMEIS 1948)

Parietal cell stain. Parietal cells and chief cells were stained by haemalun-Congo red stain (cf *ROMEIS 1948*)

Mucous neck cell stain. Mucoid cells were recognized by the PAS-stain (cf. PEARSE, 1960)

3 PROPERTIES OF ENTEROCHROMAFFIN AND ENTEROCHROMAFFIN LIKE CELLS

3 1 *The concept of the enterochromaffin system*

In 1870 HEIDENHAIN described small cells in the gastric mucosa of dogs and rabbits which became stained after fixation with solutions containing dichromate. Such cells were demonstrated by TOLDT (1880) and NICOLAS (1891) also in other species. CIACCIO (1906) reported that the staining properties of these chromaffin cells of the gut were similar to those of the chromaffin cells of the adrenal medulla and introduced the term enterochromaffin cells.

Enterochromaffin cells have also been referred to as the KULTSCHITZKY SCHMIDT CIACCIO or MASSON cells (see *e g* PENTTILÄ, 1966) Because of their characteristic granular cytoplasm, KAUFMANN WOLF (1911) introduced the term basal granular cells ("basalgekörnte Zellen") Mostly however the cells were named after their staining properties. KULL (1925) used the term chromaffin cells, and CORDIER (1926) referred to this cell type as chromoargentaffin cells. Silver reactions were soon found to be important for the demonstration of this type of cells. MASSON (1914) was first to use the term argentaffin to characterize those cells which reduced ammoniacal silver salts. Later HAMPERL (193? 1952) and ERSPAMER (1937) introduced the terms argyrophil and argentophil respectively for epithelial cells which accumulated cytoplasmic silver deposits in the presence of reducing agents. According to the initial definition of ERSPAMER (ERSPAMER, 1937a and b see also VIALLI, 1966) the enterochromaffin cell system consists of all cells hypothetically derived from the primary gut and giving the chromaffin reaction, and also of cells showing the same morphology and reactivity to argyrophilic stains. The argentaffin and/or argyrophilic character of these cells is believed to be a particularly important distinction. With the aid of these two types of silver reactions, ERSPAMER (1937a 1938) and VIALLI and ERSPAMER (1939) divided the cells of the enterochromaffin system into four classes 1) pre-enterochromaffin, non-argyrophil, ?) pre-enterochromaffin, argyrophil, 3) enterochromaffin cell proper argentaffin 4) empty enterochromaffin, argyrophil or non-argyrophil cell. This classification claimed to represent the various successive tages in the maturation (or in the functional cycle) of the enterochromaffin cells. The existence of types 1 and 4 has not been established unequivocally

The peculiar cytochemical characteristic which is reflected in the chromaffinity and argentaffinity of some of these cells resulted in many theories about the chemical identity of the reacting substance in their cytoplasm. ERSPAMER and co-workers (ERSPAMER and BORETTI, 1950 1951 ERSPAMER and ASERO, 1952a, b ERSPAMER, 1953 1954a, b 1958) presented evidence indicating that 5-HT was the specific reducing agent in the enterochromaffin cells. This hypothesis has been confirmed in subsequent investigations (see section 3.2.)

True enterochromaffin cells can be stained with a number of staining reactions, such as the argyrophil, argentaffin, ferric ferricyanide, diazo coupling and indophenol reactions. All the latter four stains detect 5-HT when present in sufficient amounts. The true enterochromaffin cell (type 3) is the only member of the enterochromaffin system which contains 5-HT in quantities that can be revealed by histochemistry.

The concept of the enterochromaffin system was later modified by ERSPAMER (1954a, 1958, 1961). He included in the enterochromaffin system all cells which, after formalin fixation, give a chromaffin and argentaffin reaction, and which are capable of coupling with diazonium salts and of showing a formalin-induced fluorescence. According to this definition, the basic criterion deciding whether a cell belongs in the system or not is the histochemical demonstration of 5-HT (or similar reducing compounds) in the cell. Consequently ERSPAMER (1961) included also the mast cells of the rat and mouse, which are rich in 5-HT (BENDITT, WOOD, ARASE and ROEPER, 1955; BENDITT, 1958), while excluding the argyrophil, non-argentaffin cells, which are morphologically indistinguishable from the argentaffin (enterochromaffin) cells, but devoid of 5-HT. From a physiological point of view this seems unfounded. The argyrophil, argentaffin and the argyrophil, non-argentaffin cells of the gastrointestinal mucosa may all have similar endocrine functions (see section 3.9).

3.2. *The typical enterochromaffin (argentaffin) cell*

Enterochromaffin cells are not readily recognized by conventional staining methods such as haematoxylin-eosin: the cytoplasm is clear and only slightly stainable; the dimension and shape of the nucleus are not different from the nuclei of adjacent cells.

The typical "true" enterochromaffin (argentaffin) cell, i.e. type 3 according to the classification of ERSPAMER (1937a, 1938), is identified by the presence of granules of particular shape and by all those histochemical characteristics which ERSPAMER described in 1954. The shape of the cells is somewhat variable; in general they are flask-shaped, being larger at the base, where the nucleus is situated. At times the base protrudes somewhat with respect to neighbouring cells, modifying the arrangement of the basement membrane; sometimes processes extend sideways from the basal portion of the cell. Towards the apical extremity the cell always becomes more narrow and in many cases exhibits a thin process which may extend towards the glandular lumen in between neighbouring epithelial cells. The granules are the most prominent characteristic of the enterochromaffin cell. From a morphological point of view they are perfectly distinguishable from the granules present in other cell types, such as PANETH's cells and the mucoid cells of the gastric epithelium (see section 3.8 on ultrastructure). In the light microscope, the granules (revealed by the silver precipitates) are minute and stand out more or less clearly against the cytoplasm. Normally they cluster more densely in the infranuclear portion of the cell; towards the apex they may or may not be present.

The enterochromaffin granules give strong chromaffin and argentaffin reactions, which gave the first clue towards identification of the enterochromaffin substance. The classical chromaffin reaction, first described by HENLE (1865) in the adrenal medulla, is—like the argentaffin reaction—believed to reflect a high concentration of reducing agents, such as *e.g.* catecholamines and 5-HT. However numerous other substances besides these amines may react with chromium solutions to form brownish pigments (see COUPLAND 1954, HALE, 1958, PEARSE, 1960). In 1940 ERSPAMER observed that acetone extracts of the digestive tract were biologically active; he called the active substance enteramine. In 1952 and 1953 enteramine was identified as 5-HT (ERSPAMER and ASERO, 1952b; DALGLIESH, TOH and WORK, 1953) on the basis of its pharmacological actions and its chromatographic properties. Since 5-HT is capable of giving a positive argentaffin and chromaffin reaction, this finding suggested that 5-HT was the specific reducing substance of the enterochromaffin cells.

The formalin-induced fluorescence exhibited after excitation with ultraviolet light is one of the characteristics of the enterochromaffin cell. An interpretation of the chemical mechanism behind this fluorescence was formulated by BAETER and PEARSE (1953, 1955) and by PEARSE (1956, 1960). The fluorescence is due to a β-carbolin resulting from the condensation of 5-HT with formaldehyde. According to VIALLI and TRAVERSO (1960) the β-carbolin compound resulting from formalin treatment of 5-HT is not an end-product but may be further converted by oxidation (see section 2.3). This assumption has since been confirmed (CORRODI and JONSSON 1965b; BJÖRKLUND, FALCK and HÅKANSON 1968; see also HESS and UDENFRIEND 1959). CASELLA and REGOLIANI (1946, 1949) were first to analyze the formalin-induced fluorophor of the enterochromaffin cells and gave the emission max. at 535 mμ. Using the FALCK-HILLARP technique, NOSEKBO (1964) described cells with an intense yellow fluorescence, typical of 5-HT, in the intestinal mucosa of the rat and cat. These cells were found to be identical with the 5-HT-containing enterochromaffin cells (PENTTILÄ 1966). The yellow formaldehyde-induced fluorophore in the gastrointestinal enterochromaffin cells has been analyzed by microspectrofluorometry which revealed an excitation maximum at 405 mμ and an emission maximum at 535 mμ (VIALLI and PRENNA, 1969; HÅKANSON *et al* 1970d). The spectral properties of the fluorophore agreed very well with those of authentic 5-HT in various model systems after treatment with gaseous formaldehyde (cf. *e.g.* AURES, BJÖRKLUND and HÅKANSON 1968; BJÖRKLUND, FALCK and HÅKANSON 1968; BJÖRKLUND, FALCK and HÅKANSON 1970a). *In the present study all gastric epithelial cells exhibiting a formaldehyde-induced fluorescence have been classified as enterochromaffin.*

3.3 *Distribution and properties of enterochromaffin cells in gastric mucosa*

Enterochromaffin cells are widely distributed in the epithelium of organs and ducts derived from the primitive gut: the trachea, gastrointestinal tract, biliary tract, pancreatic ducts, prostate and vagina (VIALLI, 1966; FALCK and OWMAN

1968) After the observation of the association between 5-HT and enterochromaffin cells, Erspamer (1953 1954a, b) and others (Feldberg and Toh, 1953 Rennick and Gray 1961 Jacobsson and Stacey 1962 Kalinoman Kardaman and Haber, 1964 Schofield Ho and Southwell, 1967) charted the distribution of 5-HT in the digestive tract of a number of species. The distribution between various parts of the gastrointestinal tract differed widely among the species, but there was regularly a striking parallelism between the distribution of 5-HT and of the enterochromaffin cells. (The rat and mouse were exceptional in that a quite considerable portion of the bowel 5-HT was found to be stored in mast cells.) Most of the data on enterochromaffin cells in the digestive tract concern the intestine only The investigations summarized in the present treatise deal specifically with their distribution in gastric mucosa (see Håkanson *et al* 1970d) In most species (*e.g* mouse, rat hamster dog, pig and man) enterochromaffin cells are present predominantly in the antropyloric mucosa. However there are species, *e.g* guinea pig and the cat, where they have a more uniform distribution in all regions of the stomach, and also species such as the rabbit where they are conspicuously more numerous in the oxyntic gland area (Fig 5) It should be noted that in the cat and rabbit enterochromaffin cells with a green formaldehyde-induced fluorescence (see definition of the enterochromaffin cell, section 3.2) have been recognized in addition to the classical type of yellow-fluorescent, 5-HT-containing enterochromaffin cells (Håkanson *et al*., 1970d) Microspectrofluorometric analysis according to the principle of Björklund Ehinger and Falck (1968) indicated that the green fluorescence in these cells was due to dopamine (Håkanson *et al*. 1970d) But also among conventional 5-HT-containing enterochromaffin cells sub-types have been observed Their sensitivity to the amine-depleting effect of reserpine is one of the factors which permit a distinction between various types of enterochromaffin cells. In the rabbit, one population of 5-HT-containing enterochromaffin cells is markedly affected by reserpine treatment, whereas another one responds not at all (Zbinden Pletscher and Studer, 1957 Pletscher, 1958 Håkanson *et al* 1970d)

3.4 *The typical enterochromaffin-like (argyrophil, non-argentaffin) cell*

In 1966 Håkanson and Owman observed by fluorescence microscopy (Falck Hillarp technique) a large population of green-fluorescent epithelial cells in the oxyntic gland area of rats, injected with L DOPA (Fig 6) * These cells

---

The rat stomach is made up of one glandular portion and one non-glandular portion, the rumen. The glandular portion is made up of two histologically different parts the pyloric gland rea (antrum) and the oxyntic gland area (sometimes referred to as the fundus, although this term is inadequate from strictly anatomical point of iew) In ou first publications in this fi ld (see Håkanson, 1965 Håkanson and Owman 1966b) w adopted the terminology of Schayer (1956 1957) in which the gland lar portion is referred to as the pyloric part and rumen is called the fundus. I our subsequent publications, histological rather than anatomical criteria have been used t characterize the various regions

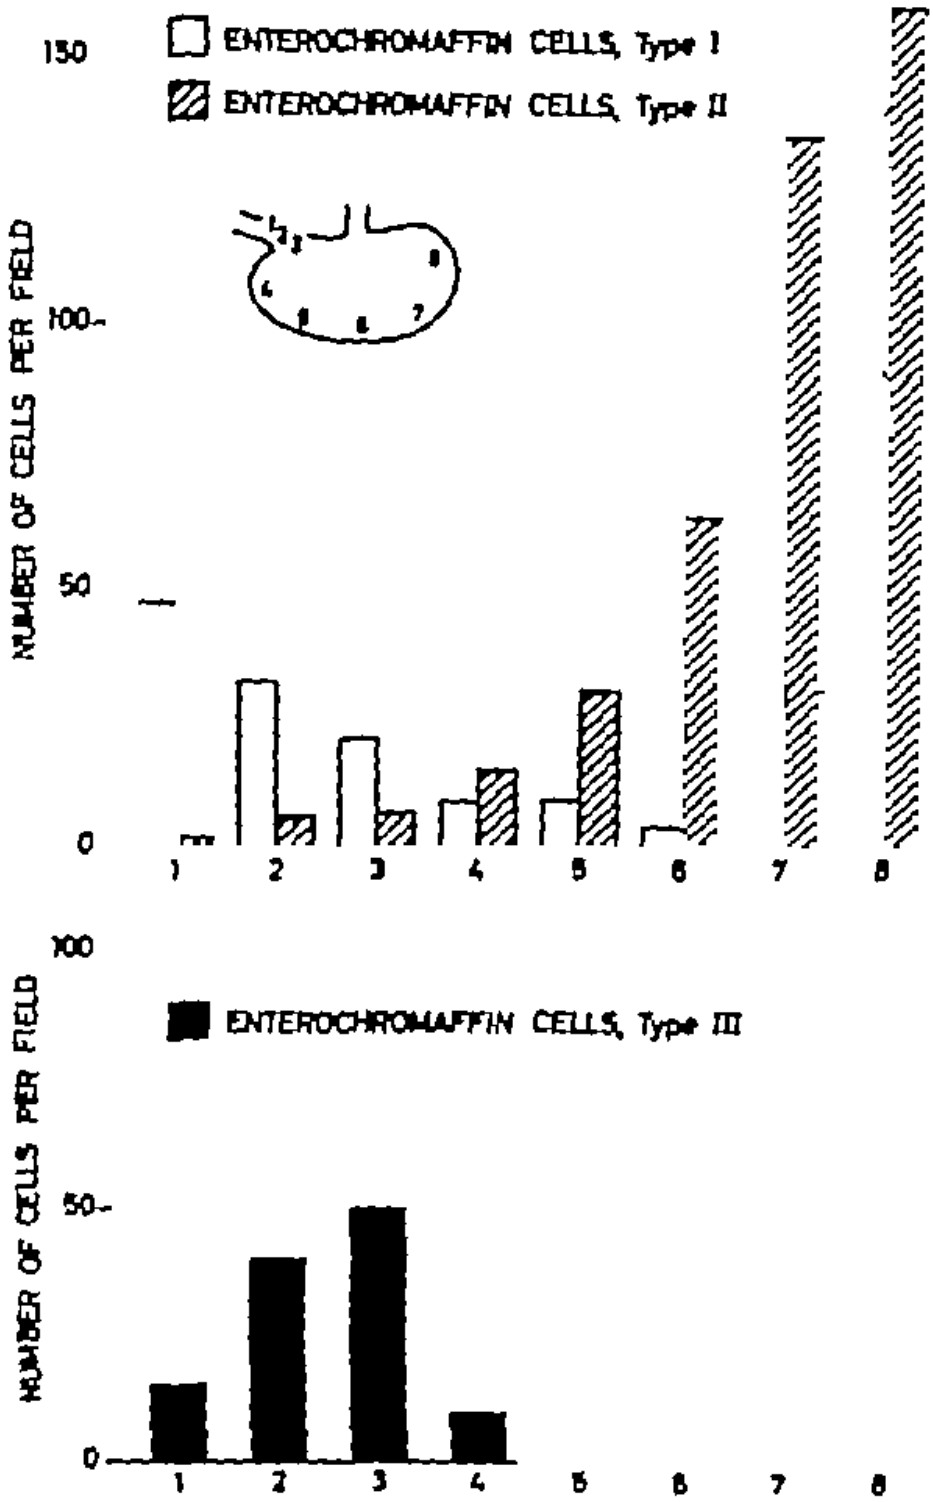

Fig. 5 Regional distribution of various types of enterochromaffin cells in the rabbit stomach. Treatment with reserpine revealed one reserpine-sensitive (Type I) and one reserpine-resistant (Type II) yellow-fluorescent enterochromaffin cell type. In addition, a third type of weakly greenish yellow enterochromaffin cells (Type III) was recognized. These cells may be identical with the enterochromaffin-like cells, which became intensely green-fluorescent after injection of DOPA (100—200 mg/kg) (For details see Håkanson et al. 1970d) Finally dopamine-containing, green-fluorescent enterochromaffin cells (Type IV) have also been demonstrated in gastric mucosa of th non-treated rabbit although few in number and with scatterred and irregular distribution.

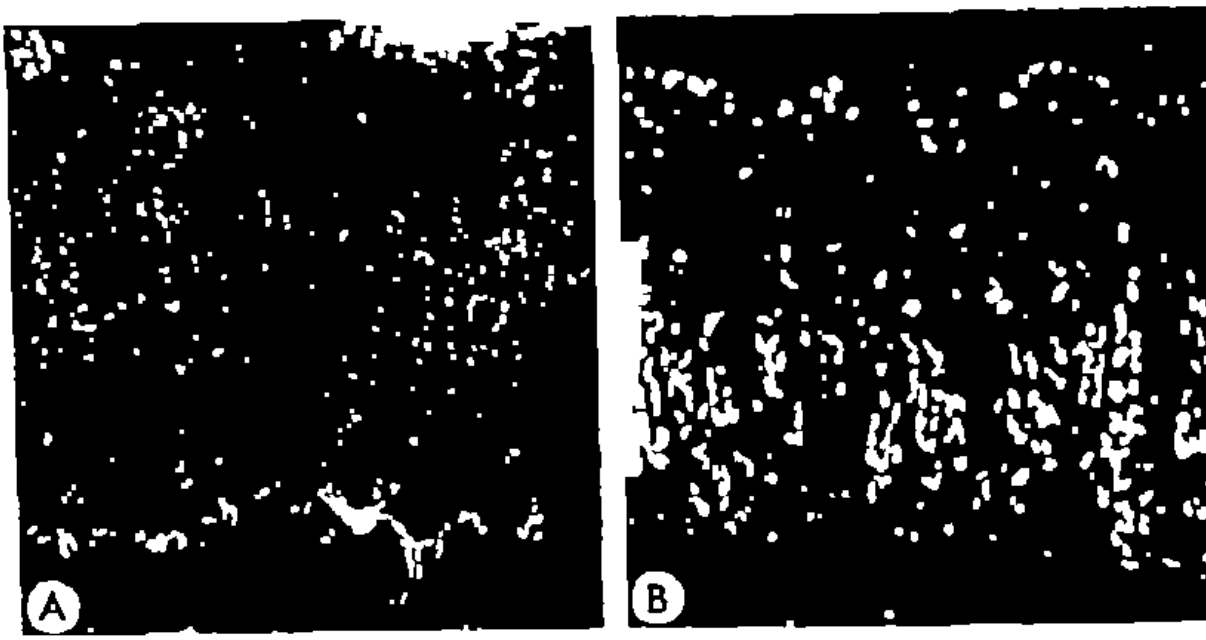

Fig. 6. Transverse sections, 100 x. Formaldehyde reaction (A) N pretreatment. Fl orescent adrenergic nerves around essel in submucosa. Mast cell with specific yellow fluorescence scattered in the submucosa, the muscle coat and t the surface of the mucosa. The glandular epithelium contains large amounts f min te granules with autofluorescence. (B) Pretreatment with L DOPA (intraperitoneal i jection, 100 mg/kg the animal was sacrificed 2 hr after injection) After this treatment numerous green-fluorescent enterochromaffin-like cells are visible in the basal part of the mucosa. Mast cell now with green fluorescence, are seen near the mucosal surface

were morphologically very similar to the yellow fluorescent 5 HT-containing enterochromaffin cells of the pyloric gland area and they were thus referred to as enterochromaffin like. It was found that the injection of L-DOPA resulted in the simultaneous accumulation of dopamine in the oxyntic gland area of the stomach (HÅKANSON 1965 HÅKANSON and OWMAN 1966b) This indicated that the green fluorescence observed in the enterochromaffin-like cells reflected the presence of dopamine rather than of DOPA, an assumption which was confirmed in subsequent studies (HÅKANSON LILJA and OWMAN 1967) It could be shown that pretreatment with DOPA decarboxylase inhibitors marked! reduced the fluorescence intensity of the enterochromaffin-like cells. Moreover administration of large amounts of dopamine failed to induce any fluorescence in these cells, indicating that the dopamine, which accumulates after L DOPA treatment, results from decarboxylation *in situ* In control rats, no fluorogenic amine could be demonstrated by the formaldehyde technique in the enterochromaffin-like cells, and dopamine was not chemically detectable. After this initial observation in the rat, a similar cell system was observed in the gastric mucosa of the mouse, hamster guinea pig, rabbit, cat, dog, pig and man (see HÅKANSON *et al.* 1970d) and it could be established that these cell were argyrophil (Fig 7) but not argentaffin in contrast to the enterochromaffin cells, which were both argyrophil and argentaffin.

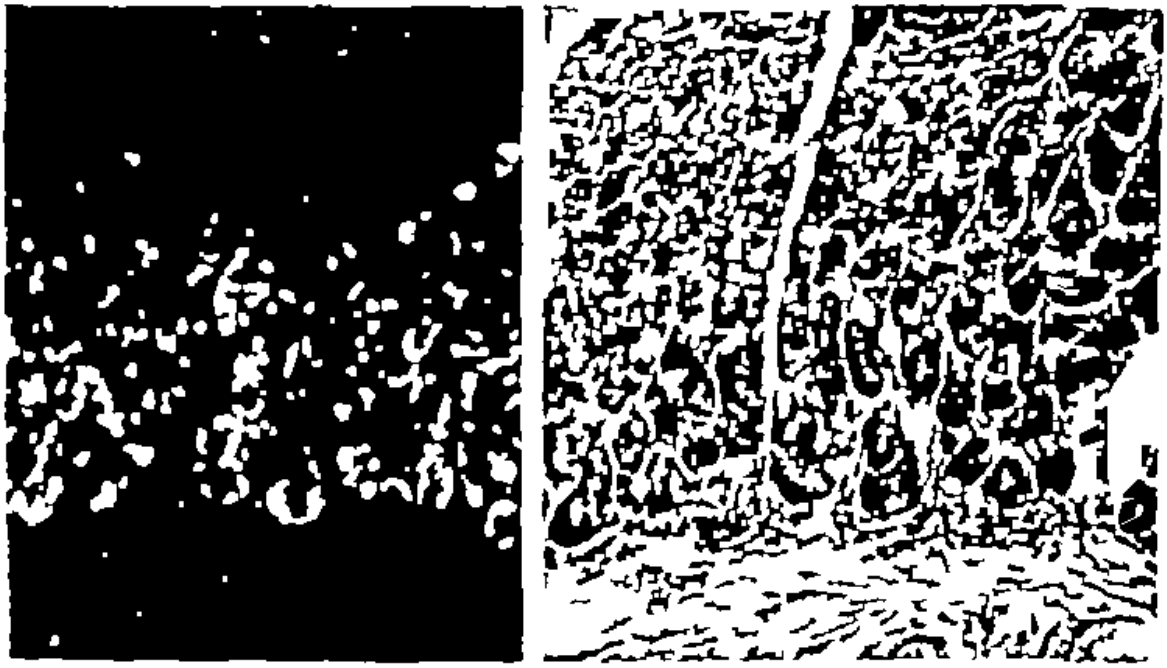

Fig. 7 Photomicrographs of rat stomach wall oxyntic gland area. Transverse section, 115 x. Pretreatment with L DOPA. Formaldehyde condensation (left) Fluorescent mast cells near the mucosal surface and in the submucosa. In the basal part of the mucosa an extensive system of fluorescent enterochromaffin-like cells. The section was subsequently silver-impregnated (right) to show the agreement between the enterochromaffin-like cells and the argyrophil cells.

The *enterochromaffin-like cell* may be defined as follows *It is an epithelial argyrophil but non-argentaffin cell morphologically indistinguishable from the usual type of 5-HT-containing enterochromaffin (argentaffin) cell but devoid of 5-HT and catecholamines and consequently not detectable by the fluorescence microscopic procedure of* FALCK *and* HILLARP *after treatment of the animal with* L *DOPA however these cells which now contain dopamine can be readily detected by their green fluorescence* Usually the yellow fluorescent, 5-HT-containing enterochromaffin cells retain their yellow fluorescence also after the administration of L DOPA (HÅKANSON *et al* 1970d) indicating that their 5-HT stores are unaffected by this treatment. In addition, the enterochromaffin-like cells in the oxyntic gland area of the rat and mouse contain histamine (HÅKANSON and OWMAN 1967 HÅKANSON OWMAN and SJÖBERG 1967) which has been established by means of the histochemical OPT technique (Fig 8) In no other species has histamine been detected in the enterochromaffin-like cells (AURES HÅKANSON OWMAN and SPORRONG, 1968 HÅKANSON LILJA and OWMAN 1969 HÅKANSON *et al.* 1970d) Recent observations on the enterochromaffin-like cells in the gastric mucosa of the rabbit suggest that they contain an amine, which reacts with formaldehyde, giving a very weak greenish-yellow fluorescence. The amine responsible for this fluorescence has not yet been identified (HÅKANSON *et al* 1970d)

The observation that the argyrophil, non-argentaffin cells are capable of tak

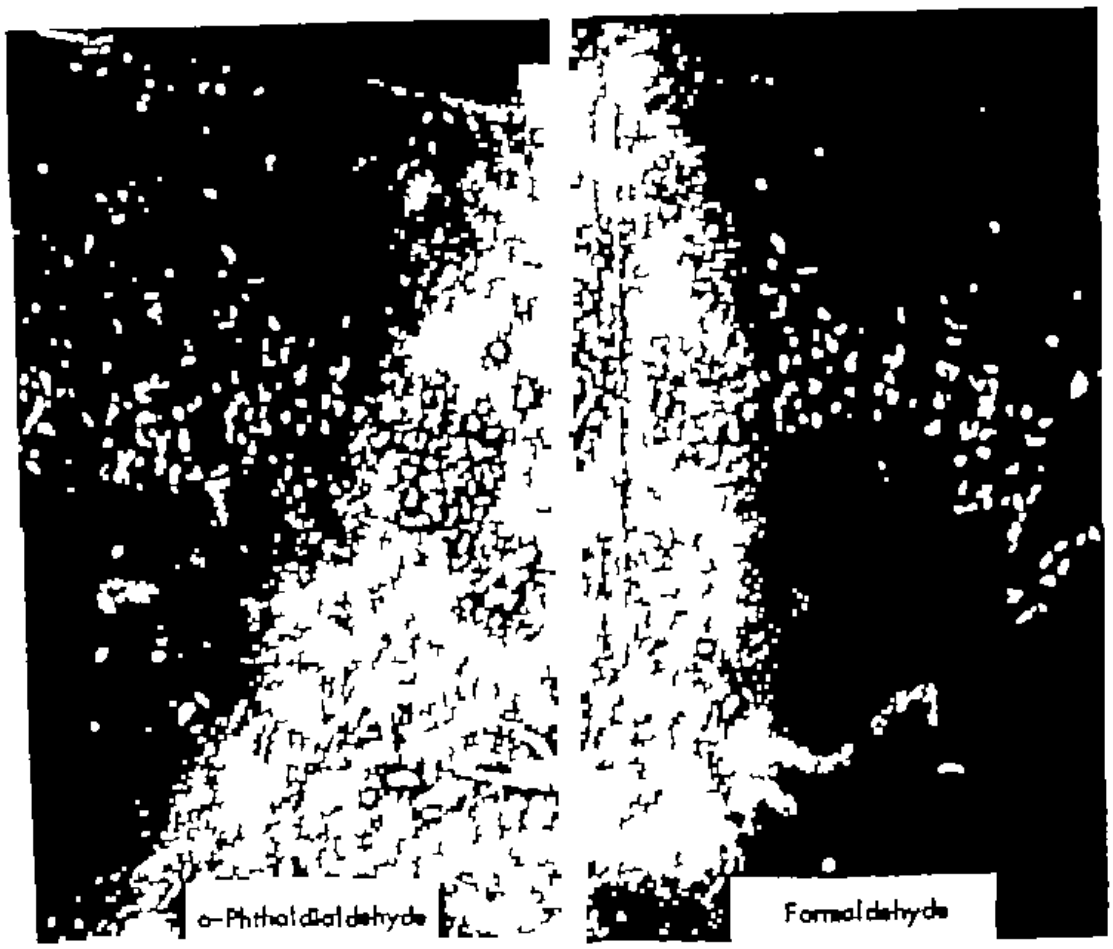

Fig. 8. Fluorescence photomicrograph of rat stomach wall, oxyntic gland area. Transverse section, 1.5 μ. Pretreatment with L-DOPA. Specimens were sectioned in a cryostat (−36° C). The same section was first treated with gaseous o-phthaldialdehyde to demonstrate the histamine-containing enterochromaffin-like cells. Most cells at the surface of the mucosa and the submucosa were found to contain both histamine and 5-hydroxytryptamine. The histamine-containing cells in the gastric epithelium (left) were found to be identical with the enterochromaffin-like cells (right). The formaldehyde treatment abolished the o-phthaldialdehyde induced fluorescence as was seen when sections from control rats (not given L-DOPA) were subjected to the same histochemical procedures.

ing up and decarboxylating certain aromatic amino acids was novel and introduced the idea that amine mechanisms may operate also in those enterochromaffin-like cells where amines have not yet been demonstrated. It was soon realized (Håkanson and Owman 1969) that the capacity to produce and store amines such as 5-HT and dopamine was characteristic of the cells earlier described in gastric mucosa by Dawson (1944, 1945, 1948) and designated as argentophil (i.e. argyrophil) cells. The granules of these cells reacted readily with the Bodian protargol method. They could not be detected with the Masson Hamperl silver method, which selectively stains argentaffin cells.

The argyrophil but non argentaffin cell of gastric mucosa has the same morphological appearance as the typical enterochromaffin cell, but it lacks many of its histochemical characteristics. The problem of the relationship between

the argentaffin and the argyrophil non-argentaffin cell types is still unsolved. Erspamer (1938) and Hamperl (1952) maintained that the argyrophil cell is a potential enterochromaffin (argentaffin) cell and may remain argyrophil or develop into a true enterochromaffin cell. Clara (1957) however believed that only a proportion of the argyrophil cells could be regarded as precursors of the enterochromaffin cells. This view is supported by recent observations by Håkanson and Owman (1969) (see section 3.5)

3.5 *Distribution and properties of enterochromaffin-like cells in gastric mucosa*

In the rat argyrophil enterochromaffin-like cells were found to be numerous in the mucosa of the oxyntic gland area and were associated chiefly with the deeper halves of the gastric glands (Fig 9) Scattered cells were also present in the pylorus and a few cells were seen in the cardiac region (Håkanson Lilja and Owman 1967) When the Masson Hamperl technique was applied to the gastric mucosa of the rat it was found that only the cells in the cardiac and pyloric zones were stained. This indicated that the numerous cells of the oxyntic gland area were not argentaffin in nature but argyrophil (Håkanson and Owman 1969) Thus, argentaffin cells occur in relatively small numbers in the rat stomach and are limited primarily to the pylorus.

The striking differences in the distribution of these two classes of cells in mammals (see Table 1 and Fig 11) are in discord with the concept of a secretory cycle from the argyrophil to the argentaffin stage, with the implicit belief that the argentaffin stage is the functionally significant one. Available evidence

TABLE 1

Regional distribution of enterochromaffin and enterochromaffin-like cells in the gastric mucosa of various mammals.

Species	Enterochromaffin cells		Enterochromaffin-like cells	
	Pyloric gland area	Oxyntic gland area	Pyloric gland area	Oxyntic gland area
Mouse	+	0	(+)	+++
Rat	++	0	0	++++
Guinea-pig	+++	++	(+)	+
Hamster	++	(+)	(+)	++
Rabbit	+(+)	++++	+	++
Cat	+	(+)	+(+)	+(+)
Dog	++	(+)	++	(+)
Pig	+++	++	+++++	++
Monkey	+	+	+	+(+)
Man	++	(+)	++	(+)

The tissue specimens analyzed were taken from the greater curvature as indicated in Fig. 5 The amount of enterochromaffin and enterochromaffin-like cells in the two stomach areas is expressed arbitrarily from 0 to +++++ as a measure of the number of such cells in the mucosa. It should be realized that the distribution of the enterochromaffin and enterochromaffin-like cells usually does not agree with the conventional histological division of the gastric mucosa into oxyntic, pyloric and cardiac gland areas, and so that these cells usually are not uniformly distributed in the region of predominance.

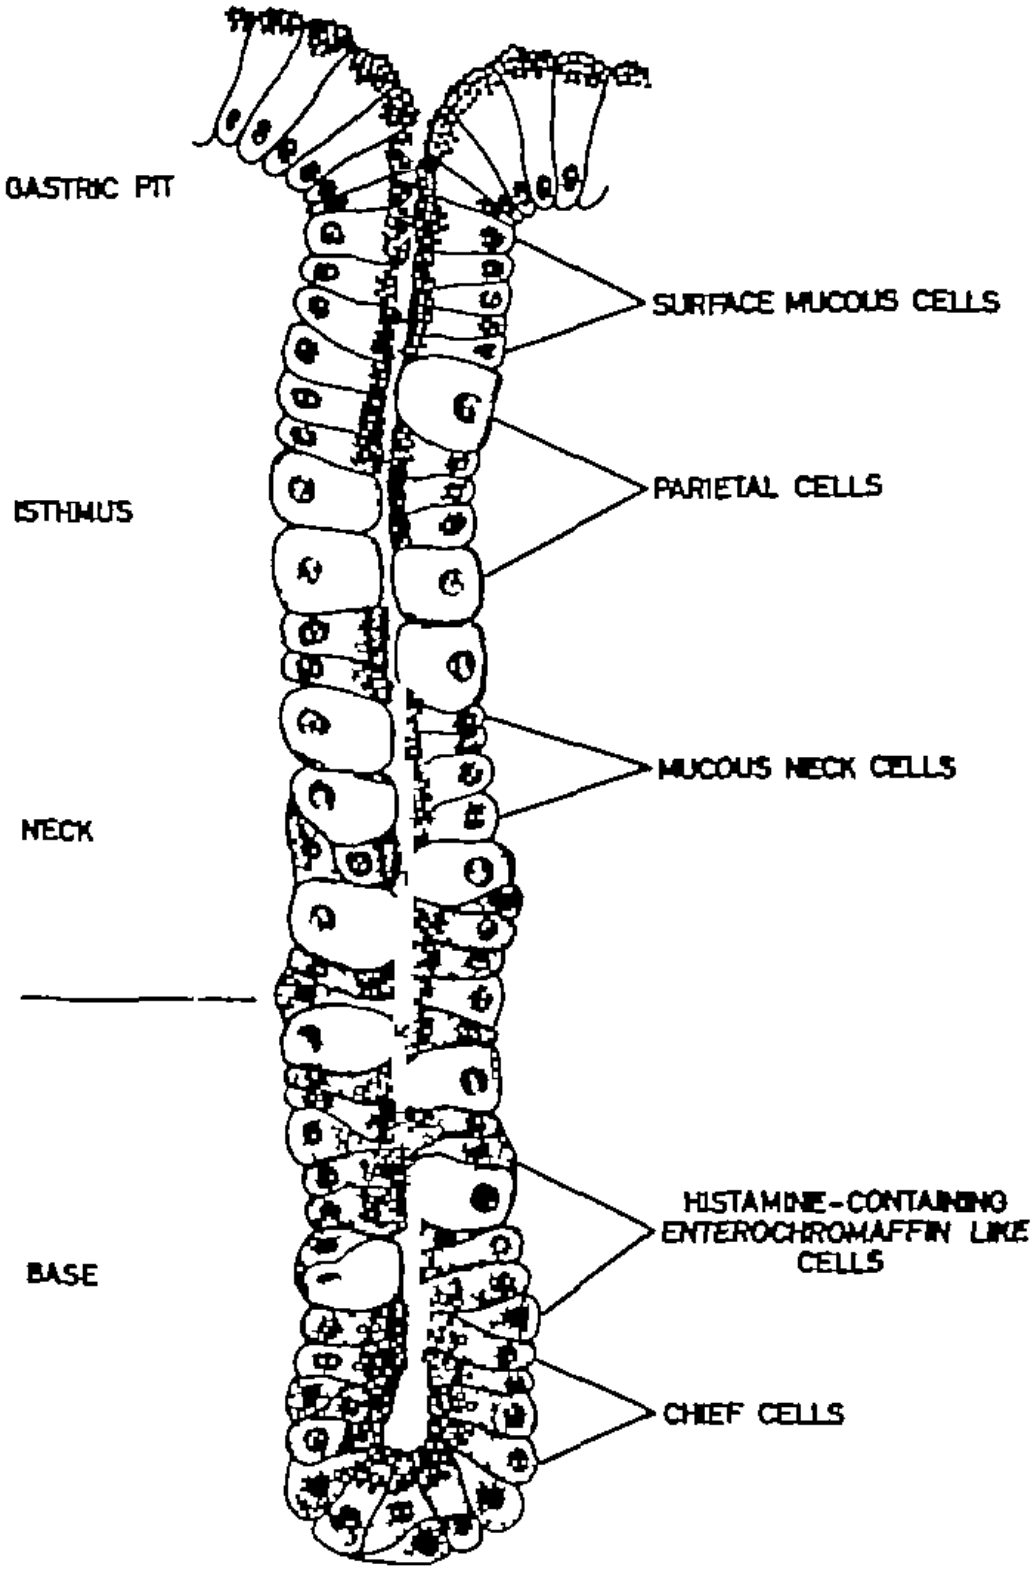

Fig. 9 Topography of an oxyntic gland in the rat stomach (modified from Ito and Winchester 1963)

strongly suggests that at least some argyrophil cells exist throughout their life history without ever reaching an argentaffin stage (Håkanson and Owman

1969 HÅKANSON *et al* 1970d) This may be the case either in restricted regions of the digestive tract, such as in the stomach, or perhaps along the entire intestinal tract. Therefore the argyrophil cell may not always represent a stage in the secretory cycle of the argentaffin cell. On the contrary it may have a physiological role of its own, similar to but distinct from that of the argentaffin cell.

It is apparent that the conventional terminology is unsatisfactory in several respects. The terms enterochromaffin, enterochromaffin-like, argentaffin and argyrophil refer to purely histological or histochemical characteristics. The subdivision of cells of the enterochromaffin system into argentaffin and argyrophil is generally considered fundamental, and a hard line of distinction is drawn between them by most workers. However classifying the cells according to their reactions to different silver stains appears arbitrary and conceivably unrelated to the physiological roles of the cells (for a discussion see section 3.9)

3.6 *Amine mechanisms in enterochromaffin and enterochromaffin-like cells of gastric mucosa*

The classical system of enterochromaffin (argentaffin) cells is the major storage site for gastrointestinal 5-HT (cf VIALLI 1966) In addition to the conventional, 5-HT-containing enterochromaffin cells, which upon formaldehyde treatment exhibits a yellow fluorescence, morphologically similar cells in the gastric mucosa of the cat and rabbit have been found emitting a green formaldehyde-induced fluorescence suggesting the presence of a catecholamine. Chemical and microspectrofluorometric analysis revealed that the compound was in all probability identical with dopamine (HÅKANSON *et al*., 1970d) These cells have also been classified as enterochromaffin (see definition, section 3.2.) The pyloric gland area of the rabbit contains another (argyrophil) cell type with a very weak formaldehyde-induced, greenish yellow fluorescense Fig. 5 Because of this fluorescence also these cells are referred to as enterochromaffin (see section 3 2) although the fluorogenic compound in the cytoplasm has not yet been identified (HÅKANSON *et al* 1970d)

Another *cell system morphologically similar to the enterochromaffin cells* and designated enterochromaffin-like, can be demonstrated by fluorescence microscopy only after the administration of certain aromatic amino acids, which give a formaldehyde-induced fluorescence in themselves or after conversion to their amine product (HÅKANSON and OWMAN 1966 HÅKANSON LILJA and OWMAN 1967 1969 ADRES *et al*., 1968 HÅKANSON *et al*., 1970d see also ROSELL, SEDVALL and ULLBERG 1963 RITZÉN HAMMARSTRÖM and ULLBERG 1965 HAMMARSTRÖM, RITZÉN and ULLBERG 1966) These enterochromaffin like cells (see section 3 4) which normally store neither 5-HT nor catecholamines—at least not in amounts detectable by fluorescense microscopy—can take up amino acids such as DOPA and 5-HTP by an active mechanism that can be blocked with cocaine

(HÅKANSON LILJA and OWMAN 1967) DOPA decarboxylase within the cell converts the amino acid to the corresponding amine, which is retained in the cytoplasm by a fairly reserpine resistant storage mechanism. After pretreatment with a DOPA decarboxylase inhibitor the administration of DOPA induced only a very weak fluorescence in the enterochromaffin like cells this may reflect the presence of non-converted L DOPA in the cytoplasm. Thus, the intense green cellular fluorescence observed after DOPA administration alone seems to reflect the presence of dopamine predominantly The conversion of L DOPA to dopamine occurs within the enterochromaffin-like cells since exogenous dopamine even in massive doses, produced only a very slight green fluorescence in this cell system (HÅKANSON LILJA and OWMAN 1967) These findings strongly suggest tthat DOPA decarboxylase is present in the enterochromaffin like cells. Apart from DOPA and 5-HTP a number of aromatic amino acids gave rise to a formaldehyde induced fluorescence in the enterochromaffin-like cells, possibly as a result of intracellular decarboxylation (AURES HÅKANSON and SCHAUER, 1968 HÅKANSON and OWMAN 1968) Both chemical and histochemical evidence supported the assumption that *e g* tryptophan was decarboxylated in these cells. This may possible be the ca als ith some of the fluorogenic aromatic amino acids tested, such as methyl *m* tyrosine, α-methyl DOPA 3 4-dihydroxyphenylser hydroxyphenylalanine, 3-methoxy-4-hydroxyphenylanine and 5 h han (AURES HÅKANSON and SCHAUER, 1968) Pretreatment wi mine oxidase inhibitors such as nialamide or pargyline markedly incr s fluorescence intensity in the enterochromaffin like cells following ration of L-DOPA (HÅKANSON LILJA and OWMAN 1967) This be presence of monoamine oxidase within these cells an assu h received further support by the histochemical demonstration of oxidase in the basal portion of the mucosa (HÅKANSON LILJA and OWMAN 1967)

By th se of the histochemical OPT method gastric mucosal histamine in the rat and mouse was found to have primarily a non mast-cell localization, being stored in a specific epithelial cell system in the basal portion of the oxyntic gland area (HÅKANSON and OWMAN 1967 THUNBERG 1967) In addition, histamine was found in gastric mast cells, which were few in the rat and somewhat more numerous in the mouse. In studies on rats, treated with L DOPA it could be shown that the histamine-containing epithelial cells, detectable with the OPT method were identical with the enterochromaffin-like cells, subsequently demonstrated in the same section by their green formaldehyde-induced dopamine fluorescence (HÅKANSON and OWMAN 1967) A high histamine forming capacity had previously been demonstrated in the gastric mucosa of the rat (SCHAYER, 1956b 1957 WELSBACH, LOVENBERG and UDENFRIEND 1961 KAHLSON *et al.*, 1964) indicating that gastric histamine was produced locally

The following observations support the view that the OPT induced fluores-

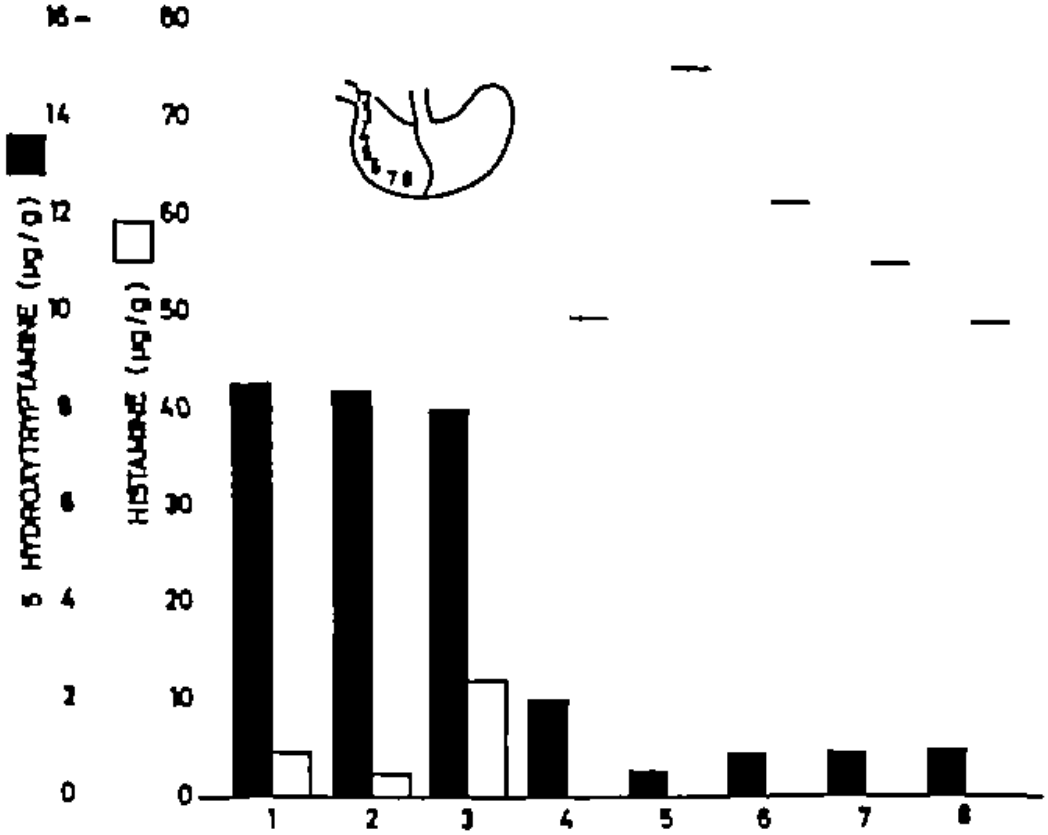

Fig. 10. Regional distribution of 5-hydroxytryptamine and histamine in the rat stomach. Small tissue samples were taken from the wall of the greater curvature as indicated in the drawing and assayed for amine content as described in section 2.1. The numbers on the abscissa refer to the locations shown in the inserted drawing. The distribution of 5-hydroxytryptamine corresponds well with that of the enterochromaffin cells; histamine, on the other hand, has a very different distribution, closely resembling that of the enterochromaffin-like cells.

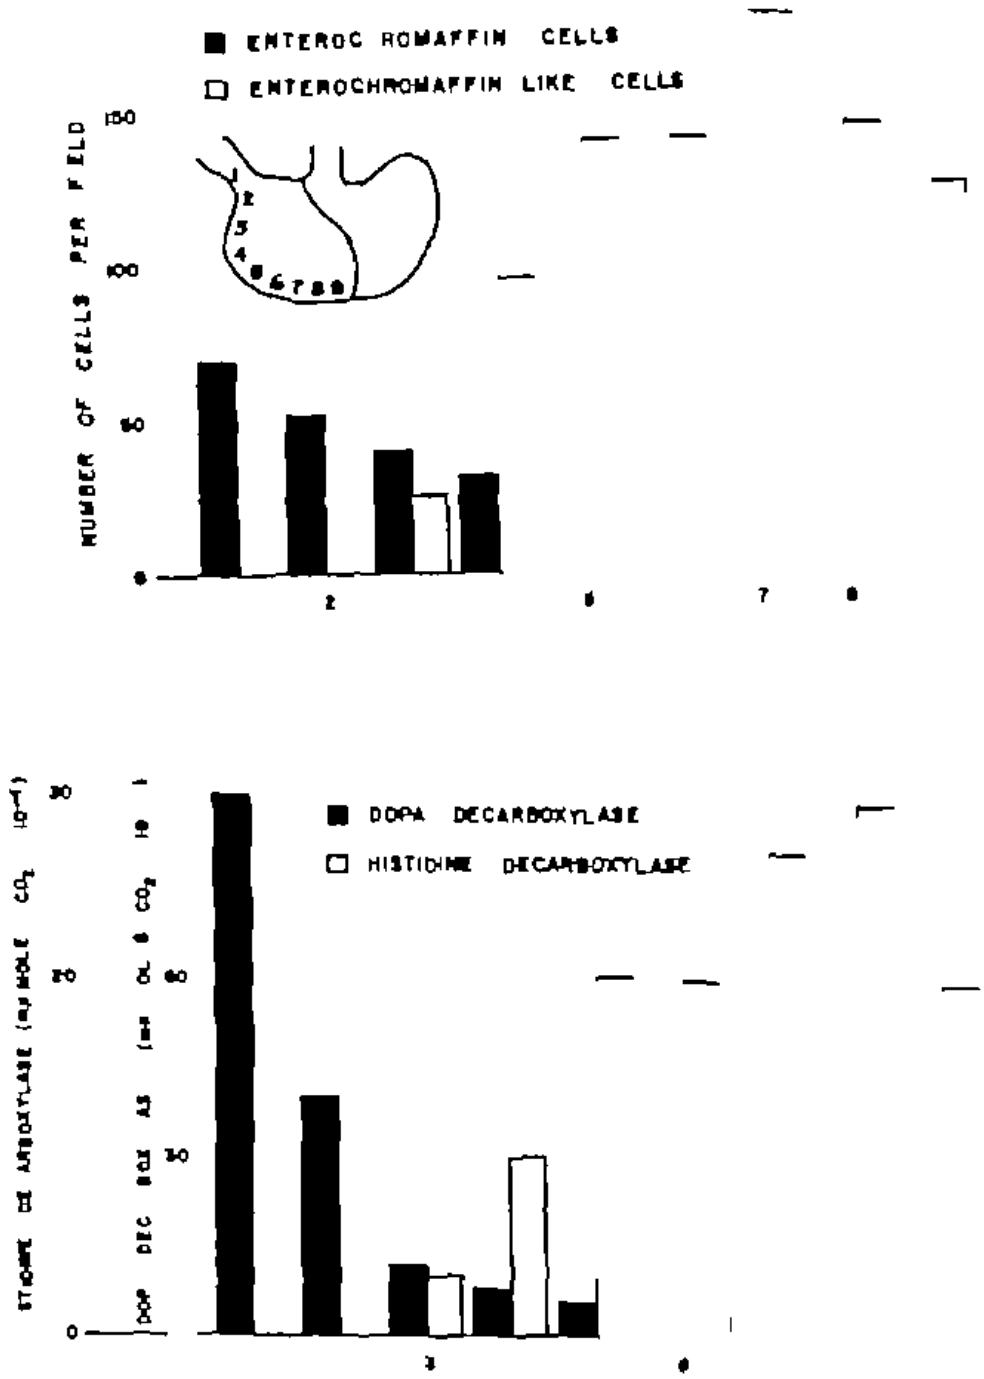
cence of the enterochromaffin-like cells reflects the presence of histamine. 1) The regional and topographical distribution of gastric histamine agreed very well with that of the OPT-reactive cells (Thunberg 1967, Aures Håkanson and Schauer, 1968; see also Fig. 10). 2) The regional and topographical distribution of gastric histidine decarboxylase likewise agreed very well with that of the OPT-reactive cells (Thunberg 1967, Aures Håkanson and Schauer, 1968). 3) The quantitative development of gastric histamine in the new-born and young rat coincided with development of the OPT-induced fluorescence in the enterochromaffin-like cells (Håkanson, Owman and Sjöberg, 1967). 4) Microspectrofluorometric analysis of the OPT-induced fluorophore in the enterochromaffin-like cells showed a good agreement with the properties of the OPT-histamine fluorophore in models (Håkanson *et al.*, 1970a). 5) Reserpine, which reduces the level of gastric histamine by about 50 per cent (Kim and Shorr, 1963; Kowalewski, 1965; Håkanson, Lindstrand, Nordgren and Owman, 1970b), was recently found to abolish the OPT-induced fluorescence in approximately 50 per cent of the enterochromaffin-like cells (Håkanson *et al.*, 1970b).



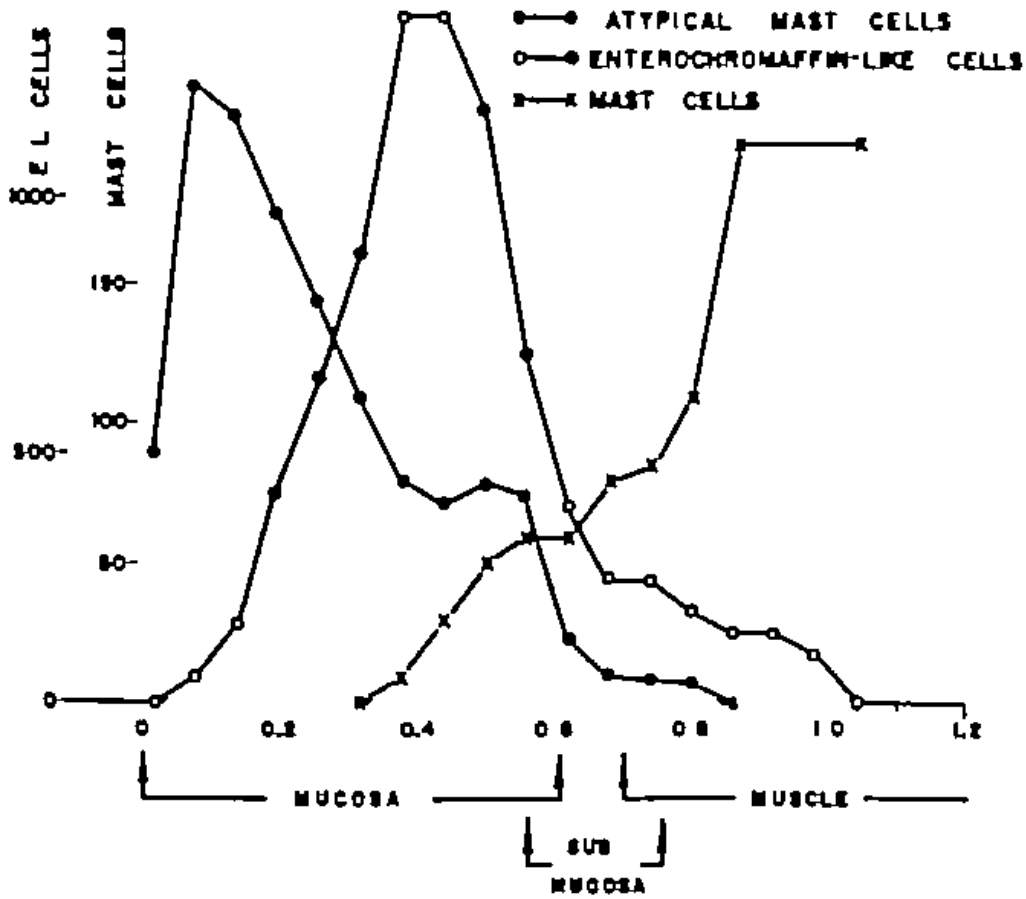


Fig. 11. Regional distribution of enterochromaffin and enterochromaffin-like cells in the rat stomach compared with the distribution of histidine decarboxylase and DOPA decarboxylase. Enterochromaffin cells were recognized by their yellow formaldehyde-induced fluorescence, enterochromaffin-like cells by their green fluorescence 1— hr after intraperitoneal injection of L-DOPA (100—200 mg/kg). The cells were counted in transverse sections at 160 × magnification. Enzyme assays were performed on small pieces of tissue (10—20 mg). (For details see Aures Håkanson and Schauer 1968)

Histamine formation in mammalian tissues may be catalyzed by at least two enzymes—one is specific and referred to as histidine decarboxylase (EC 4.1.1.22), the other one is non-specific and presumably identical with DOPA

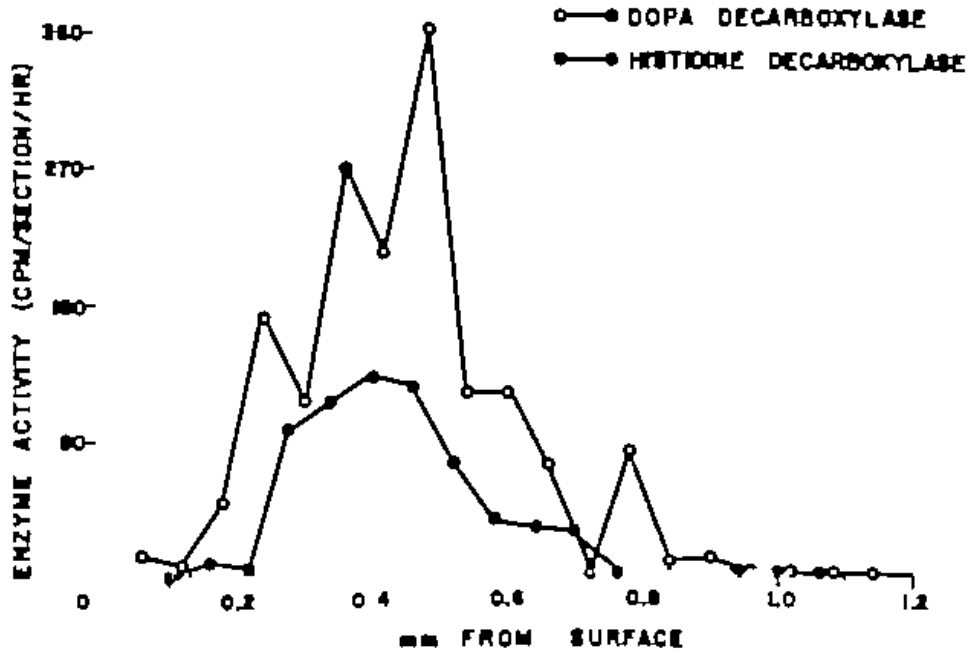

Fig. 12. The topographical distribution of histidin decarboxylase and DOPA decarboxy lase in the oxyntic gland area of the rat stomach. The localization of both enzymes agrees with that of the enterochromaffin-like cell system. There is no correlation between the enzymes and gastric mast cells. (For details see Aures, Håkanson and Schauer, 1968) Some mixing of cell populations from different levels of the mucosa occurred in individual experiments. Furthermore, th height of the mucosa varied somewhat from one experiment to another It may thus falsely appear as if enterochromaffin-like cells sometimes occurred in the submucosa th enterochromaffin-like cells, however were strictly confined to the lower half of the mucosa with the greatest number in the depth of the glands.

decarboxylase (EC 4 1 1 26) The classification of the gastric histamine-forming enzyme was unknown (Schayer, 1956 1957 Lovenberg, Weissbach and Udenfriend 1961) until the enzyme of rat and mouse stomach was identified as "specific" histidine decarboxylase by kinetic analysis (Håkanson and Owman 1966b Håkanson 1967a Aures Håkanson and Schayer, 1968)

In the rat, the system of enterochromaffin-like cells is known to contain the major portion of gastric histamine (Håkanson and Owman 1967 Håkanson Owman and Sjöberg 1967 Thunberg, 1967) and presumably also histidine decarboxylase (Thunberg 1967 Aures Håkanson and Schauer, 1968) This hypothesis was supported by the investigation illustrated in Fig 11 Samples were taken at frequent intervals along the major curvature of the stomach wall and assayed for histidine decarboxylase and DOPA decarboxylase. In parallel histochemical studies enterochromaffin and enterochromaffin-like cells were counted in sections from the same areas. There appeared to be a very close relationship between histidine decarboxylase and the enterochromaffin-like cells. The distribution of DOPA decarboxylase was well correlated to that of the enterochromaffin cells (Aures Håkanson and Schauer, 1968 see also Håkanson *et al.*, 1970d) There is no doubt, however that DOPA decarboxylase also occurs in the enterochromaffin-like cells (see Håkanson Lilja and Owman 1967) Although the enterochromaffin cells appear considerably richer in DOPA decarboxylase, whether viewed as a system or in terms of individual cells (Aures Håkanson and Schauer, 1968) Further support for the assumption that in the rat both histidine decarboxylase and DOPA decarboxylase occur in the system of enterochromaffin-like cells was obtained from experiments (Aures Håkanson and Schauer, 1968) in which pieces of the stomach wall were sectioned parallel to the mucosal surface (Fig 12) (see also Thunberg 1967) In mucosa taken from the oxyntic gland area, the topographical distribution profile of histidine decarboxylase and DOPA decarboxylase was similar to that of the enterochromaffin-like cell system, which was found exclusively in the basal layer of the mucosa. In the pyloric gland area, which was poor in histidine decarboxylase, the topographical distribution of DOPA decarboxylase and enterochromaffin cells was very similar (Fig 13)

Also the gastric mucosa of the dog is rich in histamine (see Easterlin and Kahlson 1944 Douglas Feldberg Paton and Schachter, 1951) Fluorescence microscopic analysis revealed that in this species, however gastric histamine is located exclusively in mast cells of a peculiar atypical variety (Aures *et al.*, 1968) characterized by a marked resistance to the histamine-releasing action of Compound 48/80 (see Enerbäck, 1966) After treatment with DOPA, enterochromaffin-like cells could be demonstrated in the pyloric gland area and in the adjacent portion of the oxyntic gland area (Fig 14) Under these conditions, the enterochromaffin-like cells exhibited a green formaldehyde-induced fluorescence. The pyloric region was also rich in the usual type of 5-HT-containing enterochro-

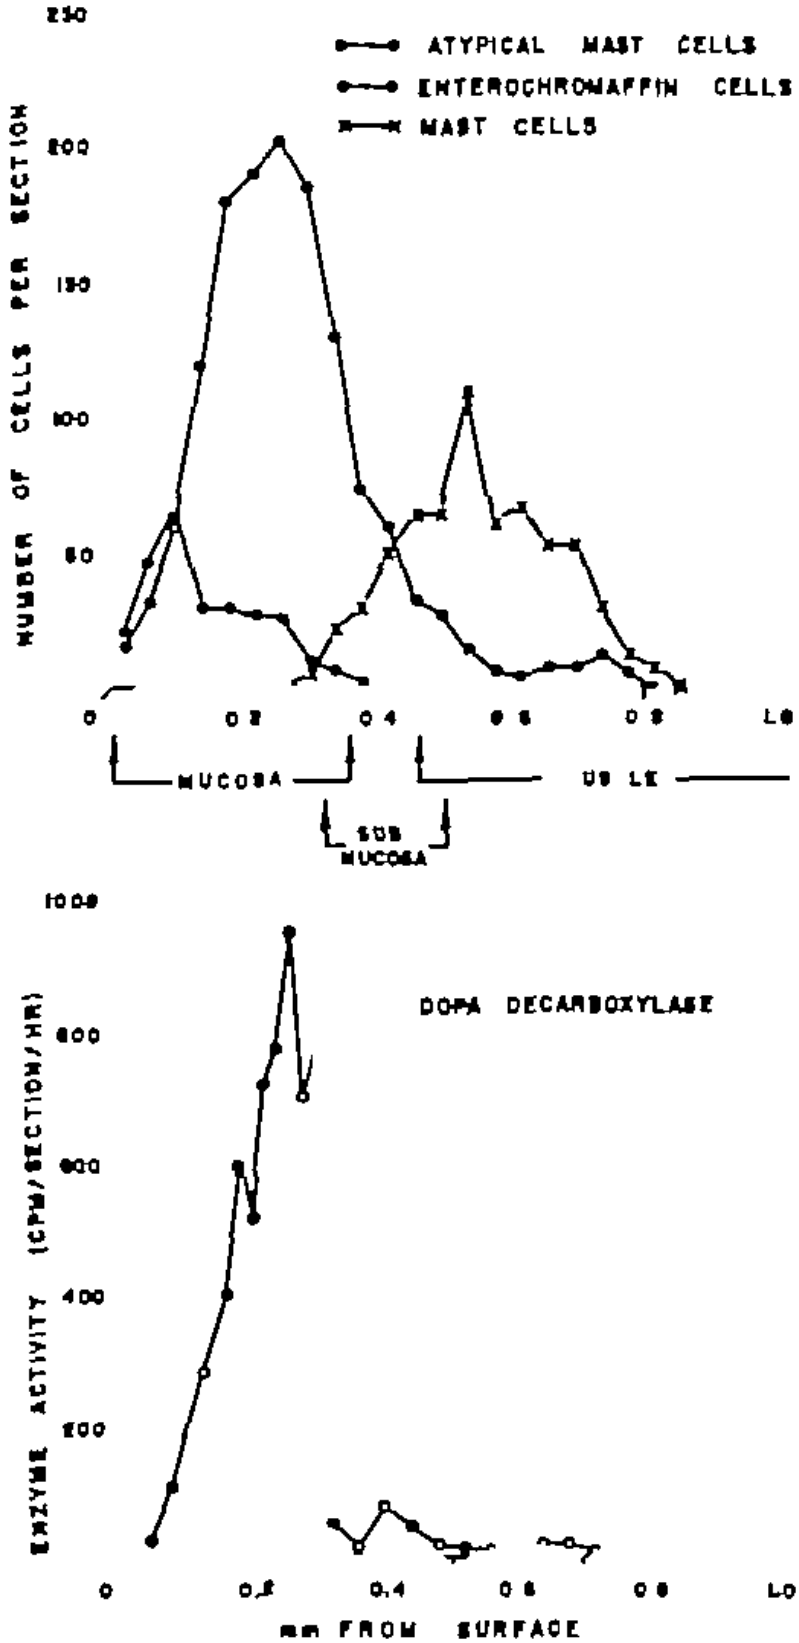

Fig. 13. The topographical distribution of DOPA decarboxylase in the pyloric gland area of the rat stomach (under the experimental conditions used histidine decarboxylase is non-measurable in this region). The enzyme activity is well correlated with the distribution of the enterochromaffin cells. (For details see Auren, Håkanson and Schaner 1968)

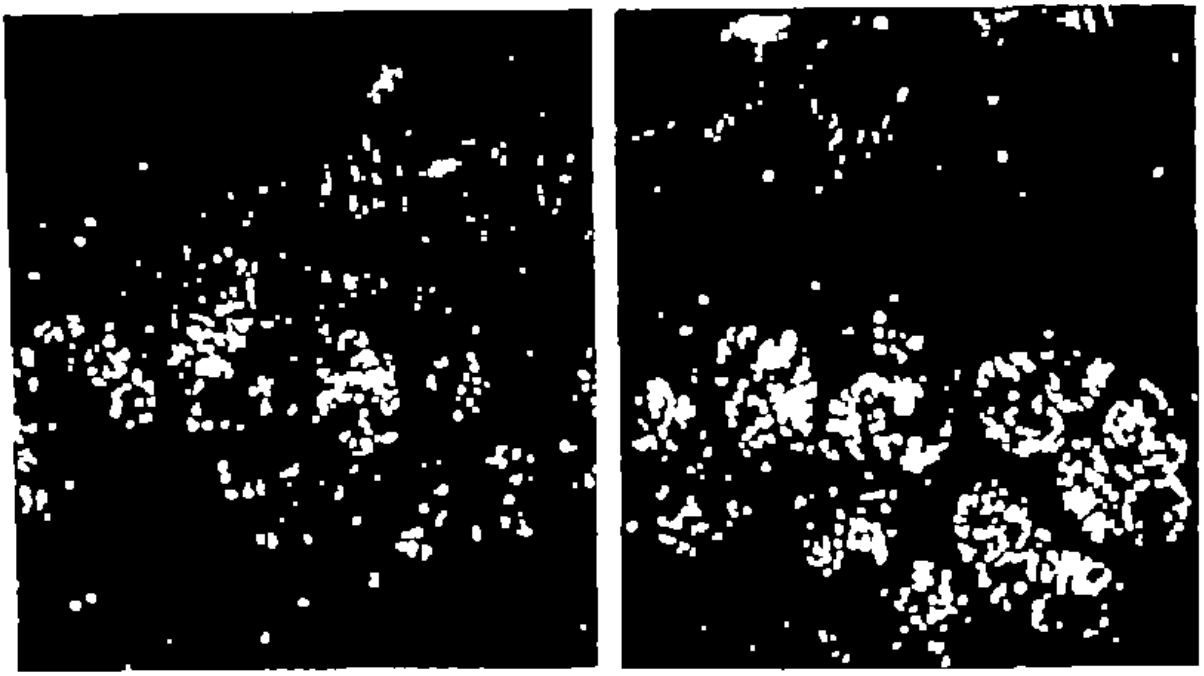

Fig. 14 Fluorescence photomicrographs of dog stomach wall. Transversally sectioned antrum region, 100 x. Formaldehyd reaction. (Left) Untreated animal: large number of intensely yellow fluorescent 5-hydroxytryptamine-containing cells in the middle and basal portions of the mucosa. Weakly fluorescent mast cells higher up in th lamina propia (Right) Specimen incubated with L-DOPA (20 μg/ml) in Tyrodes solution In addition to the yellow-fluorescent enterochromaffin cells another system of morphologically similar cells is now visible, particularly basally in the mucosa, with an intense green fluorescence.

maffin cells. These cells retained their yellow fluorescence also after treatment with DOPA, which thus permitted the simultaneous and selective detection of both enterochromaffin and enterochromaffin like cells, also when they occurred in the same region of the stomach as was the case in the dog Gastric mucosa of the dog was found to be rich in DOPA decarboxylase but the histidine decarboxylase activity was non-measurable (Aures *et al.* 1968 Aures Davidson and Håkanson 1969 Håkanson *et al* 1970d) thus markedly contrasts with the high level of gastric histamine. The origin of gastric histamine in this species is unknown. An active uptake of preformed, circulating histamine rather than a local biosynthesis is a distinct possibility (see Waton 1963 Dunpan and Waton 1969)

Also in the human stomach, gastric histamine was located exclusively in mast cells (Håkanson Lilja and Owman 1969) Both enterochromaffin and enterochromaffin-like cells were recognized in the mucosa, the enterochromaffin cells by their yellow 5-HT fluorescence, the enterochromaffin-like cells by their green fluorescence upon L-DOPA administration. Both cell types were found predominantly in the pyloric gland area and in the adjacent region of the oxyntic gland area. Histidine decarboxylase did not occur in measurable amounts in any region of the gastric mucosa. These results have recently been confirmed in experiments where the patients have been pretreated with pen-

tagastrin in order to stimulate the enzyme activity (see sections 3 10 and 5.5 in spite of this no histidine decarboxylase activity could be measured (HÅKANSON and LIEDBERG 1970b)

In a systematic study of the enterochromaffin and enterochromaffin-like cells in the gastric mucosa of a number of mammals it could be established that the rat and mouse were the only species in which histamine had a non-mast-cell localization, being present in enterochromaffin like cells (HÅKANSON *et al.*, 1970d) In the other species studied gastric histamine was found in mast cells exclusively although enterochromaffin like cells could be demonstrated in all species. The gastric DOPA decarboxylase activity was high in all species—particularly in the guinea pig—but histidine decarboxylase was measurable only in the stomach of the mouse, rat and hamster (AUREN DAVIDSON and HÅKANSON 1969) This was the case also when the enzyme assay was performed on specimens taken from pentagastrin-injected or newly fed animals.

As discussed above, there is much evidence that both the enterochromaffin and the enterochromaffin-like cells contain L-DOPA decarboxylase which is a non-specific enzyme and has been referred to as aromatic L amino acid decarboxylase (LOVENBERG WEISSBACH and UDENFRIEND 1962) It appears that the non-specific DOPA decarboxylase, although indispensable for the formation of 5-HT and catecholamines, is of no consequence in determining the identity of the amine occurring in the enterochromaffin and enterochromaffin-like cells. Since the capacity to decarboxylate aromatic amino acids and to store the resulting amine is common to both cell types, it is conceivable that the 5-HT content of the yellow fluorescent enterochromaffin cells is due to the presence of tryptophan-5-hydroxylase in these cells (see COOPER and MELCER, 1961) although it has not been possible to confirm this chemically (RENSON WEISSBACH and UDENFRIEND 1962 HÅKANSON and HOFFMAN 1967) A small number of dopamine-containing enterochromaffin cells, exhibiting a green formaldehyde-induced fluorescence, were regularly found scattered in the mucosa of the stomach, sometimes also in the stomach of the rabbit (HÅKANSON *et al.* 1970d) In analogy with the above reasoning, it may be suggested that the dopamine content in these cells reflects the presence of tyrosine hydroxylase.

The histamine demonstrated in the enterochromaffin-like cells of the rat and mouse stomach is probably produced within these cells for the following reasons (1) Treatment with large doses of histamine does not affect the gastric histamine content in general, nor the histamine content of the enterochromaffin like cells (HÅKANSON unpublished observation) (2) Injection of large amounts of L histidine does not affect the gastric histamine level. If ^{14}C-labelled or ^{3}H-labelled histidine is used, however radioactive histamine can be demonstrated in the oxyntic gland area of the stomach (SCHAYER and IVY 1958 AUREN HÅKANSON and SCHAYER, 1968) This supports the concept of a local histamine biosynthesis in the rat stomach (see also HIGH, SHEPHERD

and Woodcock, 1965 Shepherd and Woodcock, 1968) (3) The regional and topographical distribution of histidine decarboxylase agrees very well with that of the histamine-containing enterochromaffin-like cells (Thunberg 1967 Aures Håkanson and Schauer, 1968) (4) The development of gastric histidine decarboxylase activity in the new-born rat precedes the appearance of gastric histamine and of OPT reactive enterochromaffin-like cells (Håkanson Owman and Sjöberg 1967 Aures and Håkanson 1968)

The specific histidine decarboxylase is probably more important than the non-specific aromatic amino acid decarboxylase for the formation of histamine *in vivo* (Ganrot Rosenqren and Rosenqren 1961 Weissbach, Lovenberg and Udenfriend 1961 Levine, Sato and Sjoerdsma 1965) Since histidine decarboxylase is rate limiting, the enzyme activity should have a very direct bearing on the actual rate of histamine formation in the enterochromaffin-like cells of the rat stomach

In conclusion it may be pointed out that the amine mechanisms demonstrated in those types of the enterochromaffin like cells, which are devoid of fluorogenic amines, may perhaps reflect the formation and intracellular storage of some as yet unidentified amines, which cannot be detected by the conventional histochemical fluorescence methods, *i.e* the formaldehyde and OPT techniques (for a discussion see Aures Håkanson and Owman 1969 Håkanson *et al* 1970d)

3 7 *Prenatal and postnatal development of gastrointestinal enterochromaffin and enterochromaffin-like cells*

The embryological derivation of these two cell types is unknown. It has been suggested that they all develop from the primary gut. Alternatively the neural crest has been proposed as the original source of these cells (Pearse,1969b) Kull (1925) reported that in the intestines of the chick embryo, enterochromaffin cells appeared on the 15th day of embryonic life. According to Cordier (1926) they could be detected at between the 16th and 18th day However Simard and van Campenhout (1932) and Ghidini (1940) claimed that the first argentaffin cells were found in the appendix of the chick as early as on the 10—11th day of embryonic life. Monesi (1960a and b) on the other hand, reported that argyrophil cells appear at the 14-day stage and argentaffin, enterochromaffin cells approx. two days later At the 14-day stage the cells would perhaps more correctly be referred to as pre-argentaffin or pre-enterochromaffin, since at least part of the cell population later develops into "true" enterochromaffin (argentaffin) cells. Dawson and Mover (1948) observed an even earlier appearance (8th day of incubation) of argyrophil cells in the glandular portion of the chick embryo stomach. Enemar, Falck and Håkanson (1965) described the appearance of duodenal enterochromaffin cells with a yellow formaldehyde-induced fluorescence in the 14-day embryo At this stage only the basal portion of the cells contained fluorescent material These cells were numerous

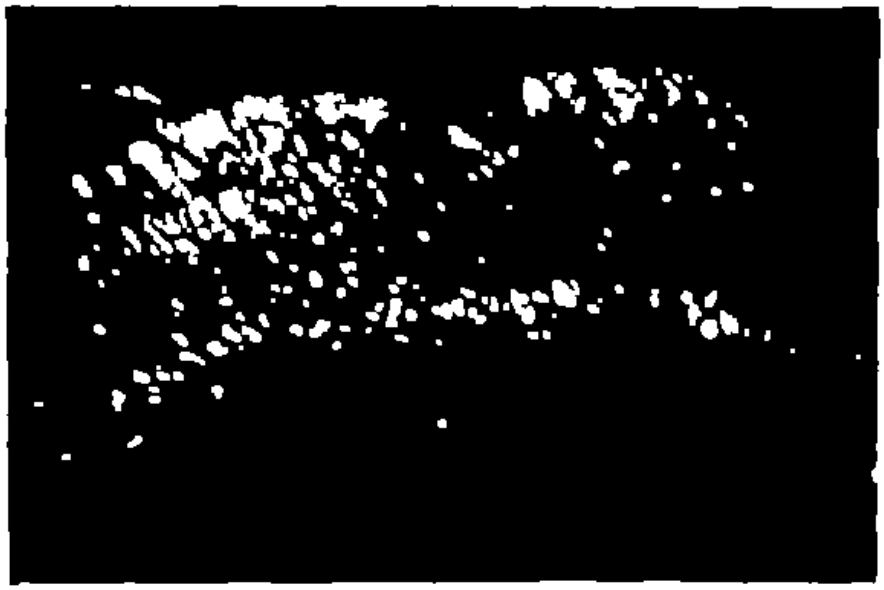

Fig. 15. Fluorescence photomicrograph of rat stomach wall, oxyntic gland area. Transverse section, 100 x. Young rat, 7 days old, injected with L-DOPA. Green-fluorescent enterochromaffin-like cells characteristically concentrated to the most basal part of the mucosa. In addition their number is considerably lower than in adult rats. Fluorescent mast cells are seen scattered in the rest of the mucosa, the submucosa, and the muscular coat.

in the 16-day embryo and at this stage they were richly supplied with fluorescent material throughout the cytoplasm. Using the same method, PENTTILA and MUSTAKALLIO (1968) and PENTTILÄ (1968) observed duodenal enterochromaffin cells in the 14-day-old chick embryo. In their studies, the identification of the cells as enterochromaffin was confirmed by argentaffin staining of adjacent sections. At this early stage the yellow formaldehyde-induced fluorescence of the enterochromaffin cells was very weak.

For human embryos, the data of CORONIA (1926) PATZELT (1931) and CLARA (1934) place the time of appearance of the enterochromaffin cells at the 12th week. CLARA (1934) reported that the appearance of the goblet cell (9th week) preceeds that of the enterochromaffin cell while the appearance of Paneth's cell follows it (17th week). FALCK, HÄKANSON, OWMAN and SJÖBERG (1967) described enterochromaffin and enterochromaffin-like cells in the gastric and intestinal mucosa (duodenum and ileum) of human embryos at between the 12th and 13th week (the embryos studied measured from 11 cm total length and more).

In many other mammals, the enterochromaffin cells have been found to appear at a corresponding embryonic age, *e.g.* in the rat on the 15—17th day (SHARPLES 1945) and in some other mammals towards the end of the gestation. The first yellow fluorescent enterochromaffin cell in the rat pyloric gland area, duodenum and ileum could be detected on the 18th day (HÄKANSON, OWMAN and SJÖBERG 1969). Gastric enterochromaffin-like cells were first observed at the time of birth. At this stage, however their number was low. Subsequently their number increased progressively (Fig. 15) and reached adult

levels at about 14 days after birth. The enterochromaffin like cells did not store histochemically detectable amounts of histamine until 8—9 days after birth (HÅKANSON OWMAN and SJÖBERG 1967)

Gastric DOPA decarboxylase could be demonstrated very early in the foetal development of both rat and man (FALCK *et al.* 1967 AURELL and HÅKANSON 1968 HÅKANSON OWMAN and SJÖBERG 1969) This seems to agree fairly well with the early appearance of the enterochromaffin cells.

Gastric histidine decarboxylase activity which was very high during certain stages of foetal development, was non measurable at time of birth the activity increased slowly but progressively during the subsequent development to reach adult or near-adult levels 21 days after birth (HÅKANSON OWMAN and SJÖBERG 1967 AURELL and HÅKANSON 1968) In the adult rat, the activity of gastric histidine decarboxylase appears to be regulated by an antral factor presumably gastrin (see AURELL HÅKANSON and SCHAUER, 1968 JOHNSON JONES, AURELL and HÅKANSON 1969 AURELL JOHNSON WAY and CLARK, 1969 HÅKANSON and LIEDBERG 1970a) so that fasting (diminished gastrin release) reduces the enzyme activity and feeding (stimulated gastrin release) or injection of gastrin causes an increase in the enzyme activity This control mechanism is not established in the young rat until 14 days of age Before this stage, neither fasting nor feeding affects the enzyme activity (AURELL and HÅKANSON 1968)

From the results of MONESI (1960a and b) it appears that initially the enterochromaffin cell is devoid of 5 HT and hence can be detected by agryrophil stains only—not by the argentaffin reaction. This pre-enterochromaffin cell then matures to its final enterochromaffin state, with a full store of 5 HT fairly early in the prenatal development. The histamine-containing (enterochromaffin-like) cell of the rat gastric mucosa which presumably remains argyrophil and non argentaffin throughout its life cycle (*i.e.* it remains enterochromaffin-like) seems to appear much later in development and to mature much slower than the enterochromaffin cell (HÅKANSON OWMAN and SJÖBERG 1967 AURELL and HÅKANSON 1968 HÅKANSON OWMAN and SJÖBERG 1969) For a diagrammatic presentation of its development see Fig 16.

3.8 *Ultrastructure of enterochromaffin and enterochromaffin-like cells*

The first electron microscopic description of a gastrointestinal argentaffin cell is that presented by CHRISTIE (1955) Subsequently KUROSUMI SHIBASAKI UCHIDA and TANAKA (1958) BULLION RAMIREZ, LANDER and SCHULTZ (1960) LUSE and LACY (1960) TAYLOR and HAYES (1961) HELANDER (1961 62 64) WETZSTEIN and DOERFLER (1962) WETZSTEIN DOERFLER and SCHWINK (1962) ITO and WINCHESTER (1963) and RATZENHOFER and LEB (1965) reported on the argentaffin and argyrophil cells of the gastrointestinal mucosa. The species studied were the rabbit, the guinea-pig, th mouse and the bat The terms argentaffin (enterochromaffin) and argyrophil seem to have been used arbitrarily by most of these authors usually the hi tochemical criteria necessary

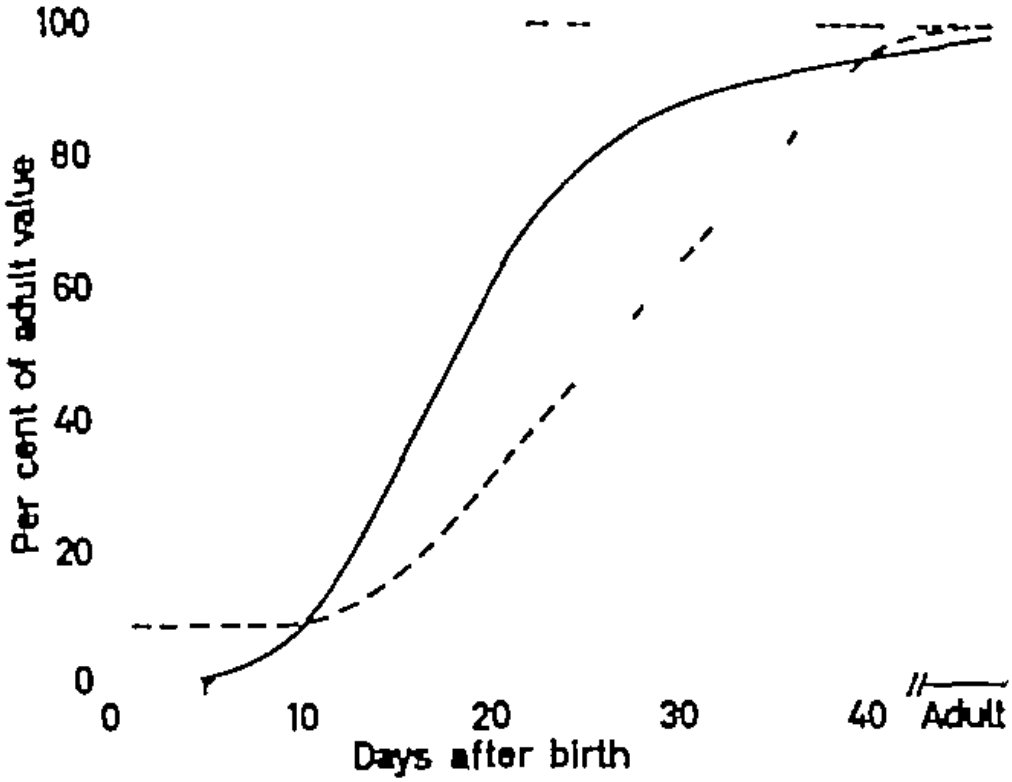

Fig. 16. Development of gastric histamine content (— — —) gastric histidine decarboxylase activity (————————) and of enterochromaffin-like cells ( ) in the new-born and young rat. The data are presented as per cent of adult values. The quantitative development of gastric histamine corresponded very well with the gradual appearance of o-phthaldialdehyde—induced fluorescence in the enterochromaffin-like cells. From results presented by Håkanson, Owman and Sjöberg (1967) Aures and Håkanson (1968) and Håkanson *et al.* (1969)

for distinguishing between argentaffin and purely argyrophil cells have not been applied. Most of these authors, nevertheless, seemed to agree that all these cells are endocrine, on the basis of their apparent lack of contact with the glandular lumen, being situated in close proximity to the basement membrane the absence of any sort of secretory capillary in their cytoplasm and the presence of secretory granules which are the primary ultrastructural characteristic of these cells. By electron microscopy as well as by light microscopy several categories of endocrine-like cells have been observed in the mammalian gastrointestinal mucosa (cf. Capella, Solcia and Vassallo 1969 Forssmann *et al.*, 1969 Pearse, 1969 Vassallo Solcia and Capella, 1969 Håkanson *et al.* 1970d Håkanson Owman and Sporrong 1970) The characteristics of these various types of cells have been extensively studied by Pearse and colleagues (Carvalheira, Welsch and Pearse, 1968 Pearse, 1969b) by Solcia and co-workers (Solcia, Vassallo and Sampietro 1967 Vassallo Solcia and Capella, 1969 Solcia, Vassallo and Capella, 1969 Capella, Solcia and Vassallo 1969) and by Forssman Orci and co-workers (Forssmann Orci, Pictet and Rouiller, 1967 Forssmann Orci and Rouiller, 1968 a and b Forssmann *et al.*, 1969 Orci, Forssmann

Forssmann and Rouiller, 1968a Orci Pictet Forssmann Renold and Rouiller, 1968b) Their observations will be only briefly summarized and discussed here. The various types of endocrine cells can be distinguished on the basis of variations in the size and shape of their secretory granules. Forssmann *et al.* (1969) thus described five different types of endocrine cells in the gastrointestinal mucosa of the rat. Also Vassallo Solcia and Capella (1969) described five types of endocrine cells in the digestive tract of the cat. More recently they reported the presence of six different types of endocrine cells in the bowel of the rabbit (Capella, Solcia and Vassallo 1969) The existence of several ultrastructurally different populations of endocrine cells in the gastrointestinal mucosa have now been amply confirmed in a number of laboratories including our own (Håkanson Owman and Sporrong 1970) It is still obscure, however whether some of the morphological distinctions described are representative of distinct cell types or merely of different functional stages of one and the same cell (see also Forssmann and Orci 1969) One type is reminiscent of the pancreatic A-cells in that they contain uniformly rounded granules varying in size (500—700 mμ) and electron density with a narrow pale area characteristically discernible between the granular membrane and its enclosed content. Another cell type contains granules (150—250 mμ) similar to those of the pancreatic D-cells. A third type contains granules of medium size (300—500 mμ) and of varying density A fourth type has granules similar to those of the chromaffin cells of the sympathetic chain. The fifth type, finally is the predominant endocrine cell type in the bowel mucosa. It is characterized by polymorphous granules of high electron density Generally the clear cytoplasm of all these endocrine cell types, provided with small secretory granules of varying density upon osmium fixation, sharply contrasts with the cytoplasm of the mucoid cells and of the parietal and peptic cells. Usually in the electron microscope these cells, which have a very characteristic proximity to the basement membrane, appear to be without contact with the glandular lumen. Sometimes, however the endocrine cell can be seen to reach the luminal surface with its upper narrow end (Luse and Lacy 1961 Ito and Winchester, 1963 Solcia, Vassallo and Capella, 1969 Forssmann and Orci, 1969)

It should be noted that by electron microscopy of osmium-fied material it is difficult to identify the different endocrine cells with the various types of enterochromaffin and enterochromaffin-like cells detectable by fluorescence microscopy or light microscopy One type of these endocrine cells has been claimed to be identical with the enterochromaffin cells because of its frequency and its regional and topographical distribution in the gastrointestinal tract. As yet, the electron-microscopic identity of the histamine-containing endocrine cell in the oxyntic gland area of the rat is unknown on the basis of combined fluorescence histochemical and electron microscopic findings it can be assumed that most endocrine cells in this region store histamine (Håkanson and Owman, 1967 1969 Håkanson Owman and Sporrong 1970)

The ultrastructure of the enterochromaffin and enterochromaffin-like cells is very similar to that of certain other endocrine cell systems. Thus, the granules of the gastrointestinal endocrine cells are similar to those described in the adrenal medulla (Sjostrand and Wetzstein 1956 Coupland 1965) in catecholamine-containing cells in the heart of cyclostomes (Bloom, Östlund, von Euler, Lishajko, Ritzén and Adams Ray 1961) in thyroid parafollicular cells (C-cells) (Azzali 1962 Luciano and Reale, 1964 Pearse, 1966a and b) in the carotid body (Lever, Lewis and Boyd 1959 Ross 1959 de Kock and Dunn 1964) in the endocrine pancreas (Munger, Carabia and Lacy 1963) and the pars intermedia of the pituitary (Kobayashi, 1965) A common characteristic of all these cells is that they have the capacity to produce and store polypeptide hormones.

3.9 *Possible physiological role of gastric enterochromaffin and enterochromaffin-like cells*

The system of argyrophil (enterochromaffin and enterochromaffin-like) cells constitute a quantitatively significant portion of the gastric mucosal cell population in all species studied. Some of these cells contain 5-HT (or dopamine) and can, as previously discussed (sections 3 1 and 3.2.) be expected to give a positive chromaffin or argentaffin reaction. The remainder of the argyrophil cells (enterochromaffin-like cells) are devoid of amines detectable by the Falck Hillarp formaldehyde technique, although they are capable of decarboxylating various exogenous aromatic amino acids and of storing the resulting amine intracellularly (Håkanson and Owman 1966b Håkanson Lilja and Owman 1967 Aures Håkanson and Schauer, 1968 Håkanson and Owman 1968 Håkanson *et al.*, 1970d) In the rat and mouse gastric enterochromaffin-like cells are rich in histamine and histidine decarboxylase (Håkanson and Owman 1967 Håkanson Owman and Sjöberg 1967 Thunberg 1967 Aures, Håkanson and Schauer, 1968) In all species enterochromaffin and enterochromaffin-like cells have the same general appearance and are characteristically interpersed among the other glandular cells in the mucosal epitheilium. It may well be that the classification of these cells into enterochromaffin and enterochromaffin-like, or into argentaffin and argyrophil is unjustified since the terms imply a distinction between these two cell types which may be functionally irrelevant. The endocrine pancreas may offer a useful analogy In some species, pancreatic islet cells, which in many respects resemble the gastric enterochromaffin and enterochromaffin-like cells, have been shown to contain 5-HT or dopamine, or varying proportions of both (Falck and Hellman 1963 1964 Crobeil, Falck and Hellman 1964 Crobeil, 1968) whereas in some other species the islet cells are devoid of histochemically detectable amines. Furthermore, pronounced variations in the concentration of the pancreatic amines with age and pigmentation have been documented (Crobeil, 1967a and b Crobeil,

1968) There is no evidence, however that the varying amine content of the islet cells from one species to another or according to age and pigmentation in one and the same species, causes the islet cells to differ in their functional characteristics.

It was very early suggested (see Feyrter, 1938) that the argentaffin and non-argentaffin, argyrophil cells of the digestive tract might have an endocrine function. This assumption was based on their apparent lack of contact with the glandular lumen and their resemblance to other cells with a well-known endocrine function (such as the pancreatic islet cells) The concept of an endocrine function of the endocrine like cells of the gastrointestinal mucosa has since received ultrastructural confirmation (Kurosumi *et al.* 1958 Helander, 1961 Ratzenhofer and Lee, 1965 Solcia and Sampietro 1965 Solcia *et al* 1967 Orci *et al.* 1968a and b Carvalheira *et al* 1969 Forssmann *et al.* 1969 Solcia Vassallo and Capella, 1969 Vassallo *et al.*, 1969) The endocrine function of these cells has not yet been defined. It has been suggested that they are active in the formation of gastrointestinal polypeptide hormones. Waddell, Coppinger and Loughry (1968) have referred to the portion of the gut immediately above and below the ampulla Vateri, including antrum, duodenum and pancreas, as the abdominal endocrine organ. The hormones of this area are concerned with the regulation of digestion, absorption, and utilization of food. All of the endocrine cells of this region are believed to arise from a limited area of the primitive foregut. The concept of an "enteroinsular axis" whereby insulin-releasing agents from the gut control the insulin release, emphasize the close functional relationship of this particular region (Unger, Ketterer, Dupré and Eisentraut 1967 Pfeiffer and Raptis 1968 Unger, Ohneda, Valverde, Eisentraut and Exton 1968 Singleton 1969) The chemical similarity between many of the polypeptide hormones of this region (see Jorpes 1968) also supports the concept of a hormone-producing locus, comprising several endocrine glands, whose functions are closely coordinated, and which perhaps are developed from the same primordial origin. Among the well-known gastrointestinal polypeptide hormones of this area are gastrin, secretin and pancreozymin-cholecystokinin. Other putative gastrointestinal hormones and related substances include enterogastrone, duocrinin, villikinin, enterocrinin, antral chalone, urogastrone, gastrone enteroglucagon, and possibly other insulin releasing hormones (see review by Grossman 1968)

Using selective histochemical and histological methods in combination with electron microscopic studies, it has been possible to distinguish between several types of endocrine cells in gastric mucosa (Carvalheira *et al.*, 1968 Cappella *et al* 1969 Forssmann *et al* 1969 Vassallo *et al.*, 1969 Håkanson Owman and Sporrong 1970) It has been suggested that one of these of cells contain gastrin (Solcia *et al.*, 1969) and another enteroglucagon (Orci *et al.*, 1968b Forssmann *et al* 1969) It is interesting, in view of the finding of high concentrations of "glucagon-like immunoreactivity" in the

gastric mucosa (Unger *et al.*, 1968) that cells which are histochemically and ultrastructurally similar to the pancreatic A-cells are found in the gastric mucosa (Munger, Caramia and Lacy, 1965) In addition to insulin -secreting B-cells and glucagon-secreting A-cells (A_2-cells) other endocrine cells has been clearly identified in the pancreatic islets (Meyer and Bencosme, 1965 Munger, Caramia and Lacy 1965) One of these cells fails to give the staining reactions characteristic of either B- or A_2-cells. It has been identified (Munger, Caramia and Lacy 1965) as the D-cell first described by Bloom (1931) It has also been designated A (Peterson 1966) The ultrastructure of the D-cell is clearly different from that of the B- and A_2-cells (Munger, Caramia and Lacy 1965) The secretory product of the D-cell has not been identified but its ultrastructure indicates an endocrine function. Histochemically identical cells have been found in the antro-pyloric area (Solcia and Sampietro 1965) Several authors have suggested that D-cells in both pancreatic islets and gastric mucosa secrete gastrin (see Solcia and Sampietro 1965) Support for this view is furnished by studies on Zollinger Ellison tumours. This tumour which secretes gastrin, has been found to consist wholly or in part of D-cells (Greider and Elliot 1964 Cavallero Solcia and Sampietro 1967 Toner, 1967) All suggestions offerred concerning the functions of the various gastric endocrine cells are thus based on their resemblance to those pancreatic islet cells, which are believed to contain glucagon (A_2-cells) or gastrin (D-cells, Zollinger Ellison tumours) These views are also based on the agreement between the localization of the gastric cells, supposed to store the hormones, and the general distribution of gastrin and glucagon in the gastrointestinal tract (Solcia and Sampietro 1965 Solcia *et al.*, 1969) It must be emphasized that most of this is mere conjecture and that differences in opinion exist. For instance, Forssmann and co-workers believe the F-cell (see Munger, Caramia and Lacy 1965) to store gastrin. They recently showed that certain gastric endocrine cells, similar to the pancreatic F-cell, were degranulated as a result of feeding and of other gastrin-releasing stimuli (Forssmann and Orci, 1969) Using an immunofluorescent technique, McGuigan (1968) recently demonstrated a gastrin-containing cell in the pyloric gland area of man and the pig the cell was non-argentaffin and characterized as enterochromaffin-like. No attempt has yet been made to correlate his findings with electron microscopy

Also the gastric antipernicious principle (the intrinsic factor IF) has been brought into the discussion concerning the functional significance of the enterochromaffin cell (Erös 1933 Jacobson 1939 Jacobson and Simpson 1946 Jacobson 1948) This hypothesis fell into disrepute because of a poor correlation between the distribution of these cells and of IF in many species (Gillman 1942 Landboe-Christensen 1950 1952) In the rat, the chief cell has been proposed to be the storage site for IF (Keuning Arends, Mandema and Nieweg 1959 Boass and Wilson 1964) It is quite evident from the literature that in several other species the chief cell is not the cellular storage

site for IF and both the oxyntic cell and the pyloric gland cell have been advocated (Hollemaekers, Abels, Wachters Arends and Nieweg 1964 1966 Hollemaekers, 1965) Current opinion appears to locate IF to different cells in different species (Chanarin 1968) From pure speculation it appeared probable that a compound with such a specific function as IF should be produced and stored in the same type of cell in all species. A series of investigations was initiated to search for a common cellular storage site for IF

It was observed that in the rat the regional and topographical distribution (Fig 17 and 18) of vitamin B_{12}-binding proteins, associated with IF activity coincided remarkably well with the distribution of the histamine-containing enterochromaffin-like cells (Håkanson Lindstrand Norddoren and Owman 1969) It should be noted, however that the distribution of the chief cells is very similar to that of the enterochromaffin-like cells and that consequently in the rat, studies on distribution and topography are insufficient in excluding either of the cell systems. However the hypothesis that IF is contained in the enterochromaffin-like cells was further supported by evidence of a correlation between the maturation of this cell system and the appearance of gastrin vitamin B binders in the neonatal rat (Håkanson *et al.* 1969)

The capacity to bind vitamin B is a necessary prerequisite for IF activity but gastric mucosa has been shown to contain vitamin B_{12}-binding proteins other than IF *i.e.* proteins that bind but do not facilitate the intestinal absorption of vitamin B_{12} (Grasbeck, Simons and Sinkkonen 1962 1965 Glass, Uchino and Schwartz, 1962 Glass 1963 Ellenbogen and Highley 1967a and b Flodh, Berglund and Olén 1968) The vitamin B_{12}-binding capacity is thus not by itself a measure of the IF content the estimation of the IF level must be based on the capacity of gastric vitamin B_{12}-binders to facilitate the intestinal absorption of cyanocobalamin. Evaluation of the IF activity of the vitamin B_{12}-binding proteins demonstrated in the oxyntic gland area of the rat was carried out using partially gastrectomized rats (the oxyntic gland area was removed) Such rats had a markedly diminished capacity to absorb vitamin B_{12}. The absorption of vitamin B_{12} was normalized if vitamin B_{12}-binding proteins from the basal mucosa of the oxyntic gland area were added. Colum chromatographic and electrophoretic analysis of the vitamin B_{12}-binders from the oxyntic gland area revealed only one major protein fraction, presumably containing the IF (Håkanson *et al* 1969) These findings together suggested the possibility that the enterochromaffin-like cells may be the common storage site of IF in all species. Subsequently the regional and topographical distribution of gastric vitamin B_{12}-binding proteins was compared with that of the enterochromaffin and enterochromaffin-like cells in the mouse, hamster guinea pig and rabbit (Håkanson Liedberg and Lindstrand, 1970 see also Fig 19 and 20) In the first two species the regional distribution of the vitamin B_{12}-binders followed that of the enterochromaffin-like cells very closely In these species enterochromaffin cells are almost exclusively found in the pyloric gland area, whereas the enterochromaffin like cells occur mainly in the oxyntic gland

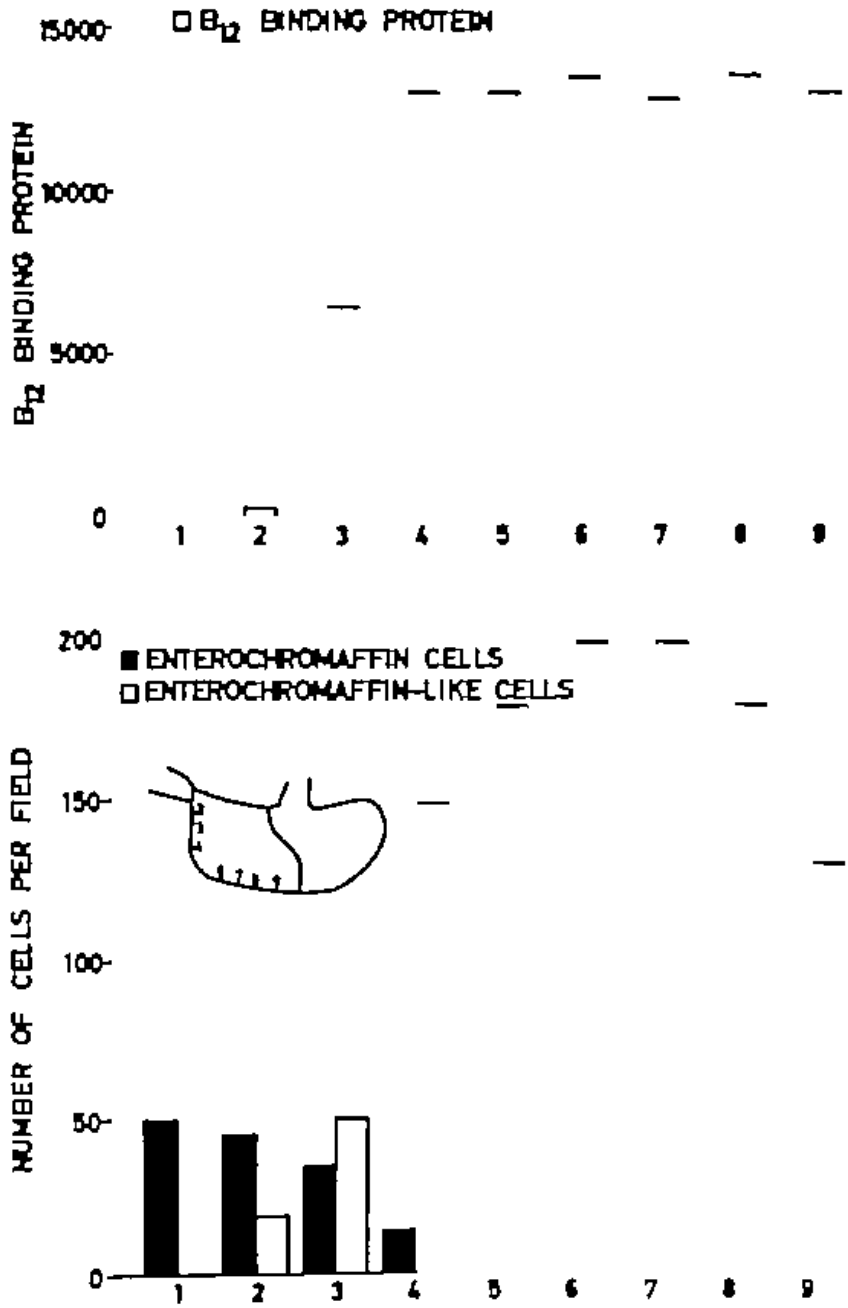

Fig. 17 Regional distribution of vitamin B binding proteins (abov) and of enterochromaffin and enterochromaffin-like cells (below) in the stomach wall of the rat. Vitamin B_{12} binding proteins are expressed as the amount of ^{57}Co-cyanocobalamin (cpm) bound per mg tissue (wet weight) The enterochromaffin-like cells were counted in the fluorescence microscope (6 μ transverse sections. 125 × magnification) after condensation with formaldehyde (L-DOPA-injected rats) or with o-phthaldialdehyde (non-injected rats)

area. Also in the guinea pig, the distribution of the vitamin B_{12}-binding proteins was well correlated with that of the enterochromaffin-like cells, which occurred in the pyloric gland area and in the adjacent portion of the oxyntic gland area. There was no correlation between vitamin B_{12}-binders and chief cells in this

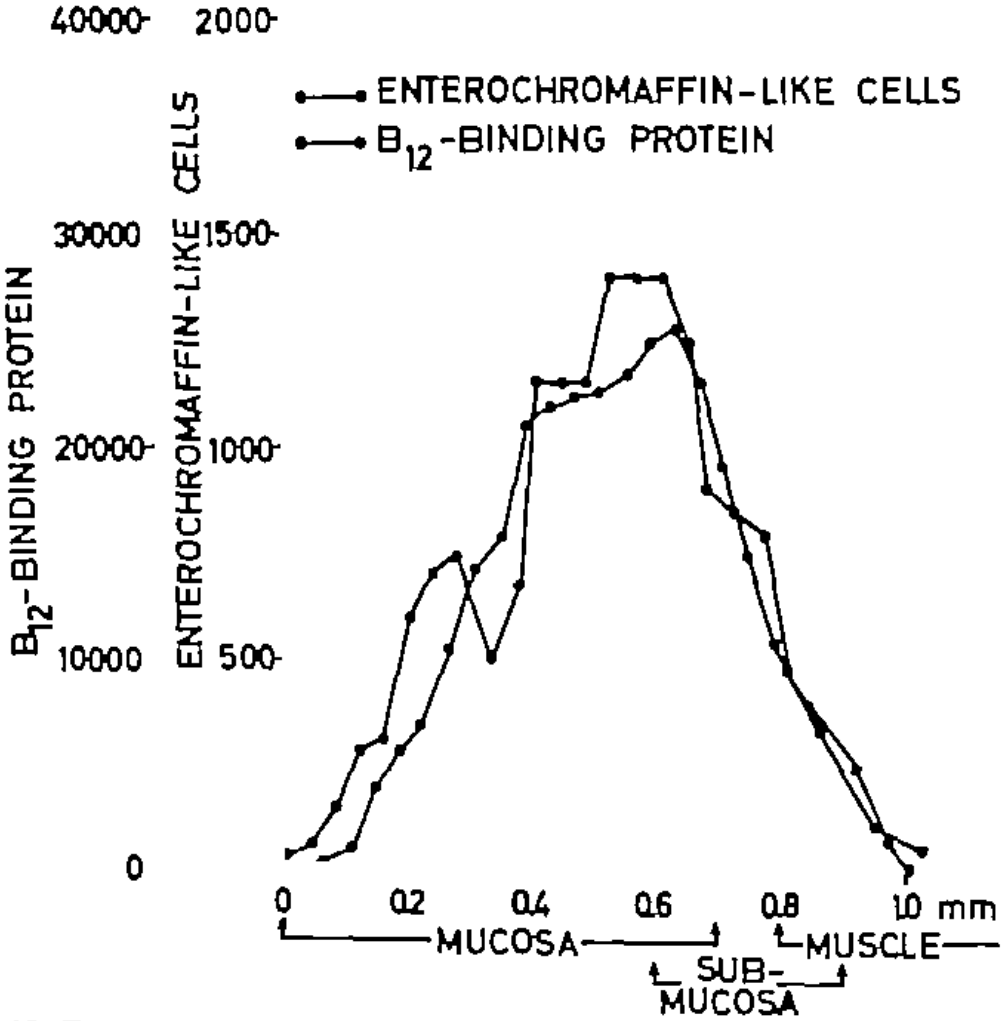

Fig. 18 Topographical distribution of enterochromaffin-like cell and of vitamin B -binding protein in the oxyntic gland area of th rat stomach. The number of cells is given per section (20 μ thick, 3—4 mm square) The amount of vitamin B -binding protein is expressed as cpm per section.

species. The rabbit was exceptional in that the distribution of the vitamin B $_{12}$-binding proteins closely agreed with that of a special type of enterochromaffin cells, which are found exclusively in the oxyntic gland area. It could be shown that in this region the vitamin B_{12}-binding proteins were restricted to the basal layer of the mucosa, a topographical distribution which corresponds closely to that of the enterochromaffin cells. This observation is not necessarily in disagreement with the assumption that IF is contained in one and the same type of cell in all species, but it rather emphasizes the very distinct possibility that the argyrophil cells of gastric mucosa (whether enterochromaffin or enterochromaffin-like) are functionally very closely related.

From these results it is evident that gastric vitamin B $_{12}$-binding proteins are not regularly associated with one particular region of the stomach and that

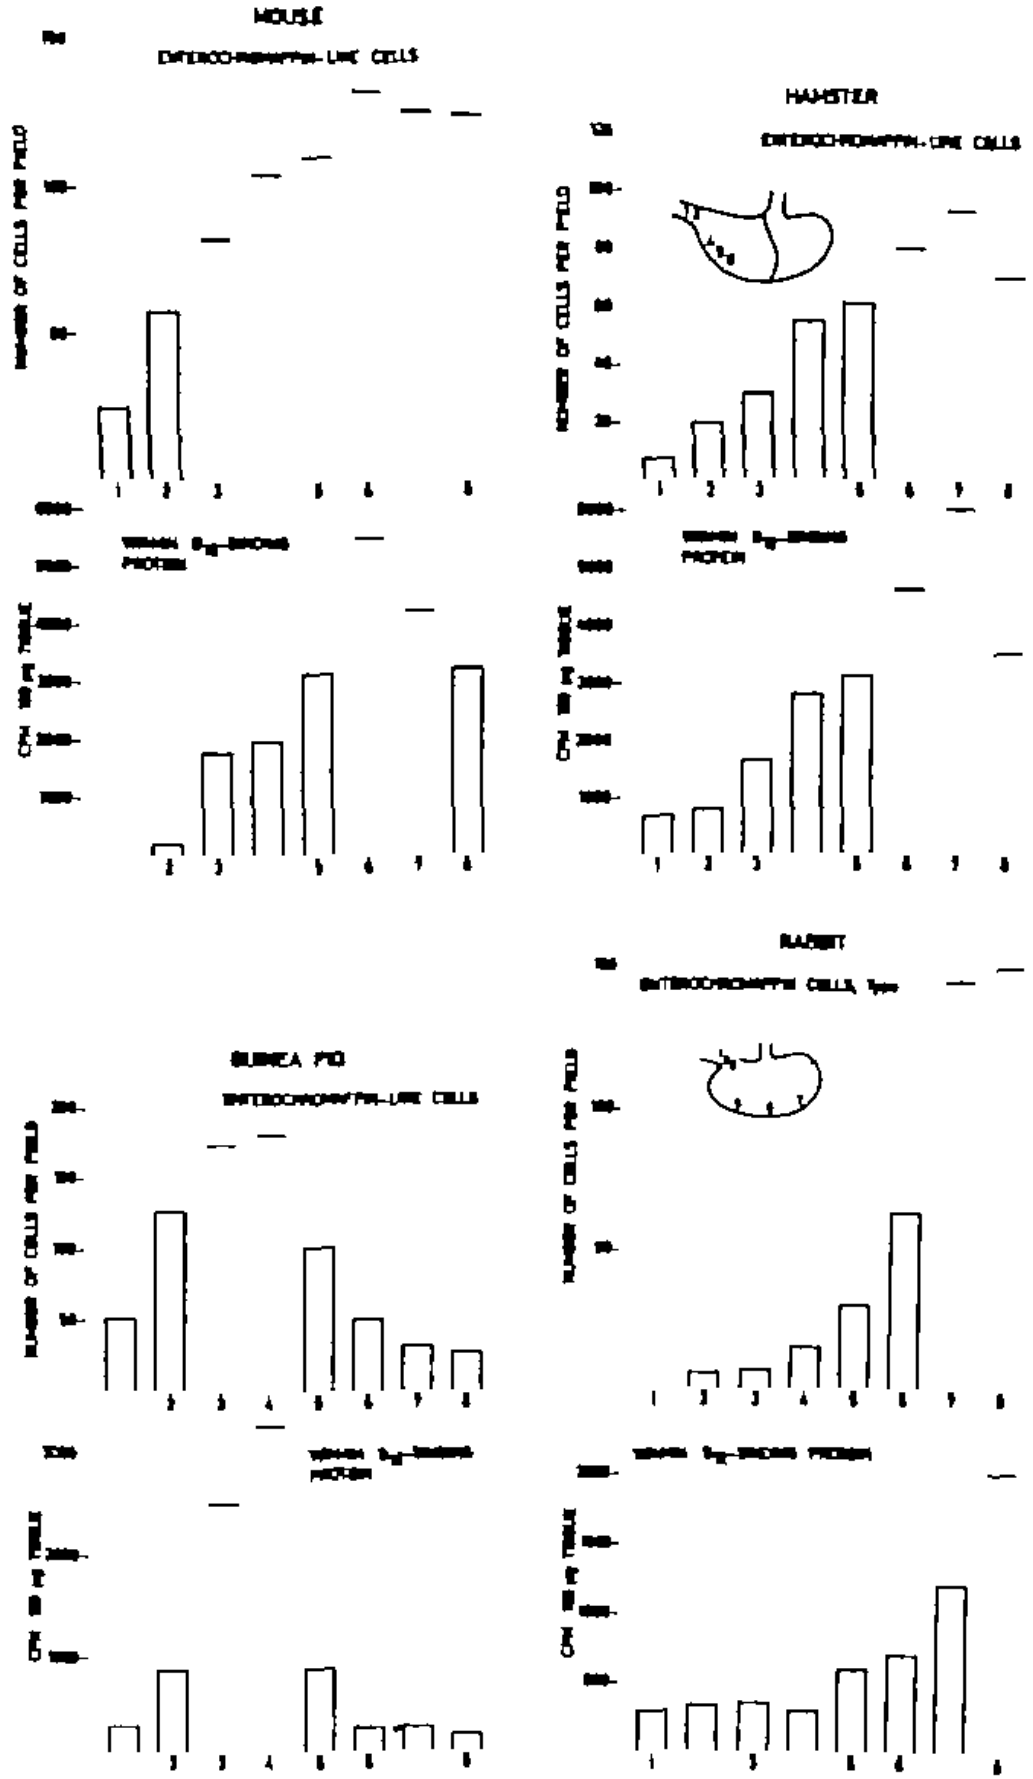

Fig. 19 Regional distribution of vitamin B -binders and gastric endocrine cells in the mouse, hamster guinea-pig and rabbit. For details see Hakanson, Lindberg and Lindstrand (1970)

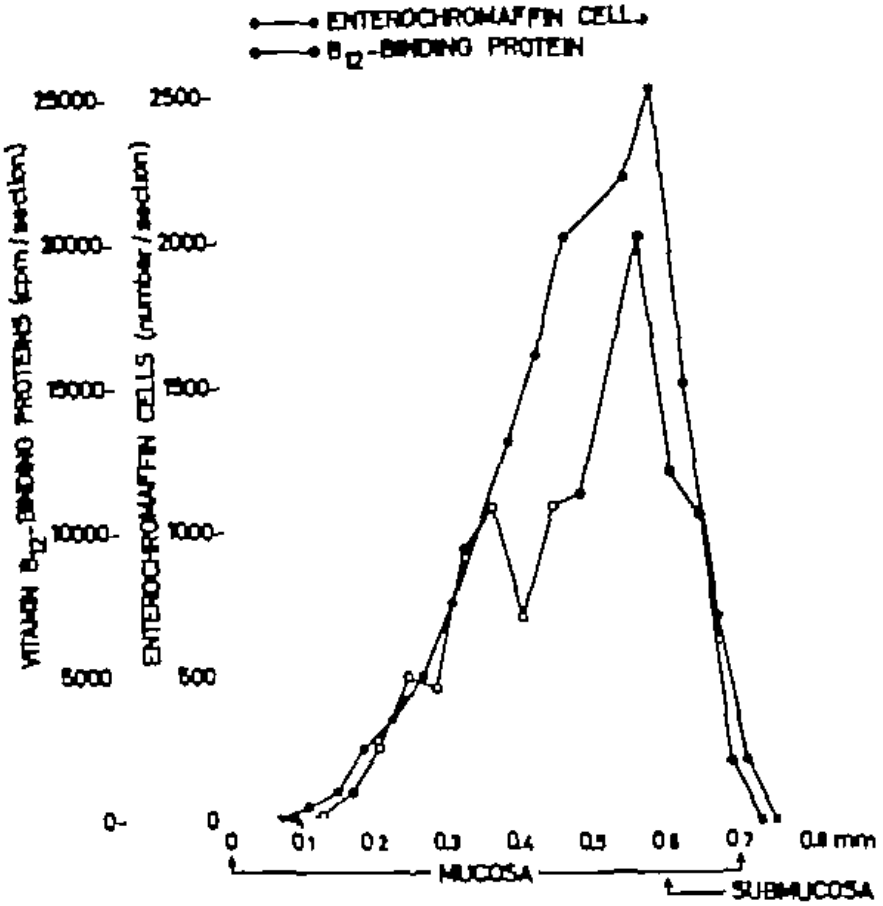

Fig 20 Topographical distribution of vitamin B_{12}-binders and enterochromaffin cells in the oxyntic gland area of the rabbit. For details see Håkanson, Liedberg and Lindstrand (1970)

no previously proposed cell type can be the single cellular storage site for such proteins. It is suggested that the enterochromaffin-like cells in the stomach of the mouse rat, hamster and guinea-pig and the enterochromaffin cells of the rabbit contain gastric vitamin B_{12}-binding proteins, which may include the IF Recently reserpine, which is known to mobilize histamine from enterochromaffin-like cells of the rat stomach, has been found to induce a simultaneous depletion of the IF stores (Håkanson *et al* 1970b) This observation provides further support for the belief that IF in the rat is contained in the histamine-storing epithelial cells of the oxyntic gland area.

Feyrter (1938) introduced the concept "diffuse endokrine epithheliale Organe The term was used to characterize the various systems of scattered endocrine cells observed in a number of exocrine (and certain endocrine) organs. The reason for introducing this new concept was to distinguish between diffuse endocrine epithelial glands (such as *e.g* the argyrophil cells of the digestive tract, the parafollicular cells of the thyroid and the numerous endocrine cells in the pancreatic ducts) and the parenchymal endocrine organs (such as the thyroid, the parathyroid and the adrenal cortex) In another communication published several years later Feyrter (1954) introduced the

term "paracrine glands" for this type of diffuse endocrine organs. Thus, Feyrter distinguished between paracrine glands ("diffuse endokrine Organe") and endocrine glands ("kompakte endokrine Organe")

In a series of communications Pearse and co-workers (Pearse, 1966a, b and c, 1968a and b 1969a and b Carvalheira, Welsch and Pearse, 1968) have pointed out certain characteristics shared by some apparently unrelated polypeptide-secreting endocrine cell systems, diffusely distributed in endocrine and exocrine glands A high content of fluorogenic amines, or alternatively the capacity to take up and decarboxylate DOPA argyrophilic reaction high activities of choline-esterase and a high content of acid proteins (carboxyl groups) revealed by "masked metachromasia" reactions (Pearse, 1969b) These characteristics are believed to reflect the production and storage of hormone precursor protein. The list includes the pituitary corticotrophs and melanotrophs, the pancreatic islet cells, the thyroid cells (parafollicular cells) the adrenal medullary cells and the gastrointestinal argyrophil and argentaffin cells. Because of their amine content or of their capacity to take up and decarboxylate DOPA these cells have been referred to as APUD cells (abbreviation for Amine Precursor Uptake and Decarboxylation) Many of the APUD cell systems of Pearse appear to be identical with the paracrine cells of Feyrter. These various systems of scattered endocrine cells are responsible for the secretion of pituitary hormones, insulin, glucagon, calcitonin and probably also for the secretion of gastrointestinal polypeptide hormones (for a discussion see Pearse, 1966c 1969b Aures and Håkanson 1968 Aures Håkanson and Owman 1970) In surprisingly many cases, however the hormones of these putative endocrine cells are still unidentified.

The endocrine like cells of the gastric mucosa are provided with many of the features characteristic of protein-secreting cells a well developed endoplasmatic reticulum, a prominent Golgi apparatus and numerous small round, oval or polymorphous secretory granules (Solcia *et al.* 1965 1967) In addition, their general morphology and the arrangement of their cytoplasmic organelles suggest some functional polarity of these cells. The micro-villi apparatus extending from some of these cells into the glandular lumen may indicate that some constituent of the luminal content, perhaps acting as a chemical stimulus for hormone secretion, may be absorbed by the cell Or alternatively this arrangement may indicate that these endocrine cells in addition perform some exocrine function (for instance, the secretion of IF) On the other hand the preferential arrangement of the secretory granules at the base of the cell suggests the delivery of the secretory product into the interstitial space, surrounding the cell. The capillary vessels, which run just beneath the basement membrane may be engaged in forwarding the secreted material.

From purely morphological observations, Feyrter (1938 1954) suggested that paracrine cells may have multiple functions. Thus, the paracrine cells were believed to have an exocrine as well as an endocrine function (Fig 21) In addition, the possibility was considered that the paracrine cells could have

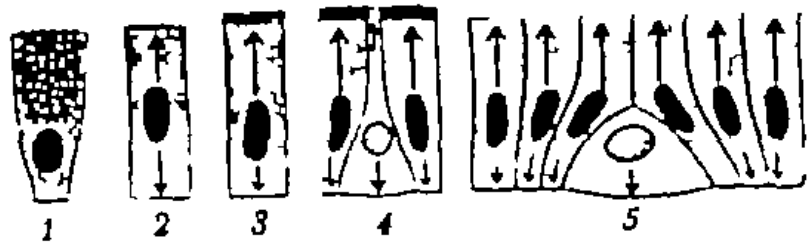

Fig. 21 This illustration is reprinted from the monograph of Feyrter (1938) with the permission of the publisher (J. A. Barth, Leipzig)

a direct local effect on neighbouring exocrine cells (Feyrter, 1938 1954) In the light of current knowledge it may perhaps be suggested that the endocrine function of these cells in the gastric mucosa is represented by the formation and secretion of polypeptide hormones the exocrine function is related to the secretion of proteins (such as IF) which are important for the intestinal absorption of certain dietary agents the local influence, finally is exerted by amines, such as 5-HT dopamine or histamine which *per diffusionem* may stimulate—or inhibit—the secretion of neighbouring exocrine gland cells. There is evidence—from experimental studies (Fyrö 1967 1968 Aures Håkanson and Schauer, 1968 Håkanson and Liedberg 1970a) as well as from *direct morphological observations* (Sikard 1934 Ratzenhofer, 1967 Håkanson Lilja and Ovrlan 1969)—that some of these endocrine cells are to be regarded as neuro-endocrine being under vagal and possibly also sympathetic control

Some of the gastrointestinal polypeptide hormones may affect not only specific exocrine target cells, but possibly also other endocrine cells, such as the *insulin-secreting cells of the pancreatic islets. The existence of an entero-insular axis* has been assumed on the basis of the capacity of gastrointestinal mucosal extracts to release insulin (Moore, Edie and Abram, 1906 Dixon and Wadia, 1926 Heller, 1929 1935 Laughton and Macallum, 1932 Dupré, 1964 Dupré and Beck, 1966) One such insulin-releasing agent is gastrin several other compounds with a B-cytotrophic effect may exist in the digestive tract (Unger, Ketterer, Dupré and Eisentraut 1967) * The possible existence of complex and sequential regulation mechanisms for the control of the secretion of hormones from polypeptide-secreting endocrine cell systems should be kept in mind.

Oral glucose is more effective in mobilizing insulin from the pancreas than is intravenous insulin. One candidate for this insulin-releasing action is the glucagon-like immunoreactivity shown by Unger *et al. (1968) to be released from the upper small* intestine of the dog in response to the intraduodenal administration of glucose.

The function of the various scattered endocrine cell systems (paracrine according to Feyrter, 1954) is not possible to establish in the traditional manner —*e.g.* by extirpation of the gland and observation of subsequent deficiency symptoms. Some information may perhaps be obtained by analyzing the symptoms occurring in disorders caused by malfunctioning of such endocrine cells, for instance carcinoid tumours. These tumours are neoplasms derived from argentaffin or argyrophil cells in the gut, bronchi and biliary duct system. It is evident from numerous observations that these tumours do not constitute a homogenous group of neoplasms. Clinical (Wilkerd and Schaefer, 1952 Thorson ,Biorck, Björkman and Waldenström 1954 Sjoerdsma, Weissbach and Udenfriend 1956 Waldenström, 1958 Oates and Sjoerdsma, 1962 Sjoerdsma and Melmon 1964 Melmon Sjoerdsma and Mason 1965 Brindley and Bonnet 1967 Shanes Dhurandhar and Blackard, 1968) histochemical (Lillie and Glenner, 1960 Stout 1962 Weichert Reid and Creech, 1967) and biochemical (Lembeck, 1953 Ratzenhofer and Lembeck, 1954 Waldenström, Pernow and Silver, 1956 Sandler and Snow 1958 Oates and Sjoerdsma, 1962 Williams and Sandler, 1963 Oates, Melmon Sjoerdsma, Gillespie and Mason 1964) distinctions have been documented. Usually carcinoids of the small intestines, appendix and cecum are argentaffin when properly preserved by prompt fixation. Tumours giving only the argyrophil reaction have also been described. Ultrastructural differences between gastric carcinoids and various intestinal carcinoids have been reported (Luse and Lucy 1960 Bensch, Gordon and Miller, 1965 Toker, 1966 Black and Haffner, 1968) This is perhaps to be expected since the progenitor cells (*i.e.* the argentaffin and the argyrophil cell) from which these tumours arise, comprise several populations of distinctly different cells. From observations on a large number of carcinoid tumours, Black and Haffner (1968) concluded that the enterochromaffin system is made up of a number of distinct cell types which are differently distributed throughout the gut, and also that carcinoids usually correspond cytologically to the type of enterochromaffin cell which is preponderant in a given region *i.e.* ultrastructurally the cells of a carcinoid have a closer resemblance to its progenitor cell than to the cells of other carcinoids.

The clinical symptoms associated with the carcinoid syndrome have been well defined and are principally manifested by flushes, cyanosis, chronic diarrhea, respiratory distress and valvular disease of the heart. 5-HT is often produced at a high rate in carcinoid tumours (see Williams and Sandler, 1963 Schiffman and Rappaport 1965) and this is reflected in markedly increased levels of urinary 5-hydroxyindoleacetic acid, which is the major degradation product of this indolamine. Atypical carcinoids have been described in which the tumours appear to secrete large amounts of 5-HTP (Sandler and Snow 1958 Oates and Sjoerdsma, 1962) histamine (Waldenström Pernow and Silver, 1956) or tryptamine (Eccleston Crawford and Ashcroft 1963) Other agents such as vasoactive polypeptides (kinins) and proteolytic enzymes

(kallicreins) have also been detected in carcinoid tumours and in the blood of patients with such tumours (Oates *et al.* 1964) 5-HT is believed to be a key substance in the development of the clinical symptoms (Thorson *et al.*, 1954) although the symptoms of the carcinoid syndrome cannot be explained by the secretion of 5-HT alone (Robertson Peart and Andrews 1962 Levine and Sjoerdsma, 1963) It appears quite possible that some of the symptoms described are caused by elevated levels of vasoactive polypeptides in the blood. Conceivably the capacity to produce kinins or kallicreins is characteristic also of the normal progenitor cells (cf Said and Mutt 1970)

3 10 *Possible function of amines in gastric enterochromaffin and enterochromaffin-like cells*

Amines such as 5-HT dopamine and histamine can be synthesized and stored by polypeptide-secreting endocrine cells in the thyroid (Falck, Larsson Mecklenburg Rosengren and Svinaeus 1964 Larsson Owman and Sundler, 1966 Owman and Sundler, 1967) anterior pituitary (Carlsson Falck and Hillarp 1962 Dahlström and Fuxe, 1966 Björklund Falck and Rosengren 1967) pancreatic islets (Falck and Hellman 1963 1964 Creutzfeldt 1968) and in the gastrointestinal mucosa (Håkanson and Owman 1966b 1967 Håkanson *et al.*, 1970d) In addition, apart from histamine, other as yet unidentified amines may well occur in those polypeptide-secreting endocrine cells, which lack 5 HT and dopamine (see Björklund and Falck. 1969a and b Håkanson *et al.*, 1970d) The presence of amines appears to be a feature common to all such endocrine cells. The amines may somehow be associated with the general physiological function of these cells, or they may be have a function of their own by exerting a "local hormone" action. It is not possible at present to decide which hypothesis is best justified and the following will be only brief summary of available evidence

According to the first assumption the amines have a secondary role and are involved in some specific cytophysiological function of these endocrine cells. It is reasonable to assume that the amines are stored in the secretory granules (Jaim Etcheverry and Ziehler, 1968a and b Ericson 1970) although the evidence of this is still surprisingly scanty The granules, which are the subcellular element common to all polypeptide or protein-secreting endocrine cells, are believed to contain the secretory products. It may be that the presence of an amine in these granules is necessary for a normal storage and/or release of the true secretory products, i.e. the protein or polypeptide hormone. A few observations from studies with reserpine provide some experimental support for the assumption that the amines and the true secretory products of these cells are functionally interrelated Reserpine causes a simultaneous depletion of histamine and IF in enterochromaffin-like cells of the rat stomach (Håkanson Lindstrand Nordgren and Owman 1970b) Moreover reserpine, which

depletes also other cellular amine stores, is known to cause a release of gastrin from the pyloric gland area (Eaas and Fyrö 1965)

In the second case, the amines are believed to function as local hormones. After being released from the endocrine cell as a result of some stimulus, the amine diffuses into the surrounding tissue, conceivably affecting some adjacent target cell. The smooth muscle of the intestines has been proposed as one important physiological target cell for intestinal 5-HT. It is well known that 5-HT affects intestinal peristalsis (for references, see Haverback and Wirtschafter, 1962 Bülbring and Gershon 1967) but the physiological importance of 5-HT in the control of intestinal motility is poorly understood (see Bennet Bocchnell and Dean 1966 Gershon 1968) even after marked reduction of bowel 5-HT induced by a diet deficient in tryptophan, motility remained normal (Boullin 1964) Judging from the strict localization of the enterochromaffin cells to the epithelium it may perhaps be assumed that these cells —as well as the enterochromaffin-like cells—serve some control function in secretory and/or absorptive mechanisms, and that the putative target cells of the gastrointestinal amines, whether it be histamine, dopamine, 5-HT or some as yet unidentified compound, are to be found among the exocrine gland cells.

The effects of 5-HT dopamine and histamine, as well as those of their immediate natural precursors, on gastric secretion have been studied in chronic gastric fistula rats (Håkanson Lilja, Owman and Thunell, 1967 see also Haverback and Wirtschafter, 1962) Both histamine and histidine stimulated gastric acid secretion, whereas dopamine and 5-HT had an inhibitory effect. While the physiological significance of these pharmacological effects of 5-HT and dopamine is unknown, histamine is claimed to be the common final chemostimulator of gastric acid secretion. This view is historically based on the effectiveness of histamine in stimulating the parietal cell, on the presence of histamine in the gastric juice, and on the high concentration of histamine in the gastric mucosa of several species. This hypothesis was originally proferred by Macintosh (1938) in a review of the subject Code (1965) concluded that stimulation of gastric secretion was a physiological function of histamine, and that no other mediator comes between histamine and the parietal cell. Grossman (1967) on the other hand, believes that in species other than the rat there is no firm evidence linking gastric secretion with endogenous histamine. During the last few years much evidence has accumulated to suggest that in the rat histamine does act as mediator in the control of hydrochloric acid secretion 1) Histamine is present in high concentration in a system of endocrine cells at the base of the mucosa in the oxyntic gland area (Håkanson and Owman 1967 Håkanson Owman and Sjöberg, 1967 Thunberg, 1967 Håkanson *et al.*, 1970d) 2) gastric histamine is produced locally within these cells at a rate which is dependent upon the physiological state of the animal (Thunberg 1967 Aures Håkanson and Schayer, 1968 see also Kahlson *et al.*, 1964) and finally 3) gastric histamine is released from its cellular store as a result of certain physiological stimuli, presumably through

the action of gastrin (KAHLSON *et al.* 1964) It is conceivable that released histamine serves to stimulate the parietal cells by way of diffusion. Moreover KAHLSON has postulated that the gastric histamine content and the activity of gastric histidine decarboxylase are inter related so that depletion of the histamine stores, caused for example by feeding or gastrin injection, induces activation of histidine decarboxylase which serves to replenish the resting levels of gastric histamine Conversely high levels of gastric histamine repress the enzyme activity (KAHLSON *et al.* 1964) However the observation that in the porta-cava shunted rat both the gastric histamine content and the histidine decarboxylase activity are markedly elevated (FISCHER and SNYDER, 1965a and b) seems to disagree with this hypothesis. In the search for an explanation of the mechanism of activation of gastric histidine decarboxylase, it was observed that agents, which cause activation of gastric histidine decarboxylase, are all either parasympathomimetics (carbachol) vagal stimulants (insulin, 2-deoxy glucose, 2-deoxygalactose) or amine-releasing agents, such as reserpine. Histamine itself and histamine liberators such as Compound 48/80 or polymyxin B either did not affect or suppressed the enzyme activity A close parallelism seemed to exist between factors which induce activation of gastric histidine decarboxylase and factors which cause the release of gastrin (see AURES HÅKANSON and SCHAUER 1968) The suggestion was made that in the rat all agents which increase histamine formation act by releasing endogenous gastrin which in turn stimulate gastric histidine decarboxylase activity in the same manner as exogenously administered hormone (AURES HÅKANSON and SCHAUER, 1968) A series of investigations has recently been carried out which seems to support this concept Antrectomy was found to reduce or abolish the enzyme activation induced by feeding insulin and carbachol, but not that induced by histamine (or pentagastrin) (JOHNSON JONES AURES and HÅKANSON 1969 see also JOHNSON WAY and CLARK, 1969 HÅKANSON and LIEDBERG 1970a) These findings suggest that endogenous gastrin, which is stored in the antrum (the pyloric gland area) is the agent responsible for the enzyme activation induced by feeding or by the injection of insulin and carbachol.

There are three major known stimulants of gastric acid secretion that may be natural mediators of the secretory response namely histamine, gastrin and acetylcholine (vagal stimulation) Whether there is a final common pathway for the action of these three agents is unknown. It is known, however that vagal stimulation releases gastrin (UVNÄS 1942 PE THIEN and SCHOFIELD, 1959 OLBE, 1966 OLBE and ELWIN 1966 FYRÖ, 1967 1968) and it is conceivable that in the rat all of these naturally occurring agents are functionally inter related. Acetylcholine (vagal stimulation) releases gastrin which has a two-fold action in that it releases gastric histamine and at the same time activates gastric histidine decarboxylase (KAHLSON *et al* 1964) to replenish the histamine store It is highly probable that all agents that activate the enzyme do so with gastrin as mediator (AURES HÅKANSON and SCHAUER, 1968 JOHNSON *et al* 1969 AURES *et al.*, 1969 HÅKANSON and LIEDBERG 1970a)

It is evident however that if such a simple relationship exists, it exists only in a limited number of species (Aures Davidson and Håkanson 1969) Firstly the cellular storage site of gastric histamine is different in different species only in the rat and mouse is gastric histamine found in endocrine cells, in all other species studied gastric histamine is found in mast cells only (Håkanson *et al.*, 1970d) Secondly specific histidine decarboxylase has been demonstrated in the gastric mucosa of the mouse, rat and hamster only in all other species studied this enzyme is non-measureable (see Aures, Davidson and Håkanson 1969) These circumstances emphasize the need to consider the concept of histamine as the final common chemostimulator of gastric acid secretion separately for each species.

4 SHORT SUMMARY

1 It is suggested that the argyrophil cells of the digestive tract (whether classified as argentaffin, non-argentaffin, enterochromaffin or enterochromaffin-like) constitute an important endocrine system—or perhaps more correctly a number of different, more or less specialized endocrine systems.

2. From a physiological point of view the conventional classification of the endocrine cells of the digestive tract (for instance in argentaffin *versus* non-argentaffin cells) appears to have little justification. The cytochemical and ultrastructural features of these cells are basically very similar suggesting closely related physiological roles. From electron-microscopic studies it may be concluded that five or six different endocrine cell types occur in the gastrointestinal mucosa.

3 The hormones produced and secreted from these cells have not yet been identified. The most plausible candidates are polypeptide hormones such as gastrin, secretin, pancreozymin-cholecystokinin and enteroglucagon. Possibly also agents such as the antipernicious anaemia intrinsic factor originates from these endocrine cells.

4 A common feature of many polypeptide- or protein-secreting endocrine cells is their capacity to produce and store amines, such as histamine, dopamine and 5-hydroxytryptamine. Apparently the various systems of gastrointestinal endocrine cells are endowed with highly specialized mechanisms for the biosynthesis of amines the amine produced and stored may thus differ from one system of endocrine cells to another It is possible that the amines are stored together with the hormones in the secretory granules, which are numerous in these endocrine cells. The amines may regulate the storage and/or release of the true secretory products. Or the amines may be released from the cell as the result of some stimulus, to affect some adjacent target cell.

5 It is suggested that the endocrine cells of the digestive tract may have a variety of functions, including the secretion of polypeptide or protein hormones (*endocrine function*) the secretion of proteins—such as the intrinsic factor—which facilitate the intestinal absorption of dietary compounds (*exocrine function*) and finally the release of amines, which by way of diffusion control the secretion of adjacent exocrine gland cells (*local regulatory function*)

PART II

5 PROPERTIES OF MAMMALIAN HISTAMINE-FORMING ENZYMES

5 1 *General characteristics of mammalian histamine forming enzymes*

Werle (1936) and Holtz and Heise (1937) were first to report on the presence of histidine decarboxylase in mammalian tissues. Following their initial observations the histamine-forming enzymes of mammalian tissues attracted much attention. Considerable disagreement as to the properties of histidine decarboxylase was soon registered. These discrepancies have since been explained by the existence of several histamine-forming enzymes with different characteristics.

The enzymatic formation of dopamine by decarboxylation of L DOPA was recognized by Holtz, Heise and Lüdtke (1938) and the participation of DOPA decarboxylase in the biosynthesis of catecholamines was postulated by Blaschko in 1939 (see also Holtz, 1959) After the discovery of this enzyme a close similarity was noted in the distribution of histidine decarboxylase and DOPA decarboxylase activities in mammalian tissues (see review by Shepherd and Mackay 1967) In these experiments histidine decarboxylase was found to have its pH optimum at 8 0—9.5 and the corresponding value for DOPA decarboxylase was between 6.5 and 7 0. The possibility was soon considered that these two activities might reside in a single enzyme. Later the activity of an enzyme catalyzing the decarboxylation of L 5-HTP was detected in mammalian tissues (Udenfriend Clark and Titus 1953 Clark, Weissbach and Udenfriend 1954) It was found that the ratio of DOPA decarboxylase activity to 5-HTP decarboxylase activity from one tissue to another was roughly constant (Westermann Balzer and Knell, 1958) and it was suggested that DOPA and 5-HTP were decarboxylated by the same enzyme (Langeman 1958 Bertler and Rosengren 1959 Fellman 1959 Rosengren 1960 Lovenberg Weissbach and Udenfriend 1962 Hagen 1962) Thus it seemed possible that the histidine decarboxylating enzyme, having its pH optimum in the range 8.0—9.5 was identical with DOPA/5-HTP decarboxylase. When purified enzyme extracts of ox adrenal and guinea pig and rabbit kidney became available, the preparations were found to decarboxylate not only these three amino acids (Fellman 1959 Rosengren 1960) but also many other natural and purely synthetic aromatic amino acids (Yuwiler, Geller and Eidusion 1959 Lovenberg Weissbach and Udenfriend 1962 Lovenberg Barchas Weissbach and Udenfriend 1963) From these results it was suggested that the non-specific decarboxylase should be designated aromatic L-amino acid decarboxylase(Lovenberg Weissbach and Udenfriend 1962)

Apart from the similar distribution of the enzyme activities in a variety of tissues, the view that aromatic L-amino acids are all decarboxylated by a single

(Kahlson Rosengren and Westling 1958 Kahlson Rosengren Westling and White, 1958 Kahlson Rosengren and White, 1960) This observation was followed by similar findings in some other tissues of the rat (Kahlson Nilsson Rosengren and Zederfeldt 1960 Mackay Marshall and Riley 1960 Håkanson 1961 Mackay Riley and Shepherd 1961 Kahlson and Rosengren 1963) mouse (Rosengren 1963 Maudsley and West 1964) and hamster (Rosengren 1965) The properties of the enzyme of the foetal rat liver were first studied by Ganrot Rosengren and Rosengren (1961) who concluded that foetal rat histidine decarboxylase was different from the histamine-forming enzyme of rabbit kidney The latter enzyme appeared to be identical with DOPA decarboxylase. Foetal rat histidine decarboxylase was not inhibited by DOPA decarboxylase inhibitors and was considered to be specific. These observations initiated much work aimed at characterizing the histamine-forming enzymes of the mammalian organism.

There is general agreement by now that at least two different histamine-forming enzymes, or groups of enzymes, occur in mammalian tissues (Ganrot Rosengren and Rosengren 1961 Mackay Riley and Shepherd, 1964 Weissbach, Lovenberg and Udenfriend 1961 Håkanson 1963 1964 1966 1967a and b Håkanson and Owman 1966b Auers Håkanson and Schauer, 1968 Auers, Davidson and Håkanson 1969) Histidine decarboxylase from the kidney of the rabbit and guinea pig differs in properties from the enzyme obtained from foetal rat liver and rat stomach. One important difference between the two enzymes is the ability of the kidney enzyme to decarboxylate a large number of aromatic L-amino acids (see above) which is reflected in the fact that the non-sepcific enzyme is strongly inhibited by α-methylDOPA, whereas the specific histidine decarboxylase is unaffected. The latter enzyme, on the other hand, is inhibited by *e.g.* α-methylhistidine, which is a weak inhibitor of aromatic amino acid decarboxylase. Another difference is reflected in the different response of these two enzymes to exposure to organic solvents, such as benzene and chloroform (Waton 1956b) Since highly purified preparations of DOPA decarboxylase retain a histidine decarboxylase activity which is inhibited by well-known DOPA decarboxylase inhibitors, it has been suggested that the capacity to decarboxylate histidine is a property of DOPA decarboxylase. However the affinity for L histidine is so low that the ability of DOPA decarboxylase to produce histamine *in vivo* has been questioned (Ganrot Rosengren and Rosengren 1961 Levine Sato and Sjoerdsma, 1965)

5.2. *Properties of aromatic amino acid decarboxylase*

Rosengren (1960) found that the chromatographic distribution of the DOPA and 5-HTP decarboxylase activities of an extract of rabbit kidney cortex were very similar The ratio of the two activities in the enzyme-containing fractions was almost constant and equal to that observed in crude extracts.

The DOPA/5-HTP decarboxylase-containing fractions also contained all the histidine decarboxylase activity of the extract. Furthermore, the decarboxylation of DOPA by the rabbit kidney extracts was found to be competitively inhibited by 5-HTP and the decarboxylation of 5-HTP by the same extract was competitively inhibited by DOPA. Rosengren (1960) also observed that when *o*-tyrosine, *m* tyrosine or caffeic acid were tested as inhibitors of the rabbit kidney preparation, the inhibition constants were the same irrespective of whether DOPA or 5-HTP were used as substrate for the decarboxylase. On the basis of similar inhibition studies with highly purified extracts of ox adrenals Fellman (1959) and Hagen (1962) concluded that both substrates are decarboxylated by one and the same enzyme. There are also inhibition studies to support the view that histidine is decarboxylated by the DOPA/5-HTP decarboxylase. Thus, with purified preparations of DOPA decarboxylase, α-methyl-DOPA and other α-methylated aromatic amino acids were found to be potent inhibitors of all three enzyme activities (Sourkes, 1954 Mackay and Shepherd 1960 Murphy and Sourkes 1961 see also Schayer and Sestokas, 1965) Lovenberg Weissbach and Udenfriend (1962) purified an extract of guinea-pig kidney by DEAE cellulose chromatography and found that the fractions that contained 5-HTP decarboxylase also catalyzed the decarboxylation of other aromatic amino acids (including α methylated derivatives) as well as histidine (see also Weissbach, Lovenberg and Udenfriend 1960) they concluded that the decarboxylation of all of these substrates was catalyzed by a single enzyme aromatic L amino acid decarboxylase.

The pH optimum of DOPA decarboxylation is at about pH 6.5—7.0 (Schales and Schales 1949 Clark, Weissbach and Udenfriend 1954 Hakanson 1967d) The corresponding value for 5-HTP decarboxylation is approximately 9.0 (Clark, Weissbach and Udenfriend 1954) and for histidine decarboxylation 8.5—9.0 (Lovenberg Weissbach and Udenfriend 1962) The K_m value for DOPA decarboxylation was found to be 5.4×10^{-4} at pH 6.8 (Schott and Clark, 1952 Fellman 1959) and 7.4×10^{-5} at pH 7.5 (Rosengren 1960) the K_m for 5-HTP decarboxylation was estimated to 4×10^{-5} at pH 8 1.7×10^{-4} at pH 6.8 (Yuwiler, Geller and Eidusson 1960 see also Clark, Weissbach and Udenfriend 1954) and 1.3×10^{-4} at pH 7.5 (Rosengren 1960) The K_m for histidine decarboxylation catalyzed by the rabbit enzyme at pH 7.8 was given as 10^{-1} by Ganrot Rosengren and Rosengren (1961) Inhibition studies performed with DOPA and 5-HTP suggested that one single enzymic site is involved in the decarboxylation of both substrates (Yuwiler, Geller and Eidusson 1959 1960 Rosengren 1960)

Waton (1956b) observed that addition of small amounts of certain organic solvents increased the rate of histidine decarboxylation in extracts from rabbit kidney Benzene, which was found to be most active, produced five- to ten-fold activation of the enzyme. The potentiating effect of benzene has since been amply confirmed in several laboratories (Schayer, 1957 Mackay Riley and Shepherd 1961 Telford and West 1961b) Lovenberg, Weissbach and

Udenfriend (1962) reported that while the ability of the kidney enzyme to decarboxylate histidine and *p*-tyrosine was increased by benzene, the ability to decarboxylate DOPA and 5-HTP was decreased. No explanation for these effects of benzene can be offered. Conceivably organic solvents, such as benzene and chloroform, alter the enzyme protein configuration thus enhancing the opportunities for attachment of the histidine and *p*-tyrosine molecules to the active site.

5.3 *Properties of specific histidine decarboxylase*

Another histidine decarboxylating enzyme appears to be specific and is probably of greater physiological significance as a catalyst of histamine formation (Ganrot Rosengren and Rosengren 1961, Weissbach Lovenberg and Udenfriend 1961, Levine, Sato and Sjoerdsma, 1965). This enzyme is generally referred to as mammalian histidine decarboxylase or "specific" histidine decarboxylase (EC 4.1.1.22). The "specific" histamine forming enzyme has been found in a limited number of tissues. Foetal rat liver (Ganrot Rosengren and Rosengren 1961, Håkanson 1963), hamster placenta (Håkanson 1967b) and murine mastocytoma (Noll, 1965, Ahres and Noll, 1966) are conspicuously rich sources of this enzyme. Considerable activities have been demonstrated also in gastric mucosa of the rat (Weissbach Lovenberg and Udenfriend 1961, Håkanson and Owman 1966b) and mouse (Håkanson 1967a), in the red bone marrow of the rat (Håkanson 1964) and in various transplantable tumours of the rat (Mackay Riley and Shepherd 1961, Håkanson 1966) (Table 2).

The kinetic properties of foetal histidine decarboxylase could be studied in some detail only after a method for its purification had been developed (Håkanson 1963). Pregnant rats were decapitated 15—20 days after mating and the litters were collected and pooled. In frozen condition (—30 C) the foetal rat tissue maintained its enzyme activity for several weeks. The tissue was homogenized in 0.1 M sodium acetate-acetic acid buffer pH 4.5 and centrifuged at 20 000×g in a refrigerated centrifuge for 20 min. The supernatant was heated at 55 C for 5 min. and centrifuged at 20 000×g for 10 min. the precipitate was discarded. The resulting supernatant was found to contain more than 90 per cent of the initial enzyme activity. The bulk of histidine decarboxylase was precipitated with ammonium sulfate at between 25 and 40 per cent saturation. This precipitate was spun down, re-suspended in 10—20 ml 0.1 M phosphate buffer pH 7.0 and dialyzed against re-distilled water at 4 C for a minimum of 18 hours with frequent changes of water. After centrifugation, the supernatant of the dialyzed extract was again treated with ammonium sulfate. The material which now precipitated at between 28 and 42 per cent saturation contained all the histidine decarboxylase activity. This precipitate was spun down, re-suspended in a small volume of the phosphate buffer and dialyzed against water for at least 6 hours with 3 changes of water.

TABLE 2

Characteristics of histidine decarboxylases from various tissue sources*

Source	pH Optimum	Substrate saturation point	Inhibition by DOPA or α-methyl DOPA	Effect of benzene	Substrat specificity	Classification	References
Mouse							
Mastocytoma	6.0—7.3	low	weak or none	none	histidine	specific	1 6 23 36
Stomach	6.0—7.0	low	—	—	—	specific	10
Maternal kidney	6.0—7 0	low	–	—	—	specific	10
Fetal tissues	6.4—7.0	low	—	—	—	specific	10 22
Rat							
Stomach	6.2—7 2	low	weak	inhibition	histidine	specific	3 12, 14 16 32, 36
Fetal tissues	6.0—7 2	low	weak or none	none	histidine	specific	4, 5 7 11 15
Bone marrow	6.5—6.8	low	none	—	histidine	specific	8, 13
Tumours							
Rous, sarcoma, hepatoma, Walker carcinoma	6.0—6.8	low	weak	none	histidine	specific	9 15 20 25 31
Mast cells	6.5—7 6	low	weak	inhibition	histidine	specific	30 33
Liver	8.0	high	strong	potentiation	aromatic amino acids	non-specific	15 25 35
Kidney	7.5	—	—	potentiation	—	non-specific?	35
Guinea-pig							
Kidney	8.0—9.5	high	strong	potentiation	aromatic amino acids	non-specific	18, 19 20 21 27 32 36
Stomach	8.0	high	—	—	—	non-specific	2, 36
Fetal tissues	8.0	—	—	potentiation	—	non-specific?	16

Rabbit							
Kidney	8.0	high	strong	potentiation	aromatic amino acids	non-specific	3, 28
Fetal tissues	8.0—8.5	—	—	potentiation	—	non-specific	16
Platelets	7.2—7.4	—	—	—	—	specific?	34
Stomach	9.0	high	—	—	aromatic amino acids	non-specific	2, 1
Hamster							
Placenta	6.0—7.2	low	—	—	histidine	specific	11, 29
Stomach	6.6—7.2	low	—	—	histidine?	specific?	2
Fetal tissues	8.0			potentiation	aromatic amino acids?	non-specific	16

It should noted that in some tissues both the specific and the non-specific histamine forming enzyme has been demonstrated (see e.g. Ref. 12). In those cases the properties of the specific enzyme are given.

The procedure described was found to result in a 200-fold purification of the enzyme. Although a single ammonium sulfate fractionation results in only a partial separation of histidine decarboxylase and DOPA decarboxylase (see Table 3) the full procedure markedly reduces the activity of the non-specific enzyme. More than 50 per cent of the histidine decarboxylase activity of the initial homogenate was preserved in the final extract. Even at —30 C the purified enzyme was stable for only a few days. The purification procedure caused an almost complete resolution of the holoenzyme, and pyridoxal 5 phosphate had to be added to the incubation mixture to restore the enzyme activity

TABLE 3

Activities of histidine decarboxylase and DOPA decarboxylase in fractions obtained by precipitating extracts from rat stomachs and foetal mice with increasing amounts of ammonium sulfate.

$(NH_4)_2SO_4$ (% saturation)	Rat stomach		Foetal mice	
	DOPA decarboxylase	Histidine decarboxylase	DOPA decarboxylase	Histidine decarboxylase
20	2±1 (3)	6±2 (3)	1±0 (3)	2±0 (3)
30	7±2 (3)	39±4 (4)	8±4 (3)	39±8 (3)
40	33±3 (3)	43±3 (4)	39±9 (3)	40±1 (3)
50	52±2 (3)	9±3 (4)	36 ± 3 (3)	15±5 (3)
60	7±3 (3)	3±1 (4)	16±2 (3)	4±1 (3)

The purification procedure described above has been found useful for the preparation of histidine decarboxylase not only from foetal rat tissues (Levine, Sato and Sjoerdsma 1965 Levine and Watts 1966 Skidmore and White 1966a 1966b Lelkweber, 1968) but also from other tissue sources, such as hamster placenta (Håkanson 1967b) kidney of pregnant mice (Håkanson 1967a) red bone marrow of the rat (Håkanson 1964) transplantable tumours of the rat (Håkanson 1966) and murine gastric mucosa (Håkanson and Owman 1966b Håkanson 1967a, Autes Håkanson and Schauer, 1968) Minor modifications have been introduced. In some cases it has been found advantageous to elevate the pH of the acetate buffer used in the initial homogenization from 4.5 to 5.5 (Levine and Watts, 1966) sometimes the heating step has been omitted, so has quite often the second ammonium sulfate precipitation. The methods described for the purification of mammalian histidine decarboxylase have recently been reviewed by Schayer (1968) and by Autes and Håkanson (1970)

The process of purification of mammalian histidine decarboxylase (EC 4 1 1.22) may be directed towards 1) high purity in absolute terms or 2) high purity in relative terms i.e. successful separation from other contaminating histamine forming enzymes. These objectives are not always identical. The purpose of the study will be decisive for selection of enzyme source. Hamster

placenta, which is low in DOPA decarboxylase (HÅKANSON 1967b) is the superior source of enzyme for extensive purification and detailed characterization of "specific" histidine decarboxylase. Murine mastocytoma, which is rich in both histidine decarboxylase and DOPA decarboxylase (AURES and CLARK, 1964; AURES and NOLL, 1965; NOLL, 1966) is an excellent source of enzyme for studies on the separation of the two enzymes.

As of yet, column chromatographic procedures have had only limited use in the purification of mammalian histidine decarboxylase (WERLE and LORENZ, 1966) and methods presented up till now have had a preliminary character. Highly purified preparations of histidine decarboxylase have been prepared (HÅKANSON and JOSEFSSON 1970) but the major problem in the purification of mammalian histidine decarboxylase by column chromatography is the extreme lability of the highly purified preparations.

Foetal rat histidine decarboxylase was found to have very characteristic kinetic properties.* The optimal pH varied with the substrate concentration (Fig. 22 and Fig. 23) from pH 6.0 at high histidine concentration

---

Mathematical treatment of kinetic data. The kinetic data were analyzed by the Lineweaver Burk transformation of the general rate equation, which was used to give the apparent maximal velocity (V'_{max}) and the apparent Michaelis-Menten constant (K_m). It has rightly been argued that whereas V'_{max} can be fairly reliably determined by the conventional Lineweaver Burk method this transformation of the general rate equation has to be used with caution for the determination of K_m since with this plot the most unreliable values of each experiment has a decisive influence on the result. Thus, in some experiments (see Håkanson, 1967c; Aures, Håkanson and Schauer 1968) the so-called Eadie transformation was used. In conjunction some authors hold this method of analysis to be superior.

The simple reaction scheme according to Michaelis and Menten

$$E + S \underset{2}{\overset{1}{\rightleftharpoons}} ES \underset{4}{\overset{3}{\rightleftharpoons}} E + P + CO_2 \qquad (1a)$$

E denotes the enzyme-coenzyme complex, S represents histidine and P and CO_2 the reaction products. The backward reaction (Reaction 4) may be neglected since wherever possible initial velocities were measured.

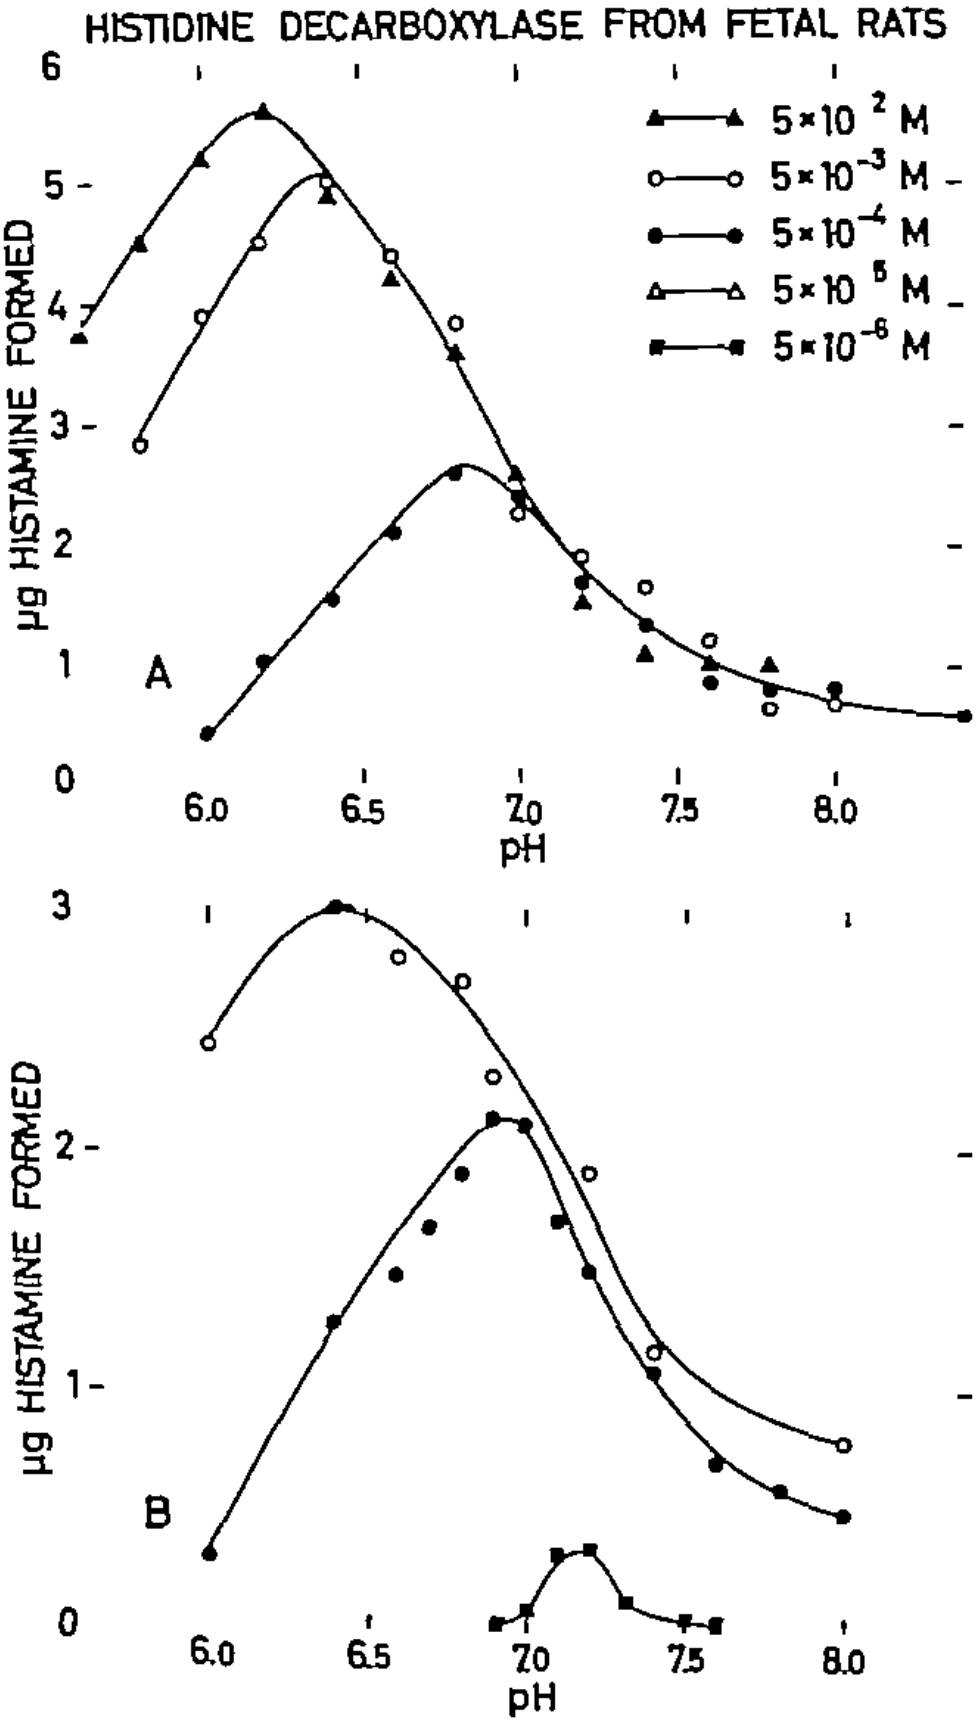
From this scheme, the usual rate equation may be derived from the assumption of a steady state:

$$\frac{d(ES)}{dt} = k_1(E)(S) - k_2(ES) - k_3(ES) = 0 \qquad (2a)$$

$$\frac{(E)(S)}{(ES)} = \frac{k_2 + k_3}{k_1}$$

$$v = \frac{d(P)}{dt} = k_3(ES) \qquad (3a)$$

Applying these relations to the conservation equation



$$(E_t) = (E) + (ES) \qquad (4)$$

and

$$V'_{max} = \left(\frac{K_m}{(S)} + 1\right) \qquad (5a)$$

where

$$K_m = \frac{k_2 + k_3}{k_1} \text{ and } V'_{max} = k_3(E_t)$$

to 7.9 at low concentrations. Similar observations were subsequently made with semi-purified preparations of histidine decarboxylase from foetal mice, hamster placenta, renal cortex of pregnant mice, red bone marrow and transplantable tumours of the rat and murine gastric mucosa (Fig. 22). The substrate saturation point of the enzyme turned out to be highly dependent on pH. At pH 7.6–8.0 a low K_m was observed; at more acid conditions K_m was markedly increased (Fig. 24). It is evident from these observations which are summarized in Table 4 that several histamine forming enzymes, or groups of enzymes, with different properties occur in mammalian tissues. Until precise chromatographic procedures have become available for the separation and identification of the various enzyme species, their kinetic characteristics will be the most important criterion in distinguishing between them. It is not enough to demonstrate that a particular histamine-forming enzyme is different from DOPA decarboxylase by means of inhibitors or by its being unaffected by the addition of benzene.* At present the only reliable method for positive identification of mammalian histidine decarboxylase is through kinetic analysis of the partially purified

---

*Neither is the responsiveness of histidine decarboxylase activity to corticoid stimuli a reliable criterion as suggested by Telford and West (1961) and Telford (1965) since conceivably the response is related to complex effects on the cell or on the tissue storing the enzyme rather than on the enzyme protein directly. The same enzyme may respond differently depending on the [illegible] which the enzyme is contained.

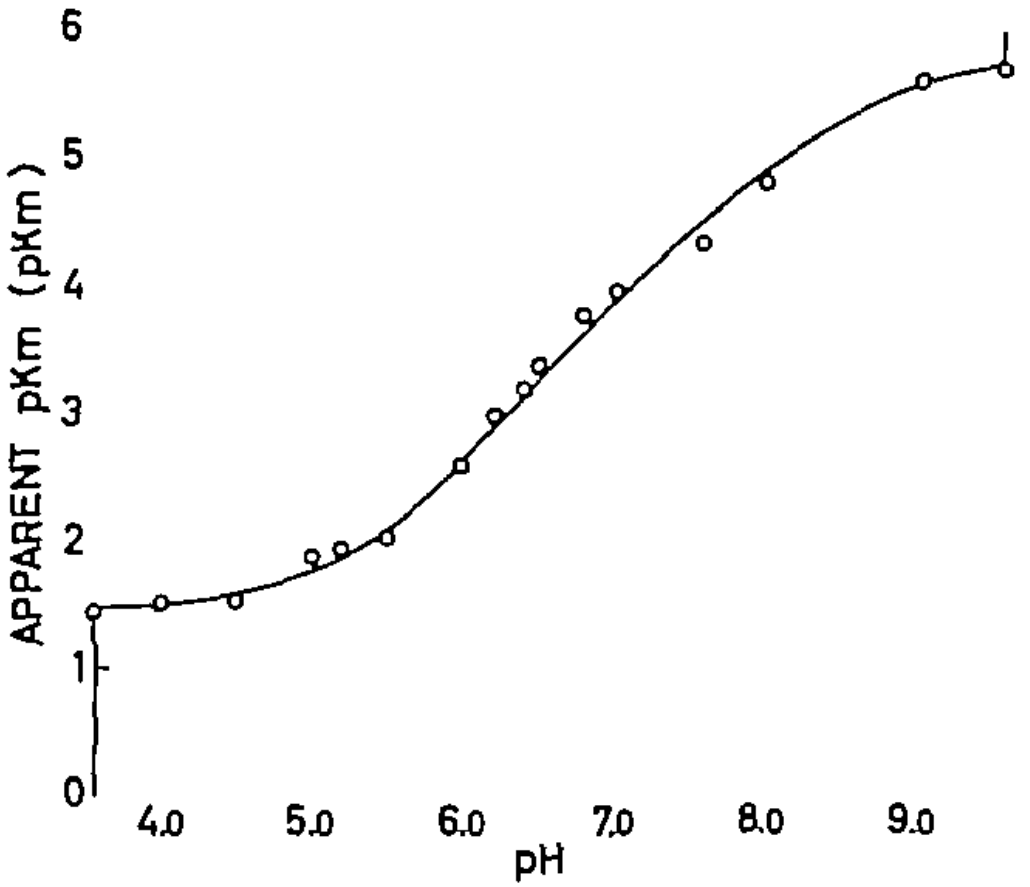

Fig. 24 pK_m *versus* pH (see Table 7)

enzyme. Available data indicate that mammalian histidine decarboxylase from a variety of tissues, such as foetal rat tissues, hamster placenta, murine mastocytoma, murine gastric mucosa, mouse kidney and rat tumours, has the following characteristics (Table 5 6 and7) 1) With high substrate concentration maximal reaction velocity is observed at pH 6 0 the maximal apparent V_{max} is at a pH value close to 5 6 (Fig 25) 2) The pH optimum of the reaction is inversely related to the substrate concentration with very low histidine concentration optimal pH is close to 7 2 (Fig 23) 3) the K_m value decreases markedly with increasing pH In contrast, the non-specific histamine forming enzyme (possibly identical with DOPA decarboxylase) has its pH optimum at about 9 and requires very high histidine concentrations for saturation at all pH values.**

** These differences have some important practical consequences. It is possible, and advisable, to select incubation conditions such as to minimise the interference of the histamine-forming capacity of DOPA decarboxylase, for instance by choosing pH 6.0—6.9 and by restricting the histidine concentration t that which is saturating or near -saturating t that particular pH valu

5.4 *Cofactor requirements of mammalian histamine forming enzymes*

With very few exceptions (Rosenthaler, Guirard Chiang and Snell, 1965) pyridoxal-5 -phosphate (PALP) is the coenzyme of amino acid decarboxylases of bacterial as well as of mammalian origin (Ono and Hagen 1959 Rothschild and Schayer, 1959 Awapara, Sandman and Hanley 1962)

DOPA/5-HTP decarboxylase however has proved difficult to resolve completely in inactive apoenzyme and free coenzyme. In extracts from certain tissues, the coenzyme seems to be rather tightly bound to the apoenzyme (Clark, Weissbach and Udenfriend, 1954) in such a case it can be very difficult to prove that a coenzyme participates in the reaction. It has been shown, however that addition of PALP to highly purified or semipurified preparations of DOPA decarboxylase from *e.g.* ox adrenal and rabbit pineal gland causes a marked increase in enzyme activity (Fellman 1959 Hårdanson and Owman 1966a) Furthermore, carbonyl trapping agents, which react with PALP are inhibitors of DOPA/5-HTP decarboxylase (Clark, 1963 Pletscher, Gey and Burkard 1966) Together these observations indicate that PALP is the coenzyme also of DOPA decarboxylase.

Fellman (1959) showed that substances which combine with SH-groups (N-ethyl maleimide and mercuric ions) inhibit ox adrenal DOPA decarboxylase. This may indicate that the non-specific aromatic amino acid decarboxylase contains SH-groups, possibly at its active center No metal ion tested activated DOPA decarboxylase, and EDTA did not inhibit.

Foetal rat *histidine decarboxylase* is almost completely resolved into free apoenzyme by the purification procedure used (Hårdanson 1963) Prolonged dialysis against carbonyl trapping agents such as semicarbazide enhances the resolution of the holoenzyme (Hårdanson 1967c) Of all the compounds initially tested (pyridoxal, pyridoxal-5 phosphate, pyridoxine, pyridoxamine, pyridoxamine-5 phosphate and the cyanohydrin derivative of pyridoxal 5 -phosphate) only PALP was capable of reactivating the enzyme (Hårdanson 1967c) Only small amounts of the coenzyme were required for maximal activation. While the addition of PALP readily activated the enzyme, the cyanohydrin derivative failed to do so. If both PALP and the cyanohydrin derivative were added to the incubation mixture, the enzyme-activating effect of PALP was inhibited, possibly through competitive inhibition. This observation is at variance with the results of Bonavita and Scardi (1958a) on glutamic-oxaloacetic transaminase but nevertheless support their conclusion that PALP is attached to the apoenzyme by the carbonyl group as well as by the phosphate ester group. In agreement with this assumption it was observed that pre incubating the enzyme with pyridoxal caused a moderate inhibition of the coenzyme activity of PALP possibly through pyridoxal occupying the carbonyl attachment site. The equilibrium constant of the coenzyme histidine apodecarboxylase complex was found to change with pH in a manner which suggests

that the reactants involved are particular ionic species of the molecules (HÄKANSON 1967c)

EDTA or EGTA in concentrations of 10^{-3} M did not interfere with the formation of histamine (see also WEISSBACH, LOVENBERG and UDENFRIEND, 1961 AURES and CLARK, 1964) In concentrations below 10^{-4} M metal ions (Mg^{++} Cu^{++} and Fe^{+++}) were inert. There was thus no evidence that metal ions are essential for the molecular mechanism of histamine biosynthesis. Iodoacetamide (final concentrations 5×10^{-4} M) added either before or after PALP failed to inhibit mammalian histidine decarboxylase indicating that SH-groups are not involved in the reaction.

In subsequent studies it was observed that phospho-5 pyridoxaminotriazole (PPIT) a condensation product of PALP and 4-amino-1 2 4-triazole, was capable of activating mammalian L histidine apodecarboxylase (AURES, HÄKANSON and WIBERMAN 1969) Previously PPIT had been found potent in activating L DOPA decarboxylase (GONNARD and NGUYEN CHI 1959) PPIT is known to be a stable compound and GONNARD concluded that PPIT *per se* acted as coenzyme (GONNARD DUHAULT CARLIER, NGUYEN PHILIPPON and BOIONE, 1967) This was in disagreement with the concept of BRAUNSTEIN and SNELL BRAUNSTEIN and SHEMYAKIN 1953 METZLER, IKAWA and SNELL 1954) but predicts that only compounds with a free or potentially free carbonyl group should act as coenzyme. However it was observed that PPIT reacts with certain amino acids (but not with all) forming condensation products with ultraviolet absorption and fluorescence spectra identical with those of their aldimines with PALP (AURES HÄKANSON and WIBERMAN 1967) It was concluded that the activating effect of PPIT on L histidine apodecarboxylase is the result of an initial transaldimination of PPIT at the enzyme site leaving the conventional holoenzyme (apoenzyme-PALP aldimine) and free aminotriazole. The affinity of PPIT for the apoenzyme may differ from that of PALP itself but after the holoenzyme complex is established, the enzyme-substrate reaction proceeds in a normal fashion.

5.5 *Histamine forming enzymes of gastric mucosa*

SCHAYER (1956b 1957) was the first to show that the glandular stomach of the rat had a high histidine decarboxylating activity and that this enzyme was different from the histidine decarboxylase of rabbit kidney This observation was later confirmed by a number of authors (KAHLSON *et al.* 1964 HÄKANSSON and OWMAN 1966b LEVINE and WATTS 1966) and the experiments of HIGHT, SHEPHERD and WOODCOCK (1965) and SHEPHERD and WOODCOCK (1968a) established beyond doubt that in the rat the glandular stomach is a major source of histamine formation *in vivo*

The kinetic properties of a crude preparation of rat stomach histidine decarboxylase was first studied by WEISSBACH, LOVENBERG and UDENFRIEND (1961) who demonstrated a much lower K_m value for this enzyme than

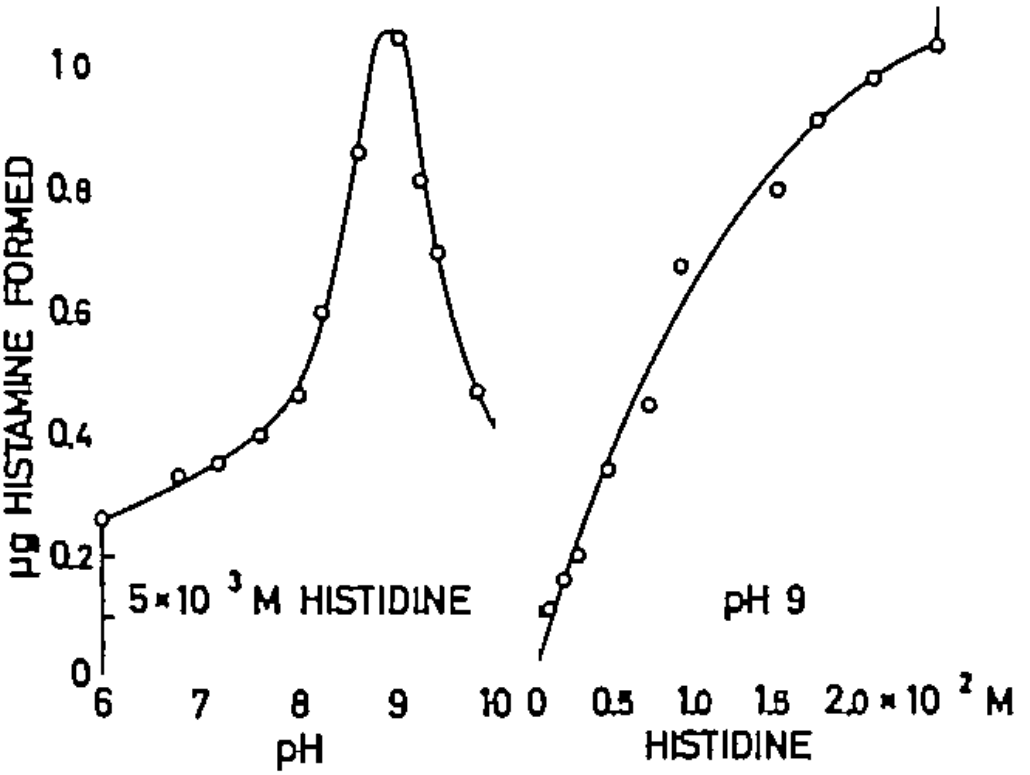

Fig. 26. Non-specific histamine-forming enzyme of rabbit stomach. (Left) Reaction velocity *versus* pH. (Right) Reaction velocity *versus* substrate concentration.

for the formation of histamine catalyzed by DOPA decarboxylase. This initial observation was confirmed by HÅKANSON and OWMAN (1966b) and by AURELL, HÅKANSON and SCHAUER (1968) using a semi-purified preparation of rat stomach histidine decarboxylase. The purification procedure was similar to that used for foetal rat histidine decarboxylase. It could be shown that the pH optimum of the enzyme varied with the substrate concentration (Fig 22) and that the K_m value increased with increasing hydrogen ion concentration (Table 7) Gastric histidine decarboxylase was thus found to have kinetic properties very similar to those of the histamine-forming enzyme of other tissue sources such as the foetal rat or the hamster placenta. It was apparent, however already from the studies of WEISSBACH *et al.* (1961) that the histamine forming enzyme of the guinea-pig and rabbit stomach (see also DAWSON MAUPAILEY and WEST 1965 HÅKANSON and OWMAN 1966b AURELL DAVIDSON and HÅKANSON 1969) was different from of the rat stomach. The histamine forming enzyme of the guinea pig and rabbit stomach was found to have kinetic properties similar to those reported for histamine formation catalyzed by DOPA decarboxylase. Thus, with these preparations the optimum pH for the histamine formation was close to 9 and the K_m value at this pH was very high (Fig. 26) Moreover it could be established that also the rat stomach had high activities of DOPA decarboxylase, in addition to the "specific" histamine-forming enzyme (HÅKANSON 1965 HÅKANSON and OWMAN 1966b AURELL, HÅKANSSON and SCHAUER, 1968)

The histidine decarboxylase of the glandular rat stomach is activated by a number of physiological and pathophysiological (Code and Hallenbeck, 1961 Kahlson *et al* 1964 Castellucci, 1965 Lilja and Svensson 1967 Fischer and Snyder, 1965a and b Johnson 1967 Håkanson and Liedberg, 1970a) and pharmacological stimuli (Kahlson Rosenberg and Thunberg 1967 Aures Håkanson and Schauer, 1968) It has been suggested that the adaptivity of the enzyme reflects a physiological control function of histamine in gastric secretion and that depletion of the gastric histamine stores caused for instance by gastrin (Kahlson *et al.* 1964) triggers the events leading to increased histidine decarboxylase activity and thus to the rapid replenishment of the histamine content of the gastric mucosa (Kahlson *et al.*, 1964)

Fasting and feeding have marked effects on the histidine decarboxylase activity of the rat stomach After 48 hours of starvation, the enzyme activity is reduced to very low levels Intake of food at this stage results in a 5-10-fold activation of gastric histidine decarboxylase within 1—2 hr The activity of gastric DOPA decarboxylase, on the other hand was not significantly affected by feeding or fasting (Aures Håkanson and Schauer, 1968) A number of drugs were tested for their effect on gastric amino acid decarboxylases. Gastrin was most effective in activating the histidine decarboxylase the activation occurred very rapidly after 1 hr the enzyme was maximally activated and the activity stayed high for another hour Insulin, 2-deoxyglucose, 2-deoxygalactose, reserpine and carbachol were also quite potent in increasing the level of gastric histidine decarboxylase (Aures Håkanson and Schauer, 1968) None of these compounds had any effect on gastric DOPA decarboxylase. Histamine and histidine failed to activate histidine decarboxylase in fact, both these compounds caused a reduction of the enzyme activity in fasted rats. Polymyxin B and Compound 48/80 did not activate gastric histidine decarboxylase, neither did they affect gastric DOPA decarboxylase (Aures Håkanson and Schauer, 1968) One possible explanation for the enzyme-activating effect of certain drugs and certain treatments is that they release endogenous gastrin, which probably is the mediator of the enzyme activation. For a discussion of this concept see section 3 10

Very little is known about the mechanism by which gastrin activates the histidine decarboxylase of the enterochromaffin-like cell system in the rat stomach. Observations by Snyder and Epps (1968) suggest that the increased histidine decarboxylase activity is a result of accelerated synthesis of enzyme protein. In this context the observation of a local protein synthesis-stimulating effect of gastrin on certain parts of the digestive tracts gains added significance (Johnson Aures and Håkanson 1969 Johnson Aures and Yuen 1969)

Observations on the regional and topographical distribution of gastric histidine decarboxylase and DOPA decarboxylase in the rat indicate that most of the histidine decarboxylase is contained in the histamine-storing enterochromaffin like cells of the oxyntic gland area, whereas the major portion of DOPA decarboxylase is found in the 5-HT-containing enterochromaffin cells of the

pyloric gland area (Aures Håkanson and Schauer, 1968) It appears well established, however that the enterochromaffin-like cells in addition also contain DOPA decarboxylase (Håkanson and Owman 1966b Håkanson Lilja and Owman 1967 Aures Håkanson and Schauer, 1968 section 3.6) although in considerably lower quantities than the enterochromaffin cells. No histidine decarboxylase activity has been demonstrated in the latter cell system and there was no evidence that the mast cells of the stomach wall add significantly to the activities of either histidine decarboxylase or DOPA decarboxylase (Aures Håkanson and Schauer, 1968)

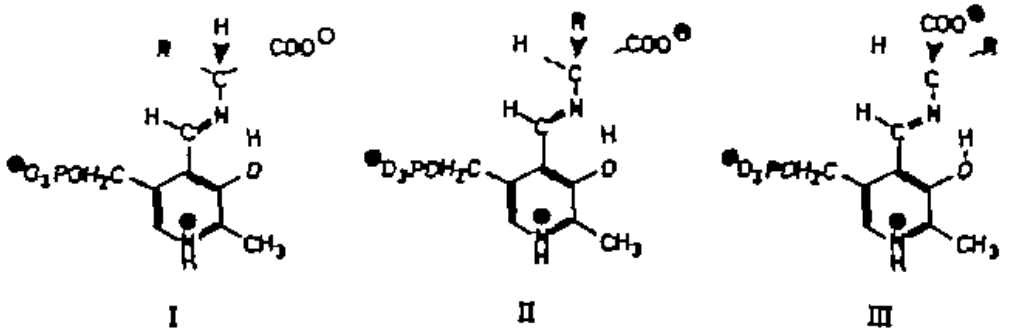
High activities of gastric DOPA decarboxylase were found in all mammals studied the regional distribution of the enzyme generally agreed very well with the distribution of the enterochromaffin cells (Håkanson *et al.* 1970d) Gastric histidine decarboxylase, on the other hand, could be demonstrated only in the mouse, rat and hamster in the other species the activity was either non-measurable or too low to permit identification of the enzyme. This was the case also under conditions which are known to result in maximal stimulation of gastric histidine decarboxylase activity in the rat, *i.e.* after the intake of food or after the injection of gastrin (Aures Davidson and Håkanson 1969) This finding, which is in agreement with previous reports from some laboratories (Weisbach, Lovenberg and Udenfriend 1961 Håkanson and Owman 1966b Aures, Håkanson Owman and Sporrong, 1968 Kim and Glick, 1969 Håkanson Lilja and Owman 1969) disagrees with those of some other groups (Kahlson Rosengren Svahn and Thunberg 1964 Kahlson Rosengren and Thunberg 1967 Werle and Lorenz, 1964 Lorenz, Pfleger and Werle, 1967 Lorenz, Hahlbach, Gerant and Werle, 1969) These conflicting observations may perhaps to some extent reflect differences in the strains of animals used and in the treatment of the animals but it appears more likely that they reflect differences in experimental technique. Lorenz and co-workers have been using a fluorometric method for the determination of histidine decarboxylase activity and Kahlson and co-workers a radiometric method, the so-called HFC assay For the discussion and evaluation of these methods see Aures Davidson and Håkanson (1969) and section 2.1 It must be emphasized, also in this context, that it is not enough to register formation of histamine the catalyzing agent has to be further characterized to permit an identification with the "specific" histidine decarboxylase.

Radwan and West (1967) described a third histamine-forming enzyme in the ruminal portion of the rat stomach, with a pH optimum of 5.5 The presence of this enzyme could not be confirmed by Aures, Håkanson and Schauer (1968) Kobayashi and Maudsley (1969) however recently reported that the enzyme occurred predominantly in male rats and convincingly documented its occurrence in the rumen and its kinetic properties. It appears that this enzyme is insoluble and unaffected by fasting and feeding. Very little is known of the factors regulating the activity of this enzyme, as well as of its properties and possible physiological significance. Kinetically this enzyme

resembles bacterial histidine decarboxylase, and the possibility that the enzyme activity reflects bacterial contamination has still not been definitely excluded.

SCHAYER (1960a and b 1963a 1964) and SCHAYER and GANLEY (1959) have reported that histidine decarboxylase in many tissues of the rat and mouse, such as skin, muscle and kidney can be markedly activated by the injection of adrenaline, histamine liberators and endotoxins. It is apparent that although gastric histidine decarboxylase and the inducible" histidine decarboxylase of SCHAYER may be similar kinetically the physiological and pharmacological factors which control their activities are quite different.

5 6. *Molecular mechanism of enzyme catalyzed histamine formation*



General mechanism of amino acid decarboxylation PALP acts as coenzyme in a number of enzyme reactions involving α-amino acids in particular It is generally accepted that for pyridoxal-enzymes the coenzyme constitutes the catalytic nucleus of the active site and that the surrounding protein structure provides the steric arrangement which accounts for the specificity of the reaction. A general scheme for PALP-catalyzed reactions was proposed by BRAUNSTEIN and SHEMYAKIN (1953) and by METZLER, IKAWA and SNELL (1954) based on their studies of the non-enzymic interaction of pyridoxal with amino acids. When solutions of pyridoxal and amino acids are mixed an immediate yellowing occurs as the result of an imine (Schiff base) formation between the two reactants. The Schiff base is a highly reactive product the subsequent transformation of the amino acid depends upon the reaction conditions and may involve deamination racemization, decarboxylation, αβ-eliminations or cleavage Addition of appropriate metal ions increases the rate of deamination and αβ-elimination reaction but inhibits decarboxylation. This may be due partially to the increased rate of other pyridoxal-catalyzed reactions that are promoted by metal ions alternatively it may result from formation of chelates in which the binding of the carboxyl group to metal ion slows its release as carbon dioxide.

General mechanisms were proposed to explain the above results. All avilable evidence suggested that the non-enzymatic reactions proceed by mechanisms closely resembling those of the corresponding enzymatic reactions. It is apparent therefore, that PALP constitutes the catalytic nucleus of the active center of each of the many pyridoxal-dependent enzymes. SNELL (1958) suggested that the apoenzyme can be visualized as replacing the metal ion in non-enzymatic reactions and in so doing plays a similar but even more effective role in the enzymatic reactions.

The original model suggested that the amino acid substrate reacted with the free carbonyl-group of enzyme-bound PALP forming a Schiff base which was subsequently degraded or modified in a specific manner depending on the stereochemical configuration of the active site. The observations of BONAVITA and SCARDI (1958a and b) introduced a slightly different concept, according

to which PALP was attached to the apoenzyme via an aldimine bond and reaction with substrate involved an initial transaldimination in which the amino acid substrate formed a Schiff base with the enzyme-bound PALP displacing the apoenzyme amino nitrogen. There are reasons to believe that in some cases the coenzyme forms an aldimine with the -amino group of a lysine residue of the apoenzyme (Fischer, Krnt Snyder and Krebs 1958 Dempsey 1960 Hughes Jenkins and Fischer 1962) Snell (1958) pointed out that the binding of the carbonyl group does not exclude the intermediary -zomethine formation between enzyme-bound PALP and substrate. On the contrary such binding may be partially responsible for substrate specificity since only certain amino compounds would compete successfully with groupings from the protein for the carbonyl group of the coenzyme Although the formyl and phosphate groups have been emphasized as the primary site of binding other functional groups of the pyridine ring may be considered. There is no evidence as yet that the phenolic hydroxyl group and the ring nitrogen are directly involved in coenzyme binding

It should be noted that Gonnard and Nouyen Chi (1959) and Murakami and Makino (1966) have refuted the catalytic mechanism proposed by Braunstein and Snell on the basis of observations showing that certain carbonyl-substituted derivatives of PALP could act as coenzyme. This has been demonstrated for a variety of amino acid decarboxylases, including mammalian histidine decarboxylase and DOPA decarboxylase. Gonnard Duhault Camier, Nouyen Phillipon and Boione (1964) interpreted the results as indicating that these derivatives function coenzymatically *per se* this is contradictory to the theory of Braunstein and Snell, which requires a free—or potentially free—carbonyl group of PALP The interpretation of Gonnard has been criticized by Torchinsky (1963) and Aurea Hakanson and Wiseman (1969) who have pointed out that the results may equally well be explained by an initial transaldimination of the PALP-aldimine at the active sites of the apoenzyme, leaving the conventional holoenzyme and stoichiometric amounts of liberated carbonyl trapping compound.

I II III

Fig. 27 Various steric conformations of the pyridoxal-5 -phosphate amino acid imine. The arrow indicates the position (perpendicular to the α-carbon) which is activated by th cofactor pi system. Conformation III is appropriate for decarboxylation.

DUNATHAN (1966) has emphasized the specific geometrical requirements for each type of chemical reaction catalyzed by PALP enzymes. The main function of the cofactor pi system is to weaken the sigma bonds around the α-carbon of the amino acid. For this purpose the stereochemical relationship of the sigma bond to the adjacent pi orbitals is important. Experimental results have indicated a clear preference for the geometry in which the bond to be broken lies in a plane perpendicular to that of the pyridoxal imine system. Conformation III as illustrated in Fig. 27 is appropriate for α-decarboxylation. The position of the enzymatic site binding the carboxyl anion of the amino acid is probably the most important factor in controlling the conformation which determines the reaction specificity. If a change is made in the configuration at the α-carbon of the amino acid and if the carboxyl binding site continues to control the conformation about the α-carbon to nitrogen bond, a different group on the α-carbon may be subject to the activating influence of the PALP ring. From theoretical considerations, however, it can be predicted that an α-decarboxylase should never show reactions involving labilizations of groups other than the carboxyl group since only the carboxyl anion can occupy the "activated" position. On the other hand, the stereochemical relationship between PALP and the carboxyl binding site is such that α-decarboxylases should be able to accept as substrates also D-amino acids. In Fig. 28 R and H may exchange positions at the active site while the carboxyl anion remains in the activated position. However, in the case of mammalian histidine decarboxylase and DOPA decarboxylase absolute stereospecificity exist, permitting enzymatic transformation of the substrate L forms only. This would indicate that the holoenzyme offers specific binding sites for other groupings on the amino acid substrate apart from the amino group and the carboxyl group; apparently this third binding site strictly determines the three-dimensional conformation

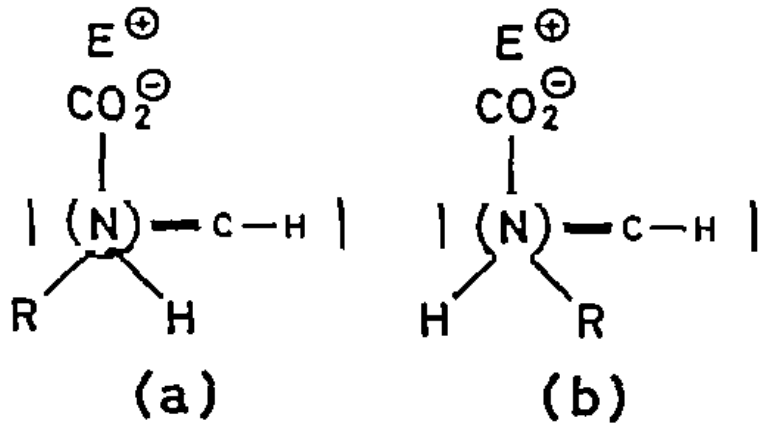


Fig. 28. Various conformations of the pyridoxal-5'-phosphate-amino acid imine as viewed along the α-carbon to nitrogen bond. The aldehydic carbon of PALP is shown (=C—) and the atoms of the pyridine ring are indicated by the rectangular box. The anionic carboxyl group is attached to a cationic group at the enzyme active site and occupies the activated position (perpendicular to the α-carbon). Theoretically both L- and D-forms, (a) and (b) can be decarboxylated, since for the reaction the positions of R and H are irrelevant.

of the enzyme-substrate complex and prevents the holoenzyme from accepting also the D-form of the substrate. With histidine this third binding site probably involves the imidazole ring with DOPA as substrate the corresponding structure may be the catechol. It should be noted that since amino acid decarboxylases appear to accept also α-methylated derivatives the α-hydrogen is not necessary for the decarboxylase activity (see MANDELES, KOPELMAN and HANES, 1954) and presumably not involved in binding to the apoenzyme.

In the interaction between pyridoxal-enzymes and amino acid substrates the first step is considered to be the transaldimination reaction which involves the enzyme-bound Schiff base of the coenzyme and the amino acid substrate (Fig. 29 I and II). It has been suggested that the reactants may be in particular ionic species of the amino acid and of the enzyme-bound PALP (HIRANSON 1963, 1966, 1967a, b, c and d, see also below). The first step in the reaction scheme is considered to be the weakening of the bonds in the α-position. The system of conjugated double bonds present in the aldimine will withdraw electrons to the electrophilic nitrogen atom of the pyridine ring to withdraw electrons to the nitrogen atom which was formerly the α-nitrogen of the amino acid. The bonds in the sigma bonds around the α carbon are thus weakened clearing the way for reactions which then results respectively in the release of a proton, or of CO_2 or of the carbanion. Subsequent rearrangements would lead to racemization, transamination, cleavage or decarboxylation of the amino acid. In the case of decarboxylation, the Schiff base looses CO_2 to form an intermediate structure (III). Addition of a proton leads to structure (IV) which is the Schiff base of the amine produced by decarboxylation of the amino acid. Transaldimination of this Schiff base gives the free amine with regeneration of the holoenzyme (the amine of PALP and apoenzyme).

Molecular mechanism of histamine formation. It has been suggested that the 4-formyl group of PALP is attached to histidine apodecarboxylase by an aldimine bond and that the reaction with the substrate involves transaldimination: the amino acid substrate forms a Schiff base with the enzyme-bound PALP displacing the apoenzyme amino nitrogen (HIRANSON 1967d). However as pointed out by JENCKS (1963) the reactants are probably particular ionic species of the amino acid and of the aldimine. From consideration of non-enzymatic reactions it may be assumed that the free amine form of the amino acid reacts with the protonated form of the enzyme-bound Schiff base. This assumption has important consequences as regards the kinetics of PALP-catalyzed enzyme reactions. The requirement that only the free base form of the substrate should react causes the K_m to become pH dependent. Moreover it may be expected that if the active ionic species of the enzyme occurs in high concentrations at a pH value much below the pK of the substrate-NH_2 group, the pH optimum of the reaction will depend on the substrate concentration. At saturating substrate concentrations the optimal pH will be determined exclusively by the pK values for the dissociation of the enzyme-substrate complex; with very low substrate concentrations the fact that

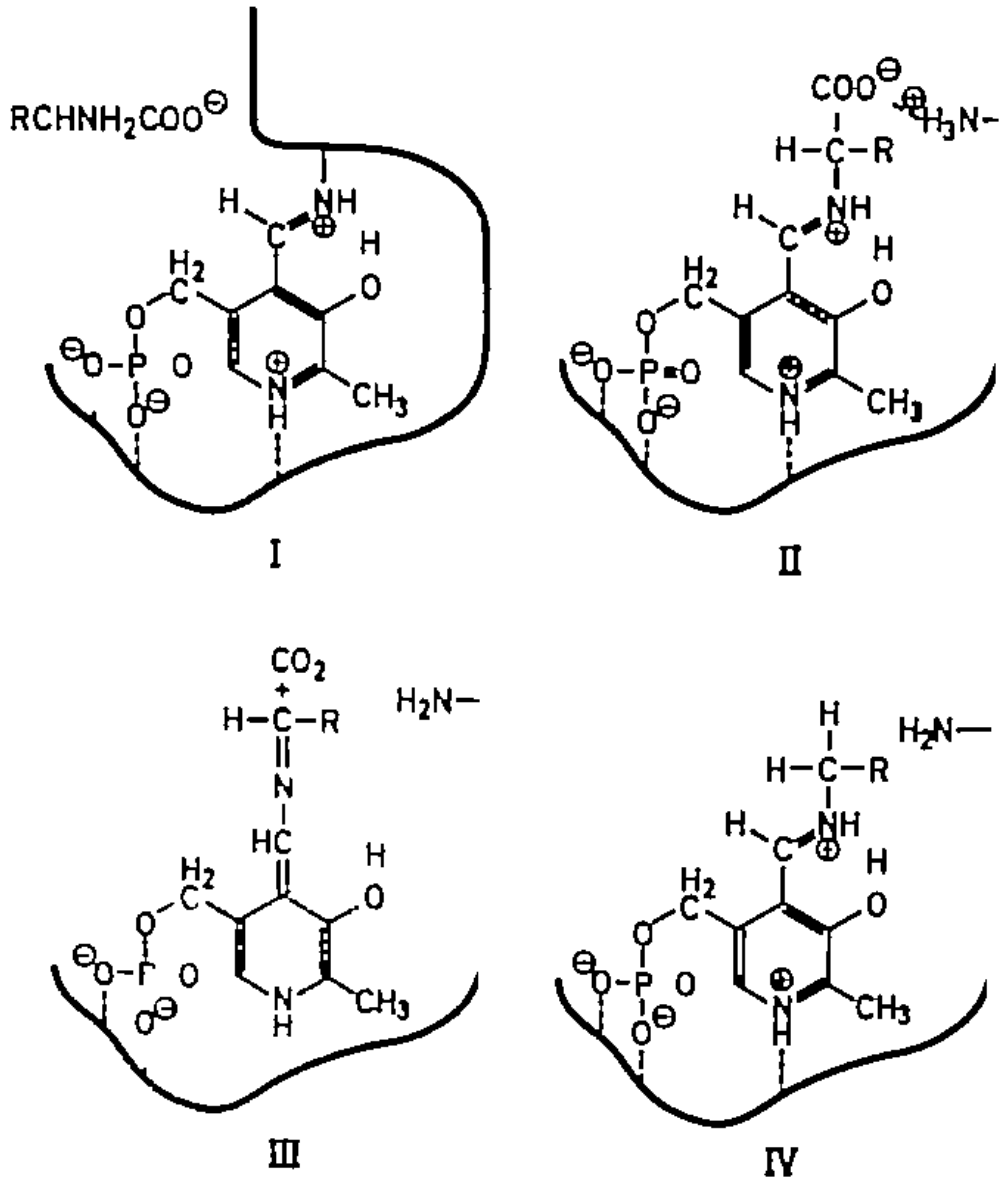

Fig. 29 Histidine decarboxylase Schematic presentation of the sequence of events leading to the formation of histamine. Non-protonated histidine and enzyme-bound protonated pyridoxal-5 -phosphat imine are about to react (I) by a process of transaldimination (II) Electrons are w thdrawn and decarboxylation takes place (III) the protonated Schiff base of histamine and pyridoxal-5 phosphate exchs with the non-protonated amino group of the enzyme activ ate (IV) which results in the liberation of histamine and the reconstitution of the holoenzyme (the protonated imine of pyridoxal 5 phosphate and enzyme amino nitrogen)

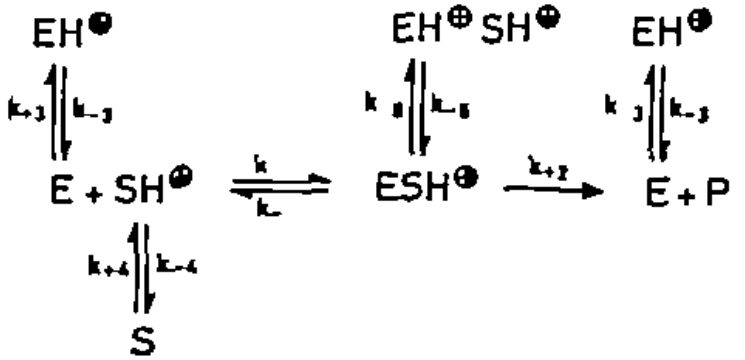
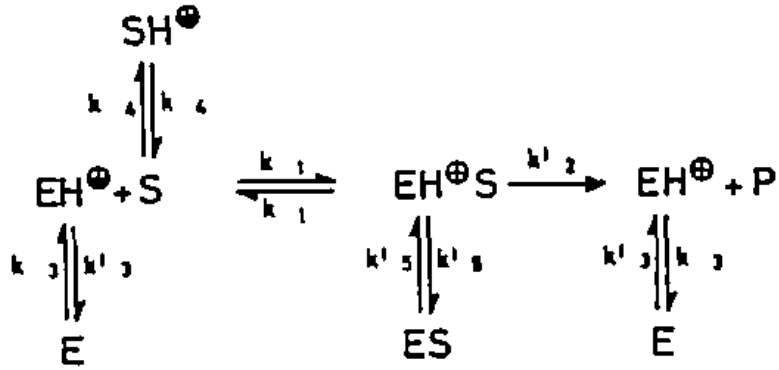
the reactive species of the substrate prevails at pH values above the pK of the substrate NH will shift the pH optimum towards more alkaline values. These effects may of course be masked by the influence of other ionizing groups of the substrate or of the enzyme Nevertheless, the kinetics of certain PALP enzymes seem to provide support for the assumption that only the non-protonated form of the substrate is involved in the reaction Davis and Metzler (1962) observed that the K_m of threonine dehydratase (deaminase) (EC 4 2.1 16)

decreased with increasing pH and concluded that the substrate anion containing a non-protonated amino group reacts with the enzyme. Some amine oxidases are PALP-dependent (Werle and Pechmann 1949 Sinclair, 1952 Davison 1956 Kapeller-Adler and MacFarlane, 1963 Yasunobu and Yamada, 1963 Blaschko and Buffoni, 1965 Buffoni, 1966 Suzuki 1966) Human plasma benzylamine oxidase (McEwen 1965a) appears to be fairly similar to pig plasma benzylamine oxidase (Buffoni, 1966) which is a cupric-PALP enzyme (Yasunobu and Yamada, 1963) The pH optimum of human plasma benzylamine oxidase is inversely related to the substrate concentration and the K_m decreases with increasing pH (McEwen 1965b) From these and similar data, Buffoni (1966) recently claimed that all plasma amine oxidases act on the non-protonated form of the substrate.



The kinetic properties (Fig 22—25) of mammalian histidine decarboxylase (EC 4 1 1.22) suggest that only the anionic form of histidine reacts with the enzyme. The observations summarized in section 5.3 are all understandable on the basis of an interaction between the protonated form of the enzyme-bound Schiff base and the free amine form of the substrate. It may be argued that the reaction between non-protonated Schiff base and protonated substrate (Eq 1b) is kinetically indistinguishable from the reaction involving non protonated substrate and protonated aldimine (Eq. 2b) (see also Jencks, 1963)

$$v = k\ (RNH_3^+)\ (>C=N-) \tag{1b}$$



$$v = k\ (RNH_2)\,(>C=NH^+-) \tag{2b}$$

However some differences in the kinetics of PALP-enzyme-catalyzed reactions may be predicted from assumptions as to the ionic nature of the reactants involved The alternative enzyme reactions may be represented by the following simplified reaction schemes.

A. Non-protonated enzyme and protonated substrate.

B. Protonated enzyme and non protonated substrate

From these reaction schemes alternative kinetic equations may be derived from the usual assumption of a steady state.

A.

$$V = v\left[\frac{K_m}{(SH^+)}\left(1+\frac{(H^+)}{K_e}\right)+1+\frac{(H^+)}{K_{es}}\right] \qquad (3b)$$

where

$$K_m = \frac{(E)\,(SH^+)}{(ESH^+)} = \frac{k_{-1}+k_{+2}+k_{+3}}{k_{+1}}$$

$$K_e = \frac{(E)\,(H^+)}{(EH^+)} = \frac{k_{-3}}{k_{+3}} \quad K_{es} = \frac{(ES)\,(H^+)}{(ESH^+)} = \frac{k_{-2}}{k_{+2}} \quad v = k_{+2}(ESH^+)$$

$V = k_{+2}(E_t)$ and (E_t) is the total enzyme concentration. If the total substrate concentration (S_t) is very large

$$V = v\left(1+\frac{(H^+)}{K_{es}}\right) \qquad (4b)$$

With a diminishing H^+ concentration v approaches V
If (S_t) is very small

$$V = v\left[\frac{K_m}{(S_t)}\left(1+\frac{K_e}{(H^+)}\right)\left(1+\frac{(H^+)}{K_e}\right)\right] \qquad (5b)$$

$$K_e = \frac{(S)\,(H^+)}{(SH^+)} = \frac{k_{-1}}{k_{+1}}$$

The value of (H^+) for maximum v at low (S_t) is $(H^+) = \sqrt{K_e K_e}$. Thus, with low (S_t) the reaction has a pH optimum which is close to the negative logarithm of $\sqrt{K_e K_e}$ but with increasing substrate concentration the pH optimum shifts towards more alkaline values. The apparent (i.e. experimentally established) Michaelis-Menten constant $(K_{m'})$ is defined with respect to the

total amount of substrate present and is related to the "true" Michaelis-Menten constant (K_m) through the following equation

$$K_m = K_m \frac{(1+\frac{(H^+)}{K_e})(1+\frac{K_e}{(H^+)})}{1+\frac{(H^+)}{K_{es}}} \qquad (6b)$$

With a diminishing H^+ concentration K_m increases. The changes in pH optimum and K_m predicted from scheme A are contrary to experimental observations and this reaction scheme is consequently not an acceptable model.

B.

$$V = v\left[\frac{K_m}{(S)}(1+\frac{K_e}{(H^+)}) + 1 + \frac{K_{es}}{(H^+)}\right] \qquad (7b)$$

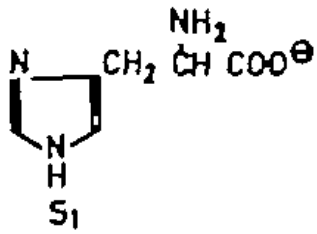
If (S_t) is very large (and hence (S))

$$V = v(1+\frac{K_{es}}{(H^+)}) \qquad (8b)$$

With an increasing H^+ concentration v approaches V
If (S_t) is very small

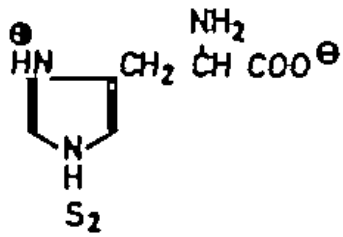
$$V = v\left[\frac{K_m}{(S_t)}(1+\frac{(H^+)}{K_e})(1+\frac{K_e}{(H^+)})\right] \qquad (9b)$$

The value of (H^+) for maximum v at low (S_t) is $\sqrt{K_e K_{es}}$. With this model the pH optimum of the reaction is inversely related to the substrate concentration in agreement with experimental observations.



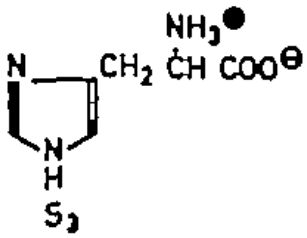
$$K_m = K_m \frac{(1+\frac{K_e}{(H^+)})(1+\frac{(H^+)}{K_e})}{1+\frac{K_m}{(H^+)}} \qquad (10b)$$

With an increasing H^+ concentration K_m increases as has also been observed experimentally with several PALP enzymes. The kinetic analysis of the two alternative models may thus provide some support for the hypothesis that the non protonated species of the amino acid is the "true" substrate. This may also be the case with mammalian DOPA decarboxylase (Hägerman 1967d). It may in fact, be a general characteristic of all PALP-catalyzed transformations of amino compounds.

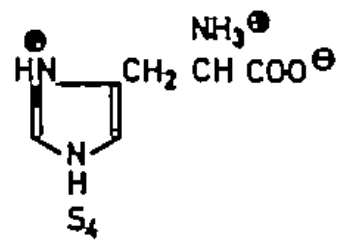


The assumption that the enzyme reacts only with the non-protonated form of histidine is also supported by the following analysis of the pH-dependent variation of the K_m value

It has been suggested that a constant true K_m value can be arrived at from the assumption that the enzyme attacks a specific ionic variety of histidine (HARRISON 1963 1966b) The various ionic species of histidine existing within the experimental pH region are given below The corresponding conservation equation for histidine is



$$(S_t) = (S_1) + (S_2) + (S_3) + (S_4) \tag{1c}$$



S_1

S_2

S_3

S_4

The concentration of each ionic variety of histidine is governed by the law of mass action and given by the following equations, which are derived from the conservation equation. (The K values are approximated to 10^{-6} and 10^{-9} the carboxyl group is assumed to be charged within the entire experimental pH region.)

$$(S_t) = (S_1)\ (1 + \frac{(H^+)}{10^{-6}} + \frac{(H^+)}{10^{-9}} + \frac{(H^+)^2}{10^{-15}}) \tag{2c}$$

$$(S_t) = (S_2)\ (1 + \frac{10^{-6}}{(H^+)} + \frac{10^{-6}}{10^{-9}} + \frac{(H^+)}{10^{-9}}) \tag{3c}$$

$$(S_t) = (S_3)\ (1 + \frac{(H^+)}{10^{-6}} + \frac{10^{-9}}{10^{-6}} + \frac{10^{-9}}{(H^+)}) \tag{4c}$$

$$(S_t) = (S_4)\ (1 + \frac{10^{-6}}{(H^+)} + \frac{10^{-9}}{(H^+)} + \frac{10^{-15}}{(H^+)^2}) \tag{5c}$$

A k_m value, which is fairly constant between 5.5 and 9.5 may be calculated from the apparent $K_m(K_{m'})$ by the relation.

$$K_{m'} = k_m f_{S_1} \quad K_{m'} = k_m \left(1 + \frac{(H^+)}{10^{-6}} + \frac{(H^+)}{10^{-9}} + \frac{(H^+)^2}{10^{-15}}\right) \text{ (Table 8)} \quad (6c)$$

The other ionic species of histidine (S_3, S_5 and S_7) give K_m values which vary markedly within the experimental pH region. However the enzyme may attack several ionic varieties of histidine indiscriminately

$$(S_1) = (S_0)\left(1 + \frac{(H^+)}{10^{-6}}\right) \quad (S_3) = (S_1) + (S_2) \quad (7c)$$

$$(S_4) = (S_6)\left(1 + \frac{(H^+)}{10^{-6}}\right) \quad (S_6) = (S\ ) + (S\ ) \quad (8c)$$

$$(S_7) = (S_7)\left(1 + \frac{10^{-6}}{(H^+)}\right) \quad (S_7) = (S_5) + (S\ ) \quad (9c)$$

$$(S_4) = (S_8)\left(1 + \frac{10^{-6}}{(H^+)}\right) \quad (S_8) = (S_5) + (S\ ) \quad (10c)$$

A k_m value, which is constant between pH 4.5 and 9.5 may be calculated from the apparent $K_m(K_{m'})$ by the relation

$$K_{m'} = K_m f_{S_0} \quad K_{m'} = K_m \left(1 + \frac{(H^+)}{10^{-5}}\right) \quad (11c)$$

The other ionic species of histidine (S_2, S_7 and S_8) give K_m values which vary markedly within the experimental pH region (Table 8)

Both relations (6c and 11c) are based on the assumption that the enzyme reacts with specific ionized varieties of histidine (S or S) and the role of functioning groups on the enzyme is not considered. Evidently the K_m values obtained from these formulae must be regarded as approximations. Work is in progress to identify the substrate attachment sites of the holoenzyme.

The process of enzymatic histamine formation involves three separate molecules apoenzyme, PALP and histidine. Normally reaction takes place between histidine and the complex of apoenzyme and PALP However under artificial conditions it is possible to study also the reaction between the apoenzyme and the histidine PALP aldimine (HÅKANSON 1967c) The reaction between histidine and PALP can be followed spectrophotometrically and appears to go to completion in the presence of high amounts of histidine and at pH values above 5 A high rate of histamine formation was observed after the addition of apoenzyme to a solution containing the Schiff base of histidine and PALP The kinetics of the decarboxylation of the Schiff base were different from that of the conventional holoenzyme-catalyzed histidine decarboxylation. The pH optimum of the aldimine decarboxylation was close to 6.2 at all substrate concentrations tested. The K_m value was found to decrease from 5×10^{-4}

TABLE 8

Km calculated from Km

The hypothetical substrate species is given in parenthesis

6.8	0.8×10^{-6}	1.3×10^{-7}	1.3×10^{-4}	2.1×10^{-5}	0.9×10^{-6}	1.3×10^{-4}	1.5×10^{-4}	2.1×10^{-5}
6.9	0.8×10^{-6}	1.1×10^{-7}	1.1×10^{-4}	1.4×10^{-5}	0.9×10^{-6}	10^{-4}	1.2×10^{-4}	1.4×10^{-5}
7.0	10^{-6}	10^{-7}	10^{-4}	10^{-5}	1.1×10^{-5}	10^{-4}	1.1×10^{-4}	10^{-5}
7.6	2.3×10^{-6}	5.6×10^{-6}	5.6×10^{-5}	1.4×10^{-5}	2.4×10^{-6}	5.9×10^{-5}	5.8×10^{-5}	1.5×10^{-5}
8.0	1.3×10^{-5}	1.3×10^{-6}	1.3×10^{-5}	1.3×10^{-7}	1.3×10^{-6}	1.4×10^{-5}	1.3×10^{-5}	1.4×10^{-7}
9.0	1.2×10^{-4}	1.2×10^{-6}	1.2×10^{-5}	1.2×10^{-6}	1.2×10^{-6}	2.4×10^{-6}	1.2×10^{-6}	2.4×10^{-6}
9.5	1.4×10^{-4}	4.6×10^{-10}	4.6×10^{-7}	1.4×10^{-10}	1.4×10^{-6}	1.9×10^{-6}	4.6×10^{-7}	0.6×10^{-10}

at pH 5 to 3×10^{-7} at pH 9 (HÅKANSON 1967c) There is thus a marked difference between the pH-dependent change of the K_m of aldimine decarboxylation and that of the conventional enzymatic decarboxylation of histidine. If the pH-dependent change in the K_m value of histidine decarboxylation, particularly notable between pH 6 and 8 is caused by a lower availability of "true" substrate at more acid pH, it is to be expected that this pH-dependent change is abolished when the reaction takes place between apoenzyme and the Schiff base.

In conclusion, it may be noted that also the formation of holoenzyme (the reaction between PALP and apoenzyme amino nitrogen) should proceed according to the rule that only the non-protonated amino group reacts. This may provide a starting point for a mathematical analysis of this interaction as well, ultimately permitting the identification of the various ionic species of the reactants engaged in the formation of the holoenzyme complex.

6. SHORT SUMMARY

1 Several histamine-forming enzymes exist in mammalian tissues. One is non-specific and probably identical with DOPA decarboxylase. Another one appears to be specific and hence is referred to as specific histidine decarboxylase. DOPA decarboxylase has a wide distribution in the mammalian organism. The specific histidine decarboxylase has been demonstrated only in a limited number of tissues. The kinetics of the formation of histamine as catalyzed by DOPA decarboxylase seems to justify the conclusion that the histamine forming capacity of DOPA decarboxylase is negligible *in vivo*. The pH optimum of the reaction is at 8.0—9.5 and very high concentrations of histidine are required for saturation of the enzyme. The kinetic properties of histidine decarboxylase are quite different. The pH optimum is dependent upon the substrate concentration: at high concentrations the pH optimum is at about 6.0; at low concentrations the corresponding value is 7.2. The Michaelis-Menten constant increases markedly with diminishing pH. This behaviour can be explained by the assumption that only the non-protonated species of histidine is decarboxylated by the enzyme. This assumption is supported by mathematical analysis of the kinetics of enzymatic histamine formation.

2. Gastric mucosa of all species studied is rich in DOPA decarboxylase. In addition, gastric mucosa of the mouse, rat and hamster contains histidine decarboxylase, kinetically identical with histidine decarboxylase from foetal rat tissues and hamster placenta. Histidine decarboxylase in the glandular portion of the rat stomach is located in the histamine-containing enterochromaffin like cells of the oxyntic gland area; these cells also contain DOPA decarboxylase. The major portion of gastric DOPA decarboxylase, however, appears to be located in the 5-HT-containing enterochromaffin cells, which are devoid of histidine decarboxylase. Gastric histidine decarboxylase is adaptive. The mechanism of activation of gastric histidine decarboxylase has been studied in some detail only in the rat. Starvation markedly reduces the enzyme activity; this reduction is reversed by the injection of gastrin, by the intake of food, and by other treatments known to cause the release of endogenous gastrin. The activity of DOPA decarboxylase in the rat stomach is resistant to all the treatments which affect the histidine decarboxylase activity.

Noradrenaline Uptake Mechanisms *in the Mouse Atrium*

A Biochemical and Histochemical Study

BY

CHARLOTTE SACHS

STOCKHOLM 1970

STOCKHOLM 1970
KUNGL. BOKTRYCKERIET P. A. NORSTEDT & SÖNER

Summary

Isolated mouse atria were incubated *in vitro* in Krebs-Ringer bicarbonate buffer containing ^{3}H noradrenaline and the radioactivity taken up and accumulated was determined. In representative types of experiments, ^{3}H-noradrenaline and ^{3}H metabolites were determined by specific chemical procedures and the amount of metabolites recovered was in most cases very small. The sorbitol space ($\approx$ extracellular space) was found to be about 23 % and could be efficiently cleared in 5 min of incubation.

The extraneuronal uptake was studied by using atria from mice pretreated with 6-hydroxydopamine, a drug known to cause a selective destruction of the adrenergic nerves. Incubation in a low concentration of ^{3}H noradrenaline (10^{-7} M 30 min) resulted in a relatively low extraneuronal uptake and retention of ^{3}H noradrenaline, corresponding to 12 % of the uptake in innervated atria. This value increased with an increasing concentration of ^{3}H noradrenaline in the medium, being about 32 % after 10^{-6} M and 75 % after 10^{-4} M, 30 min. There was no true accumulation of amine in the tissue, compared with the medium. The noradrenaline taken up extraneuronally was easily washed out and was not observed to be localized in any specific tissue structures, but was evenly distributed in the muscle cells of the atrium.

The uptake and accumulation of ^{3}H noradrenaline was investigated in atria from untreated mice, and mice pretreated with nialamide (a monoamine oxidase inhibitor) and reserpine + nialamide or H44/68 (a tyrosine hydroxylase inhibitor). The initial uptake was the same in atria from the four different groups, whereas, after longer incubation times, markedly less ^{3}H noradrenaline was recovered in atria from reserpine + nialamide pretreated animals. This latter finding certainly reflects an impaired retention of the amine taken up, and is not an effect of reserpine on the axon membrane pump. The neuronal uptake accumulation capacity is very rapid and efficient, and the concentration of amine in the varicosity of the adrenergic nerve was calculated to be about 30,000 times higher than in the medium, after incubation in 10^{-7} M ^{3}H noradrenaline for 30 min. It was concluded that the axon membrane pump is most important for the initial uptake, while the granular uptake mechanism is essential for the total uptake, storage and retention of noradrenaline accumulated in the neuron.

The neuronal noradrenaline uptake and accumulation was considerably

reduced at 0° C and showed temperature and pH optima of 37—40° C and pH 7.4 respectively. The uptake disclosed stereospecificity with a small preference for the *l*-isomer probably localized to the amine storage granules.

Studies on the effect of various doses of nialamide on the uptake in atria from reserpinized mice showed the uptake and accumulation of ^{3}H noradrenaline to increase, and the formation of deaminated metabolites to decrease with an increasing dose of nialamide. It was concluded that, in order completely to prevent the deamination of noradrenaline taken up in the nerves, monoamine oxidase has to be efficiently inhibited, since a relatively small enzyme activity can cause a decreased accumulation of noradrenaline.

The dose of H44/68 (*the methylester of α-methyl-p-tyrosine*) used caused a 60 % reduction of the heart noradrenaline content. The uptake and accumulation of ^{3}H noradrenaline was the same as that in untreated mice, while the net uptake was markedly increased. It was found, however that the original noradrenaline content could not be completely restored by exogenously administered noradrenaline, which could be due to the possibility that exogenous noradrenaline does not easily mix with the endogenous noradrenaline pool(s). Another possibility is that H44/68 impairs the storage capacity for noradrenaline.

Introduction

During the last decade considerable interest has been focused on tissue catecholamine uptake mechanisms, especially those in adrenergic nerves, due to their significant role in the inactivation of circulating catecholamines and transmitter released at the nerve endings. The fact that these uptake mechanisms can be affected by certain drugs, such as reserpine, guanethidine or tricyclic antidepressants, some of which are clinically important, is also of great interest.

There is at present strong evidence for the view that adrenergic nerves possess two main uptake-accumulation mechanisms operating at different levels of the nerve. One the so called "membrane pump" is energy requiring and probably located at the axonal membrane, while the other is considered to be restricted to the intraneuronal amine storage granules. An extensive literature on this subject has appeared in recent years (see among others, Carlsson *et al.* 1963 Euler and Lishajko 1963a, Stjärne 1964 Carlsson 1966a, b Malmfors 1965 1967 Hamberger 1967 Iversen 1967)

The present study is concerned with the uptake and accumulation of NA[1] in the isolated mouse atrium *in vitro* with special reference to the specific neuronal uptake. Biochemical isotope and histochemical techniques have been used. The extraneuronal uptake has been possible to elucidate by pretreatment of the animals with large doses of 6-OH DA, a drug known to cause within a short time, a severe damage of the NA uptake-storage mechanisms of the adrenergic nerves and later a destruction of the nerves (Tranzer and Thoenen 1967 1968 Malmfors and Sachs 1968b Jonsson and Sachs 1970a) The stereospecificity of the NA uptake and the effect of temperature and pH of the incubation medium on the NA uptake has been investigated. Experiments using reserpine, MAO or tyrosine hydroxylase inhibition were designed with a view to obtaining information on the relative importance of the different uptake processes, and on the significance of different factors regulating the uptake, storage and retention of exogenously administered NA.

[1] *Abbreviations used*: NA = noradrenaline; NM = normetanephrine 6-OH DA = 6-hydroxydopamine MAO = monoamine oxidase; COMT = catechol-O-methyltransferase PCA = perchloric acid.

Material and methods

Albino mice (NMRI 25—30 g) and in a few experiments albino rats, (Sprague Dawley about 200 g) were used for the studies.

Immunosympathectomized mice obtained from Dr L. Olson, were prepared by giving the antiserum to nerve growth factor NGF (Wellcome Research Laboratories England through Dr D C. Edwards) Each mouse received 0.05 ml of serum/g body weight, *s.c* immediately after birth and on the four following days. The mice were sacrificed when 9 months of age (weight, 25—30 g)

The animals were sacrificed by dislocation of the neck under ether anaesthesia and from the atria right and left auricles were carefully cut out (and in some experiments irides from rats were dissected out under a microscope see Malmfors 1965) The tissue was immediately immersed in cool Krebs-Ringer bicarbonate buffer pH 7 4

In vitro incubation

The incubation medium used was a Krebs-Ringer bicarbonate buffer[2] containing 10^{-8}—10^{-4} M *dl* ^{3}H NA and 0 2 mg/ml ascorbic acid (Merck *p.a.*) saturated with 93.5 % O_2 and 6.5 % CO_2 (Umbreit *et al.* 1951) Unlabelled *dl* NA was added to the medium in order to obtain concentrations higher than 10 M In some experiments *l* ^{14}C-NA (10^{-7} or 5×10^{-7} M) and *dl* ^{3}H metaraminol (10^{-7}—10^{-3} M) were used. Other substances added to the incubation medium were *d* NA, *l* NA reserpine malamide and guanethidine. At the start of the incubation each flask containing Krebs-Ringer bicarbonate buffer and atria (or irides) was gassed for 10—15 sec and then sealed with a tight fitting rubber stopper The tissue was incubated for various periods of time at 37 C (except for studies on the effect of temperature on ^{3}H NA uptake) using a metabolic shaker The incubation volume was one ml per two atria (or irides) When the effect of changes in pH of the incubation medium on H NA uptake was studied Krebs-Ringer phosphate buffer[3] containing

Krebs-Ringer bicarbonate buffer (g/liter) NaCl 6.92 KCl 0.35, $CaCl_2$ 6 H_2O 0.28, KH_2PO_4 0.16, $MgSO_4$ H_2O 0 29 $NaHCO_3$ 2.10, glucose 1.8.

Krebs-Ringer phosphate buffer (g liter) NaCl 7 45 KCl 0.38, $CaCl_2$ 6 H_2O 0.30, KH_2PO_4 0.17 $MgSO_4$ 7 H_2O 0 31 Na_2HPO_4 2 H_2O 0.42, N HCl 1 98 ml, glucose 1.8.

ascorbic acid, saturated with 100 % O_2 was used. After the incubation the atria were immersed in cool buffer for a few sec and then in most cases re-incubated for 10 min in isotope-free buffer at 37 C, in a volume of two ml buffer per two atria. When incubations were performed for longer periods of time, the incubation flasks were regassed every 30 min. There was no significant decrease of radioactivity of the medium after termination of the incubation.

After the incubation procedure, two atria were carefully blotted on a filter paper and weighed together on a Cahn electrobalance. Mean wet weight of two atria was 5 2 mg (range 3.5—6.4 mg) Since the uptake values per weight unit were found to be the same for right and left atria, no care was taken to get atria from the same animal for each analysis.

Determination of total radioactivity

The atria were dried overnight at 37 C on filter paper in a closed vessel and then combusted in counting vials in an oxygen atmosphere to water and CO_2 according to Gupta (1966) and Maurer (1968) The ^{3}H-water formed in this way was condensed by chilling the glass vial for about 10 sec in liquid nitrogen. No loss of radioactivity occurs during this procedure. Ten ml of a toluene scintillation solution[4] was added and the radioactivity measured in a Packard Model 3002 Tri-Carb Liquid Scintillation Spectrometer In some experiments the uptake of *l*- ^{4}C-NA in mouse atria and rat irides was studied and in these cases the tissue was dissolved in 0.5 ml Soluene^{TM} 100 (Packard Instr Co., Inc.) and 10 ml toluene scintillation solution was added before determination of radioactivity The samples were counted for 10 min. Efficiency was determined by adding a standard amount of ^{3}H toluene or ^{14}C-toluene to representative samples and recounting the vials. All values are expressed per weight unit.

Specific determination of H NA, H NM and H-deaminated metabolites

In representative experiments ^{3}H NA, H NM and ^{3}H-deaminated metabolites were determined by specific chemical analytical procedures. Two atria were after incubation in ^{3}H NA, homogenized and extracted with 4 ml cool 0.4 N PCA. The extracts were chromatographed on ion-exchange columns (Dowex

Scintillation solution for combustion 900 ml of toluene scintillation solution containing 5.0 g PPO (2.5-diphenyloxazole) and 0.5 g DM POPOP (1 4-bis 2(4-methyl-5-phenyloxazolyl)-benzene) per liter of toluene, 50 ml ethanol, 50 ml dioxane and 80 g naphtalene.

50W X4 diameter 4 0 mm and height at pH 1 120 mm) The amines were adsorbed to the resin, whereas the acid and neutral catabolites passed through in the effluent (Carlsson and Waldeck 1963) The amines were eluted with N HCl. The first 7 ml were discarded, NA was thereafter eluted with 8 ml and NM with 13 ml N HCl (see Fig. 1) There was a 7 % overlap of NA into the NM fraction, which was corrected for in the calculations. The acid eluates containing ^{3}H NA and ^{3}H NM respectively were freeze-dried in counting vials, and the radioactivity was taken up in 1 ml ethanol and 10 ml toluene scintillation solution. The effluent was after acidification (pH 2) shaken with 300 ml ether (Rutledge and Jonason 1967) the volume reduced to dryness under a hood, and the radioactivity taken up in 1 ml ethanol/0 01 N HCl and 5 ml toluene scintillation solution, from which a 5 ml aliquot was counted. Recovery for NA was 82 ± 2.9 % (n = 7) and for NM, 84 ± 7 4 % (n = 4) Recovery for ^{3}H-deaminated metabolites has not been determined. No corrections for recovery have been made.

NA assay

NA content in whole heart was determined according to Bertler *et al* (1958) Each determination was performed on six pooled mouse hearts which had been homogenized with an Ultra Turrax apparatus (Janke and Kunkel Freiburg) and extracted with 10 ml ice-cold 0 4 N PCA. To the extracts 0 1 ml ascorbic acid (?0 mg/ml) and 0.2 ml Na_2EDTA (100 mg/ml) were added and thereafter chromatographed on ion-exchange columns (Dowex 50W X4 diameter 4 0 mm and height at pH 1 50 mm) NA was eluted with 8 ml N HCl and the isolated NA was after oxidation, measured fluorimetrically Recovery of NA was 79 ± ? 4 % (n = 5)

In vivo infusion of H NA

Infusions of ^{3}H NA *in vivo in mice were performed by cannulation of a tail* vein. The animals were anesthetized with nembutal (50 mg/kg *i.p.*) Each mouse received 0 1 mg/kg ^{3}H NA (113 mCi/mM) during 14 min from an automatic infusion apparatus. The rate of infusion was 16 µl/min. The animals were immediately killed six hearts pooled for each determination and extracted with 10 ml 0.4 N PCA. NA was isolated by ion-exchange chromatography (see *NA assay* above) and an aliquot taken for determination of ^{3}H NA by liquid scintillation counting The rest was used for fluorimetric determination of NA (Bertler *et al.* 1958)

Determination of sorbitol space

Sorbitol space of mouse atria was determined by incubation of the atria in Krebs-Ringer bicarbonate buffer containing 1.25 μCi/ml ^{14}C-sorbitol (7.0 mCi/mM) according to Morgan *et al.* (1961). After incubation, two atria were blotted on filter paper, weighed and homogenized in 1.5 ml ethanol and centrifuged (12 000 × g, 10 min). A 1 ml aliquot of the supernatant was added to 10 ml toluene scintillation solution and the radioactivity determined. After correction for efficiency the sorbitol space was calculated by comparing the radioactivity equilibrated in the tissue with the radioactivity in the medium.

Determination of MAO-activity

MAO-activity of atria was determined according to the method of Wurtman and Axelrod (1963). Atria from one mouse were after weighing, homogenized in 0.5 ml 1.15 % KCl using a glass homogenizer with a tightly fitting glass pestle. Of the homogenate 25 μl was added to 250 μl 0.5 M phosphate buffer pH 7.4 and 25 μl ^{14}C-tryptamine (2.5 μCi/ml) in a centrifuge tube. The tubes were incubated at 37° C for 20 min and the reaction was terminated by adding 0.2 ml 2 N HCl. Toluene (6 ml) was added and the tubes shaken for 5 min. After centrifugation (3,000 × g for 10 min) 4 ml of the supernatant was added to 10 ml of a toluene scintillation solution in a counting vial and the radioactivity determined. Boiled tissue homogenate or buffer instead of the sample, was used for obtaining blank values. Each determination was performed in duplicate and MAO activity was expressed as cpm/mg tissue.

Fluorescence histochemistry

Mouse atria were studied with the histochemical fluorescence method of Falck and Hillarp (Falck *et al.* 1962, Falck 1962, Carlsson *et al.* 1962, Falck and Owman 1965, Corrodi and Jonsson 1967). Some hearts were perfused with Indian ink in order to demonstrate the blood vessels and the adrenergic nerves in the same preparation. The tissue was prepared as whole mounts on microscope slides with the endocardium directed upwards, dried about one hr in a desiccator containing phosphorous pentoxide (see Malmfors 1965) and treated with formaldehyde gas of optimal humidity generated from paraformaldehyde (see Hamberger 1967) at 80° C for one hr. Some atria were freeze dried, treated with formaldehyde gas and sectioned (8μ). The slides were thereafter examined in a fluorescence microscope. For details see Dahlström and Fuxe (1964) and Falck and Owman (1965).

Combined fluorescence histochemistry and ^{3}H NA measurements

Atria from the immunosympathectomized mice were after incubation *in vitro* in ^{3}H NA, prepared as whole mounts, exposed to formaldehyde gas and examined in the fluorescence microscope to check the completeness of the immunosympathectomy. After examination, the atria were scraped off of the slides, homogenized and the radioactivity determined (Olson *et al.* 1968).

Drugs and substances

The following drugs and substances were used: *dl* noradrenaline 7 ^{3}H HCl 5—10 Ci/mM, *dl* metaraminol 7 ^{3}H HCl 6.5 Ci/mM, tryptamine 2 ^{14}C bisuccinate 10.9 mCi/mM (New England Nuclear Corp. Boston, Mass.) Sorbitol ^{14}C 7 mCi/mM, *l* ^{14}C-noradrenaline bitartrate 57 mCi/mM (The Radiochemical Centre Amersham England) *dl* noradrenaline HCl (Calbiochem) *l* noradrenaline bitartrate (Sigma) *d* noradrenaline (Sterling Winthrop Lab.) nialamide (Niamid® Swedish Pfizer) guanethidine sulfate (Ismeline®) reserpine (Serpasil®) reserpine phosphate, dissolved in 5.5 % glucose (Swedish Ciba) the methylester of α-methyl-*p*-tyrosine HCl (H44/68) 6-hydroxydopamine HCl (H88/39) *dl* metaraminol HCl (H99/13 AB Hässle).

Concentrations of drugs and substances were calculated as free base. When used for injection they were dissolved in 0.9 % NaCl, except for nialamide which was dissolved in a small amount of N HCl diluted with 0.9 % NaCl and pH was adjusted to about 5 with N NaOH. The volume for *i.p.* administrations was 0.5 ml and for *i.v.* injections (in tail vein) 0.2 ml.

The purity of H NA, ^{14}C-NA and ^{3}H metaraminol was checked with *ascending paper chromatography* on Whatman nr 1 paper. The systems used were n-butanol/N HCl 4 1 n-butanol/acetic acid/aqua 4 1 5 and 2 N HCl/isopropanol 63 35. The distribution of radioactivity on the chromatograms showed only one peak which R_f-value was identical to that of the standard substance.

Results

Metabolism of ^{3}H-NA during in vitro incubation

In order to obtain information on the metabolism of ^{3}H NA during *in vitro* incubation of mouse atria under the various experimental conditions used in this study ^{3}H NA, ^{3}H NM and ^{3}H-deaminated metabolites were determined by specific analytical procedures in representative types of experiments (Table I and Fig 1) This information was furthermore of importance for the evaluation of results from experiments where total ^{3}H radioactivity was determined. For the detailed schedules of the pharmacological pretreatments see below

When atria from *untreated mice* were incubated for 30 min in a medium containing 10^{-7} M ^{3}H NA, very small amounts of metabolites were detected, they made up about 3 % of the total radioactivity recovered. Relatively more metabolites were found when the medium contained higher concentrations of ^{3}H NA and after longer incubation times. The relative amount of metabolites was generally somewhat lower when the tissue was reincubated in an isotope free medium for 10 min, after the ^{3}H NA incubation.

After *nialamide* pretreatment only small amounts of ^{3}H NM, and no detectable amounts of ^{3}H-deaminated metabolites were found after incubation in 10^{-7} M ^{3}H NA. However incubation in 10^{-6} M ^{3}H NA for 120 min (wash-out omitted) yielded a relatively large amount of ^{3}H NM, 24 % Pretreatment with *reserpine and nialamide* resulted in 73—87 % unchanged ^{3}H NA, and the recovered metabolites consisted mainly of ^{3}H NM (see Fig. 1 B, *cf* Fig. 1 A) *H44/68* pretreatment gave a metabolite pattern which was similar to that derived from untreated animals. Since the amount of metabolites recovered in mouse atria was rather low in most cases, total radioactivity has generally been determined The radioactivity values obtained, will thus mainly represent *unchanged ^{3}H NA and therefore total ^{3}H radioactivity has in most cases* been presented as ^{3}H NA. In one series of experiments using reserpine pretreatment, when a considerable catabolism of NA is known to occur ^{3}H NA was determined specifically

After pretreatment with *6-OH DA* there was an increase of the relative amounts of ^{3}H NM and ^{3}H-deaminated metabolites formed during the incubation, while the absolute amounts were practically the same as those from untreated animals. Reincubation of the tissue in isotope-free medium for 10 min

TABLE I *Metabolism of H-V4.* Atria from differently pretreated mice were incubated *in vitro* in a H NA containing medium. Determinations of H NA, H NM and H-deaminated metabolites were performed either directly after incubation or after 10 min reincubation in fresh buffer. The figures are expressed as per cent of the sum of the total H-radioactivity recovered. Each val represents the mean ± S.E.M. from 4—9 determin tions.

resulted in a relative increase in the wash-out of metabolites compared with untreated. The total uptake of radioactivity after 6-OH DA pretreatment, however was found to be considerably less than the total uptake in intact atria (see below)

Sorbitol space

Sorbitol space[3] was determined by incubation of atria in Krebs-Ringer bicarbonate buffer containing ^{1}C-sorbitol at 37 C (Fig 2) There was a rapid equilibration of sorbitol in the tissue—between 10 and 30 min the equilibration curve flattened off After 30 min incubation, the sorbitol space was about 23 % (22.8 % ± 1 1 n = 1[2])

Clearance of the sorbitol space was studied by incubating atria in ^{1}C-sorbitol for 30 min and then transferring the tissue to isotope-free buffer for further incubation for different periods of time (Fig. 3) A rapid clearance of C-sorbitol from the tissue was observed within 5 min and after 10 min only some 4 % was left. The clearance of the sorbitol space in 10 min at 0° C was, however markedly diminished compared to that seen at 37 C—about 36 % of the radioactivity initially present, remained in the tissue. In atria which had

$$\text{sorbitol space} = \frac{\text{dpm } ^{14}\text{C-sorbitol/mg atrial tissue}}{\text{dpm } ^{14}\text{C-sorbitol/}\mu\text{l medium}} \times 100.$$

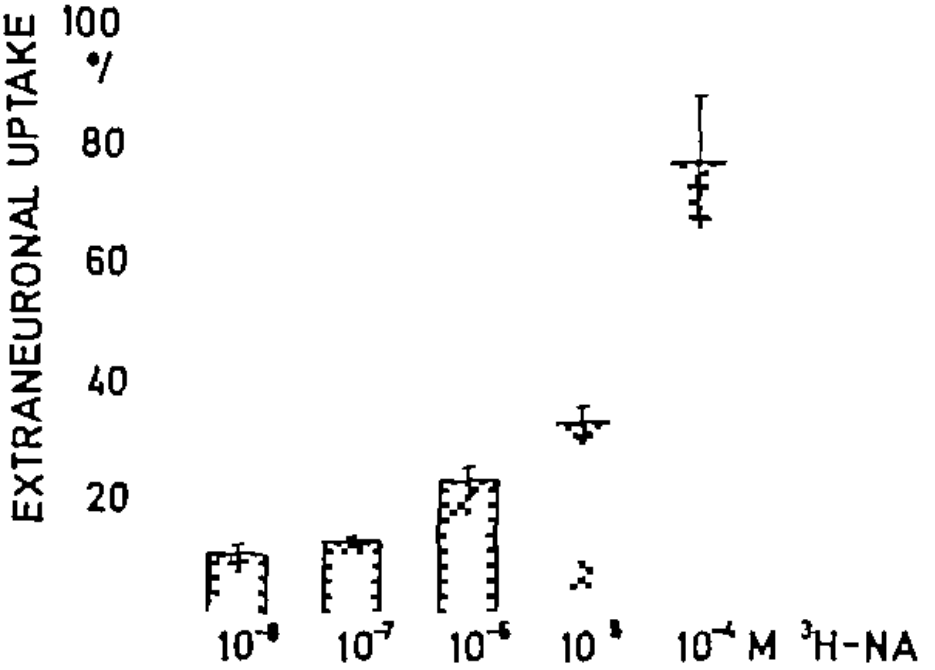

Fig. 4. Uptake of radioactivity in atria from 6-OH DA (2 × 50 mg/kg i.v. 16 and 2 hr) pretreated mice incubated in various H NA concentrations in the medium. The values are expressed as per cent of the uptake in atria from untreated animals. The incubation time was 30 min, followed by 10 min reincubation in fresh buffer. Each column represents the mean ± S.E.M. from 6–12 determinations.

to that of atria from 6-OH DA pretreated mice. The ^{3}H NA taken up after 6-OH DA pretreatment can thus, be taken as a measure of the extraneuronal uptake.

There was a gradual increase in the extraneuronal uptake, with increasing concentration of ^{3}H NA in the medium. The uptake was about 12 % of untreated after incubation in 10^{-7} M ^{3}H NA for 30 min followed by a 10 min wash-out, whereas using a medium concentration of 10^{-4} M ^{3}H NA this value was about 75 % (Fig 4). These figures are calculated on total radioactivity values obtained and would be somewhat lower when corrected for formed metabolites. The uptake ratios[6] were in all cases below one. The extraneuronal uptake of radioactivity increased with time although this uptake calculated as a percentage of the uptake in atria from untreated animals, identically incubated, was approximately constant during the whole incubation period (Fig. 5).

Fluorescence histochemistry of atria from 6-OH DA pretreated mice incubated in a high concentration of NA revealed no specific structures able to

$$\text{Uptake ratio} \quad \frac{\text{g NA/mg atrial tissue}}{\text{ng NA/}\mu\text{l medium}}$$

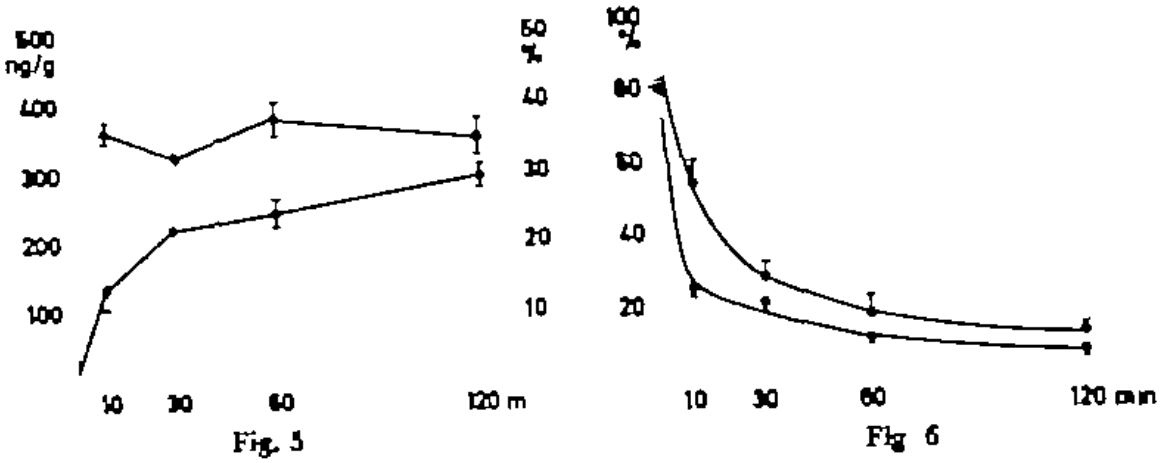

Fig. 5 Fig 6

Fig 5. Time-course of H-radioactivity uptake (H NA, 10^{-5} M) in tria from 6-OH DA pretreated mice (2×50 mg/kg *i.v* 16 and 2 hr) (●——●——●) The tissue was reincubated in fresh buffer for 10 min. Extraneuronal uptake is expressed as per cent of that in intact tria for corresponding incubation times (○——○——○) Each point represents the mean ± S.E.M. from 4—8 determinations.

Fig. 6. Disappearance of H radioactivity previously taken up during a 30 min incubation of tria from 6-OH DA (2×50 mg/kg *i.v* 16 and 2 hr) pretreated mice. Concentrations of H NA in the medium were 10^{-5} M (● ● ●) or 10^{-6} M (○——○——○) The values are expressed as per cent of the amount present at zero time Each point represents the mean ± S.E.M from 6—8 determinations.

take up and accumulate NA The NA fluorescence observed was diffusely located in the whole atrial tissue as observed in stretch preparations (micrograph 3 B) In sections (8μ) from atria it was seen that the NA fluorescence was evenly distributed throughout the muscle fibres (micrograph 2 C) The intensity of the fluorescence was moderate and slightly higher than in control after incubation in 10^{-5} M NA for 30 min and very intense after 10^{-4} M 30 min No differences in fluorescence intensity were observed in control atria and atria incubated in NA concentrations below 10^{-5} M 30 min.

NM in a concentration of 2×10^{-6} M had no effect on the uptake of ^{3}H NA (10^{-5} M 30 min) in atria from untreated or 6-OH DA pretreated mice, while NM in a concentration of 2×10^{-5} M caused an about 20 % inhibition of the uptake both in untreated (21.2 % ± 0.9 n = 4) and 6-OH DA (20.4 % ± 0.8, n = 4) pretreated. Reserpine (10 mg/kg *i.p* 16 hr) and nialamide (100 mg/kg *i.p* 2 hr) did not cause any change of ^{3}H NA uptake (10^{-7} 10^{-6} or 10^{-5} M ^{3}H NA, 30 min and 10 min wash-out) in atria from 6-OH DA pretreated mice compared to the uptake in atria from mice pretreated with 6-OH DA alone.

The H NA uptake (10^{-7} M 30 min) at 0° C in atria from 6-OH DA treated mice was about 30 % (32.8 ± 2.6 % n = 4) lower than that at 37 C,

TABLE II NA content in whole heart of mice after various pretreatments. Six hearts were pooled for each determination and each value represents the mean ± S.E.M. from 4–12 determinations. Recovery: 79 %. Corrections for recovery have been made.

Pretreatment	ng/g	%
Untreated	0.59±0.040	100±6.8
Nialamide (100 mg/kg *i.p.* 2 hr)	0.69±0.061	117±10.3
Reserpine (10 mg/kg *i.p.* 16 hr) + *Nialamide* (100 mg/kg *i.p.* 2 hr)	0.05±0.015	8±2.5
H44/68 (500 mg/kg *i.p.* 16 hr)	0.24±0.034	41±5.8
6-Hydroxydopamine (2×50 mg/kg *i.v.* 16 and 2 hr)	0.04±0.021	7±3.6

while the uptake at 25 C and 45 C was the same as 37 C. Varying the pH of the medium (pHs 6, 7.4 or 8.0) did not affect the ^{3}H NA uptake (10^{-7} M, 30 min, 37 C) in atria from 6-OH DA treated mice.

The retention of radioactivity taken up was investigated in atria from 6-OH DA pretreated animals by subsequent incubation of the tissue in fresh buffer for different periods of time (Fig 6, *cf* 18 A). There was a rapid wash-out of ^{3}H radioactivity previously taken up (10^{-7} M ^{3}H NA, 30 min) about 45 % had disappeared in 10 min. The disappearance was more pronounced when atria had been incubated in a higher ^{3}H NA concentration (10^{-5} M) but the wash out curves showed a similar general appearance for the two concentrations.

Uptake and accumulation of NA — effects of reserpine, MAO and tyrosine hydroxylase inhibition

Whole hearts or atria from the following groups of mice have been studied: A. untreated. B. pretreated with nialamide (100 mg/kg *i.p.* 2 hr). C. pretreated with reserpine (10 mg/kg *i.p.* 16 hr) and nialamide (100 mg/kg *i.p.* 2 hr). D. pretreated with H44/68 the methylester of α-methyl-β-tyrosine (500 mg/kg *i.p.* 16 hr).

NA content. The NA content of whole heart from the different groups of mice is shown in Table II. The NA content in *atria* from untreated mice was indirectly estimated after an injection of 10 μCi ^{3}H NA per mouse, *i.v.* 30 min.

The atria and the rest of the heart were weighed and homogenized separately in 0 4 N PCA and the ^{3}H NA taken up was determined. The uptake of ^{3}H NA in two atria was found to be 10 % of that taken up in whole heart. If the circulatory and diffusional conditions are presumed to be the same and if the uptake and the NA content per nerve unit is constant in atria and in the rest of the heart, then the uptake would reflect nerve density and NA content. Atria would consequently contain 10 % of the NA present in the whole heart, corresponding to a NA concentration in atria of about 1.3 μg/g This value is in good agreement with that obtained by an enzyme assay for NA (Jonsson and Sachs, unpublished observations)

Fluorescence histochemistry In *untreated* mice the adrenergic nerves form a ground-plexus in the endocardium, as observed in the fluorescence microscope (*cf* Ehinger *et al* 1966 Jonsson and Sachs 1969 1970a) (micrograph 1) The nerve fibres run 3—4 together in bundles exhibiting a rather strong fluorescence intensity Single fibres with pronounced varicosities leave the bundles. After Indian ink perfusion the vessels appeared dark in the fluorescence microscope and the adrenergic nerves could be seen both in the direct vicinity of the vessels and located outside, independently of the vessels. In the myocardium single nerve terminals could be seen to run in between the heart muscle cells (micrograph 2 A and B) Incubation of atria in 10^{-6} or 10^{-5} M NA for 30 min, gave a fluorescence morphological picture quite similar to that of atria incubated in amine-free buffer except that 10^{-6} M NA gave a slight increase in the background fluorescence. Using 10^{-4} M NA, a very intense background fluorescence was observed making it difficult to judge any differences of the fluorescence intensity of the nerves. Incubation of atria in Krebs-Ringer buffer up to 130 min, the longest incubation time studied, did not cause any changes in morphology or fluorescence intensity of the adrenergic nerves.

Nialamide treatment (micrograph 5) resulted in a slight increase in the fluorescence intensity of the non-terminal axons and this was more pronounced after incubation in NA (10^{-6} or 10^{-5} M, 30 min)

Reserpine treatment induced a complete disappearance of the NA fluorescence in the adrenergic nerves, and incubation in NA (10^{-6} or 10^{-5} M, 30 min) did not restore the fluorescence of the adrenergic nerves. Incubation of atria (10^{-6} or 10^{-5} M NA, 30 min) from *reserpine + nialamide* pretreated mice resulted in a restitution of the nerve fluorescence, but the non-terminal axons were more prominent and the terminals exhibited a rather smooth appearance (micrograph 6, *cf* Hamberger *et al.* 1964 Jonsson and Sachs 1969) After *H44/68* pretreatment only a few faint adrenergic nerve terminals could be observed. After incubation in NA (10^{-6} or 10^{-5} M, 30 min) there was a resti-

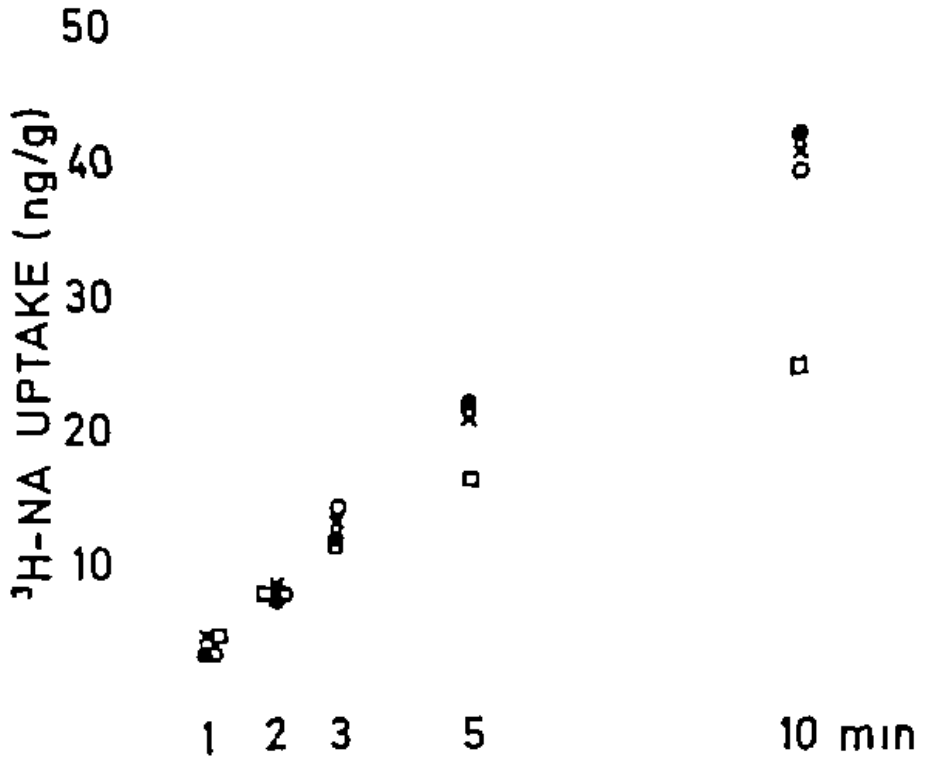

Fig. 7 Time-course of H NA uptake (10^{-7}M) in atria from differently pretreated mice. No reincubation in fresh buffer has been made The values ha been corrected for radioactivity present in the sorbitol space.

tution of fluorescent nerves with a morphology and fluorescence intensity quite similar to normal (micrograph 7 *cf* Malmfors and Sachs 1968a, Jonsson and Sachs 1969)

Uptake and accumulation of ^{3}H NA in vitro The uptake of ^{3}H NA (10^{-7} M) was linear and very similar for the four different groups up to 3 min of incubation, while after 5 min the uptake in atria from reserpine + nialamide pretreated mice started to deviate from linearity and was considerably lower at 10 min (Fig. 7) For the other groups the deviation from linearity started after about 10 min Using a medium concentration of 0.5×10^{-7} M ^{3}H NA the uptake was found to be approximately linear with time up to about 60 min, except for the reserpine + nialamide group (Fig 8) At higher medium concen-

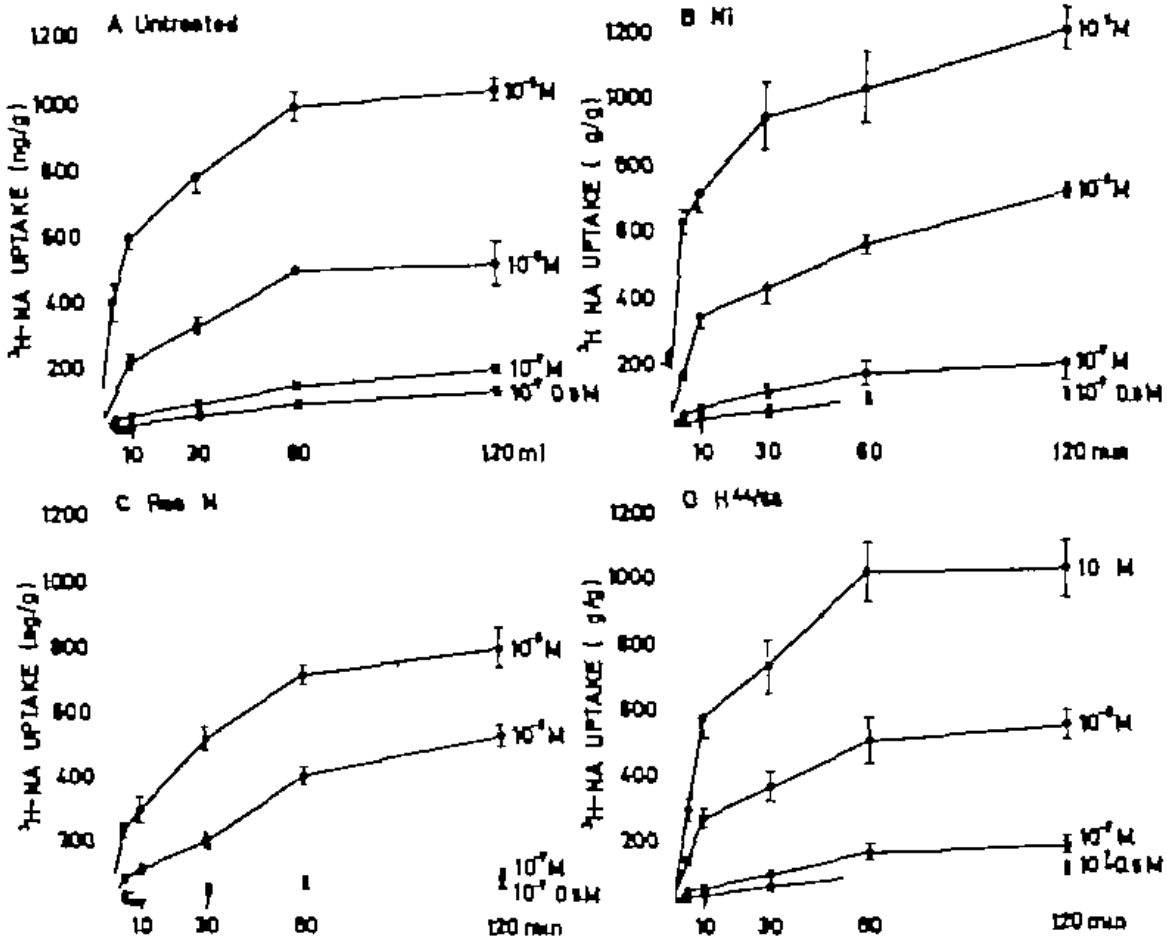

Fig 8. Time-course of H NA uptake ($0.5 \times 10^{-}$ 10^{-} 10^{-6} nd 10^{-5} M) in tria from variously pretreated mice. The tissue was reincubated in isotope-free medi m for 10 min, after the incubation.

A. untreated

C. reserpine (10 mg/kg i.p. 16 h) + nialamide (100 mg/kg i.p. 2 hr)

D. H44 68 (500 mg/kg i.p. 16 hr)

Each point represents the mean ± S.E.M. from 4—16 determinations.

trations of ^{3}H NA deviation from linearity occurred earlier between 10 and 30 min.

Uptake and accumulation of ^{3}H NA was studied for five different concentrations of ^{3}H NA in the medium, using an incubation time of 30 min and a 10 min reincubation in isotope free buffer (Fig 9). The *uptake ratios* in atria from untreated mice were calculated to be about 6 at 10^{-7} M and 0.5 at 10^{-5} M NA. Atria from nialamide pretreated mice showed an uptake-accumulation of ^{3}H NA which was 30—60 % higher than in atria from untreated mice, with a tendency of increased uptake compared with the control when using lower

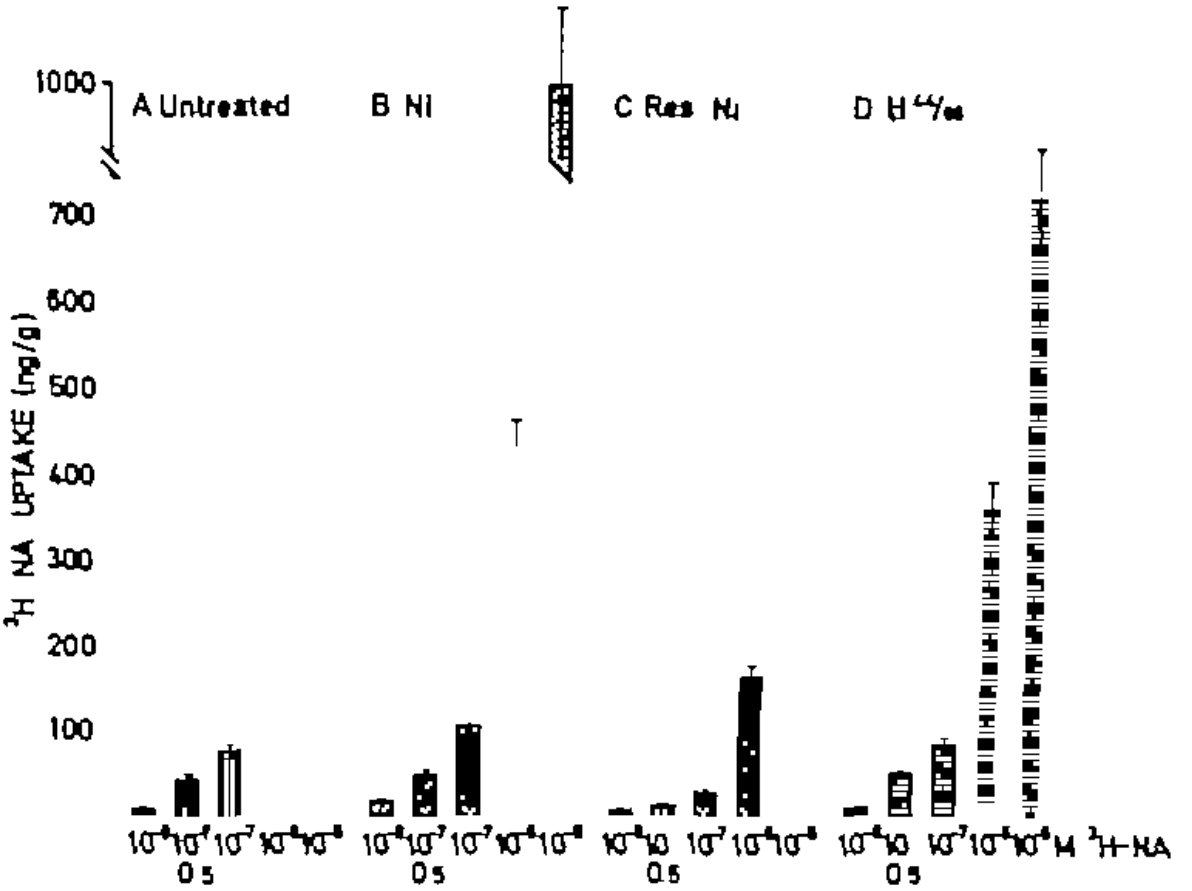

Fig 9 Uptake and accumulation of H NA in tria from mice pretreated with different drugs. The tria were incubated in various concentrations of H NA. The incubation time was 30 min, followed by 10 min reincubation in isotope-free buffer

A. untreated

B. nialamide (100 mg/kg *i.p.* 2 hr)

C. reserpin (10 mg/kg *i.p.* 16 hr) + nialamide (100 mg/kg *i.p.* 2 hr)

D. H44/68 (500 mg/kg *i.p.* 16 hr)

Each column represents the mean ± S.E.M. from 5–9 determinations.

concentrations of ^{3}H NA in the medium. Reserpine + nialamide pretreatment caused a reduction of the uptake-accumulation which was most pronounced with lower concentrations of ^{3}H NA in the medium, but with fairly great variations. The reduction was less pronounced when reincubation in isotope free buffer was omitted. H44/68 pretreatment resulted in a slightly higher uptake and accumulation of ^{3}H NA for each concentration used, compared to the uptake in untreated atria.

Reciprocal analysis of the 5 min uptake values in atria from the different groups of mice, according to Lineweaver and Burk (1934) revealed that the uptake process obeyed Michaelis-Menten kinetics, $Km = 3.26 \times 10^{-6}$ M (Fig 10)

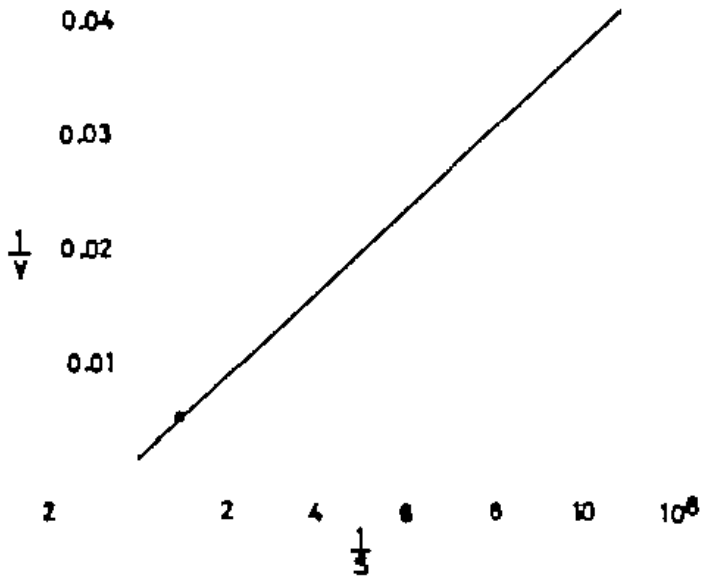

Fig 10 H N \ uptake in atria from untreated mice, plotted according to Lineweaver and Burk. The incubation time was 5 min. No reincubation in isotopo-free buffer was performed. The values are corrected for radioactivity present in the sorbitol space Each point is the mean of 5 determinations. The line was calculated by linear regression analysis, correlation coefficient = = 0.98. Velocity (V) = uptake of H NA ng/g/5 min. Substrate concentration (S) = M H NA. Km = 3.26×10^{-6} M and \ max = 854 7

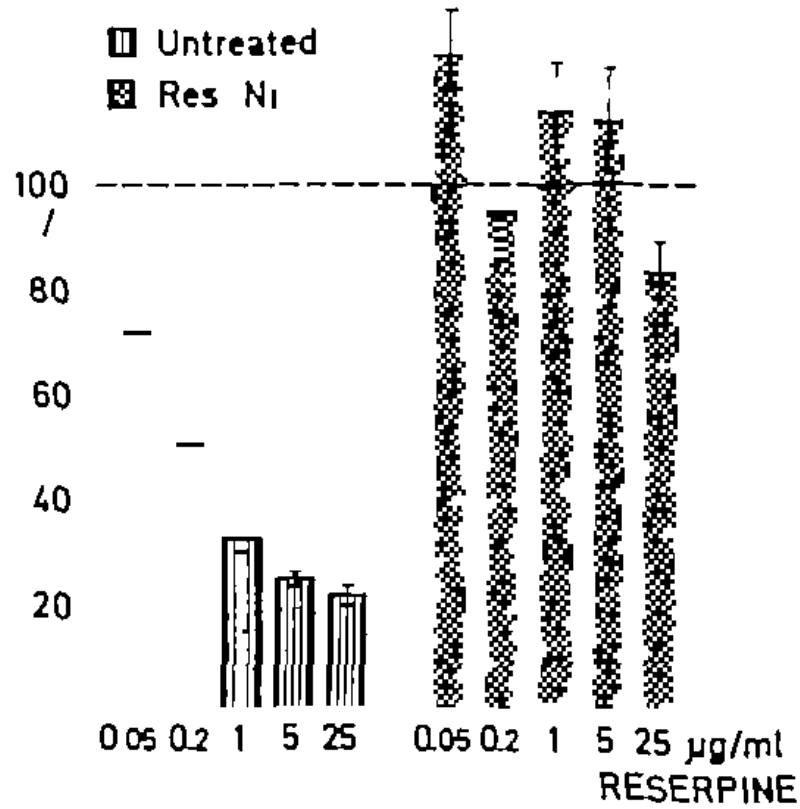

Fig 11 Effect of various concentrations of reserpine *in vivo* on the ptake of H-NA (10^{-7} M) in tria of untreated or reserpine (10 mg/kg *i.p.* 16 hr) + nialamide (100 mg/kg *i.p.* 2 hr) pretreated mice The incubation time was 30 min, followed by 5 ml reincubation in fresh buffer The lues are expressed as per cent of control value (untreated, 67 3 ± 10.6 ng/g; reserpine + talamide 43 4 ± 3.8 ng/g) Each column represents the mean ± S.E.M of 6–8 determinations.

TABLE III *Uptake of H NA in vivo in whole hearts after various pretreatments* H NA (0.1 mg/kg) was infused *i.v.* during 14 min and the animals were sacrificed immediately afterwards. Six hearts were pooled for each determination.

Pretreatment	H NA infusion	NA content (g/g)	Total H-NA uptake (g/g)	H-NA net uptake (ng/g)	Exchange (ng/g)
Untreated	—	544 ± 55.1	—	50	48
	+	594 ± 15.5	98 ± 2.9

The figures represent the mean ± S.E.M from 7 determinations. The values are corrected for recovery

The effect of reserpine (0 05—25 μg/ml) *in vitro* on the uptake of ^{3}H NA, was studied in atria from untreated and from reserpine + nialamide pretreated mice (Fig. 11) In atria of untreated animals there was a gradual decrease of radioactivity recovered from the tissue with higher concentrations of reserpine in the medium. In atria from reserpine + nialamide pretreated animals there was no apparent difference between the various reserpine concentrations, except for 25 μg/ml when the uptake was somewhat reduced.

Uptake and accumulation of NA in vivo In experiments *in vivo* slow *i.v.* infusions of ^{3}H NA (0.1 mg/kg during 14 min) were performed in untreated, H44/68 and 6-OH DA pretreated mice. The animals were sacrificed immediately afterwards and six whole hearts were pooled for each determination and extracted with PCA. After isolation of NA by ion-exchange chromatography the NA content was determined fluorimetrically and the ^{3}H NA taken up, estimated by liquid scintillation counting (Table III) H44/68 pretreatment resulted in a reduction of the endogenous NA content to 42 % of untreated and 6-OH DA a reduction to 10 % of untreated. The total uptake of ^{3}H NA was 11 % higher in hearts from H44/68 pretreated mice than in normal, while the uptake after 6-OH DA pretreatment was reduced to 22 % of normal. The net uptake expressed as the difference between the mean NA content of the

TABLE IV *NA content of whole heart after in vivo administration of* (-)-NA (1.5 mg/kg) was injected *i.p.* in variously pretreated mice. The mice were sacrificed after 1 or 4 hours. Six hearts were pooled for each determination. The figures are corrected for recovery and represent the mean of 3 determinations.

Pretreatment	1 hr		4 hr		Control	
	μg/g	%	μg/g	%	μg/g	%
Untreated	0.68	117	0.56	97	0.58	100
H44/68 (500 mg/kg *i.p.* 16 hr)	0.47	81	0.41	71	0.24	41
6-Hydroxydopamine (2 × 50 mg/kg *i.v.* 16 and 2 hr)	0.06	10	0.09	16	0.04	7

The control value from untreated mice was set to 100 %.

^{3}H NA infused group and the mean NA content of the group infused with fresh buffer was 62 % higher after H44/68 treatment compared to untreated. The exchange of ^{3}H NA with endogenous NA was 9 % in untreated, 19 % in H44/68 pretreated and 8 % in 6-OH DA pretreated mice.

The NA content in mouse heart after injection of a high dose of unlabelled NA (1.5 mg/kg *i.p.*) in untreated, H44/68 and 6-OH DA pretreated mice is shown in Table IV.

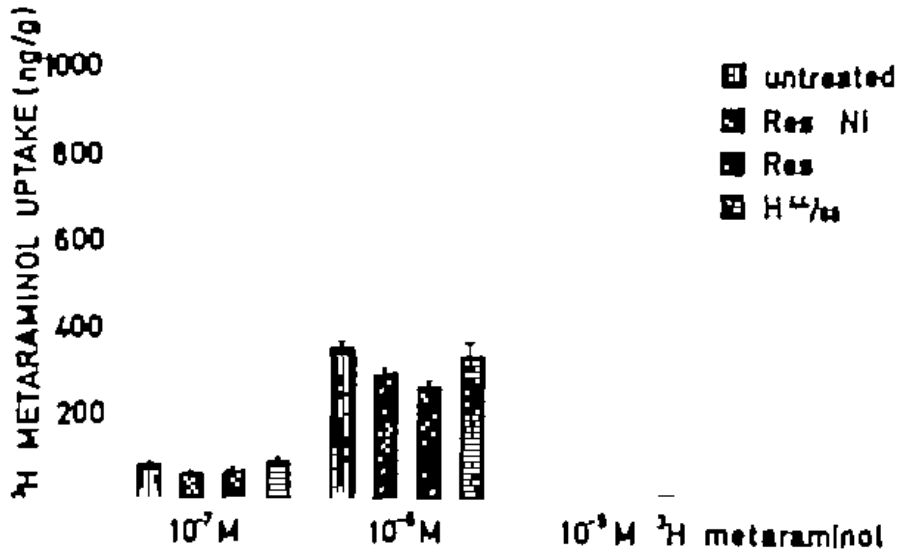

Fig. 12. Uptake of H metaraminol (10^{-7}, 10^{-6} or 10^{-5} M) in vitro from untreated reserpine + nialamide reserpine or H44/68 pretreated mice. The incubation time was 30 min followed by 10 min preincubation in fresh buffer. Each column represents the mean ± S.E.M. from 8 determinations.

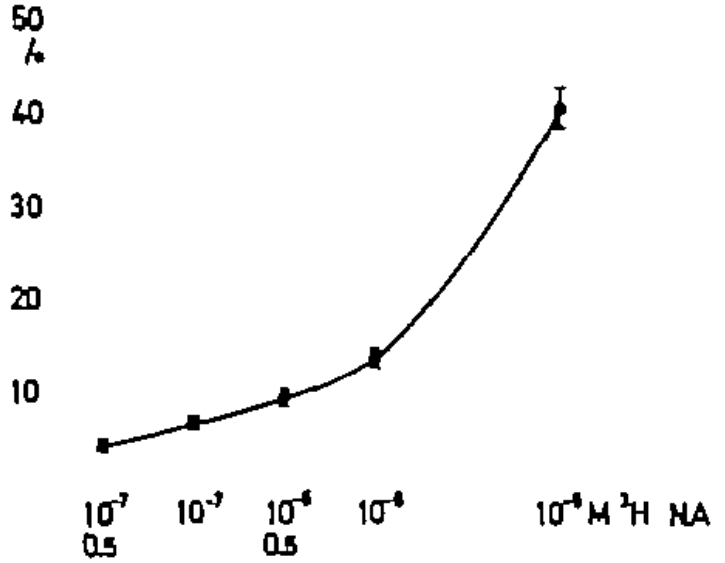

Fig. 13. Uptake of H NA in atria at 0° C, with varying H-NA concentration in the medium. The incubation time was 30 min, followed by 10 min reincubation t 0° C in fresh buffer The values are expressed as per cent of the uptake at 37° C (wash-out t 37° C) Each point represents the mean ± S.E.M. of 6—8 determinations.

Uptake and accumulation of ^{3}H metaraminol in vitro The uptake of H metaraminol *in vitro* was studied in atria from untreated mice and mice pre treated with reserpine + nialamide, reserpine and H44/68 (Fig 1?) in order to compare this uptake in the different groups, with that of ^{3}H NA. The ^{3}H metaraminol uptake was found to be rather similar in all groups for each concentration used.

The ^{3}H metaramnol uptake in atria from 6-OH DA pretreated mice was after incubation in 10^{-7} M (30 min and 10 min wash-out) 10.3 % ± 0.1 of untreated, while after 10^{-6} M and 10^{-5} M the uptake was ?1.8 % ± 1 6 and 41 1 % ± 3 6 respectively (n = 4)

Effect of temperature and pH on the uptake and accumulation of H NA in vitro

The uptake of ^{3}H NA at 0° C was considerably reduced compared to that found at 37 C (Fig. 13) being about 7 % after 10^{-7} M ^{3}H NA for 30 min. The uptake increased, with increasing concentration of ^{3}H NA in the medium and reached a value of about 40 % after 10^{-5} M for 30 min. The ^{3}H NA uptake at different temperatures of the incubation medium is presented in Fig. 14 disclosing an uptake optimum between 37 and 40° C. Fluorescence histochemistry revealed no changes in morphology or fluorescence intensity of the adrenergic nerves, for the various temperatures used.

The effect of pH on the ^{3}H NA uptake was studied by incubation of atria in Krebs-Ringer phosphate buffers, of different pHs (Fig 15) There was an increase of ^{3}H NA uptake with increasing pH of the medium, reaching a

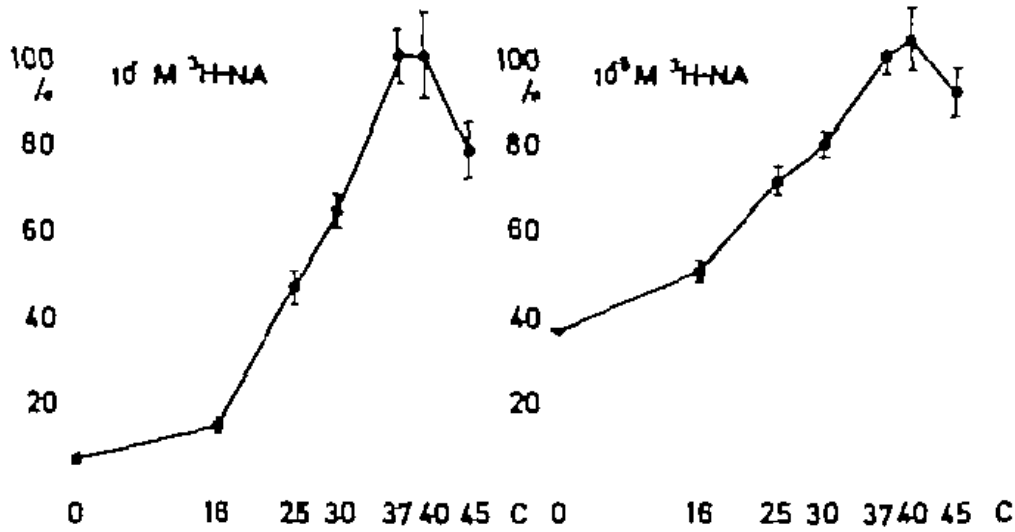

Fig. 14. Effect of temperature on the uptake of H-NA (10^{-7} M or 10^{-8} M) in mouse atria. The incubation time was 30 min. No reincubation in fresh buffer has been made. The values are expressed as per cent of the 37° C uptake value and are corrected for the amount of radioactivity located in the sorbitol space. Each point represents the mean ± S.E.M. of 6—8 determinations.

maximum at pH 7.4. In a control experiment the NA concentration (10^{-8} M) of media of different pHs (5.8, 7.4 and 8.0) which had been used for 30 min incubations, were determined fluorimetrically. No differences were observed in the NA concentration of the various media. Fluorescence histochemical studies were made on atria, incubated for 30 min in Krebs-Ringer phosphate buffer of

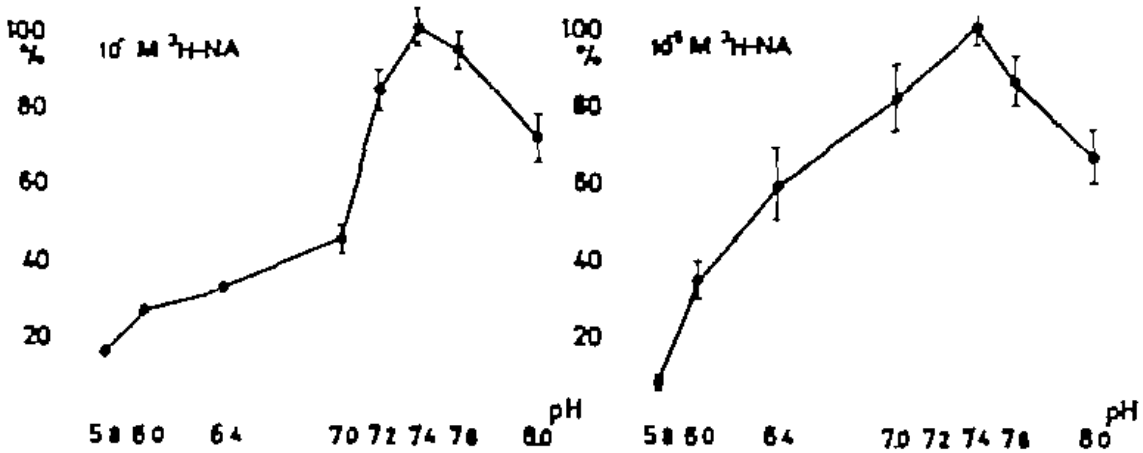

Fig. 15. Effect of pH on the uptake of H-NA (10^{-7} M or 10^{-8} M) in mouse atria. The incubation time was 30 min and no reincubation in fresh buffer has been made. The values are expressed as per cent of the uptake at pH 7.4 and are corrected for the amount of radioactivity located in the sorbitol space. Each point represents the mean ± S.E.M. of 6—8 determinations. The H-NA uptake at pH 7.4 was after incubation in 10^{-7} M H-NA, 68.2 ± 4.30 ng/g and in 10^{-8} M H-NA, 680.6 ± 76.5 ng/g.

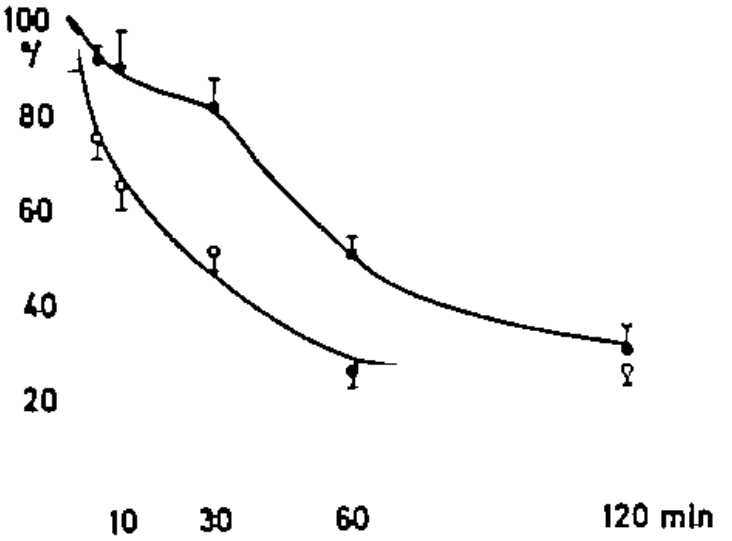

Fig 16. Time-course of disappearance of H-NA previously taken up (10^{-7} M, 30 min) in mouse atria at pH 8.0 (● ● ●) and pH 6.0 (○——○——○) The wash-out was performed in fresh buffer of pH 7 4 The values are expressed as per cent of the amount present in the tissue at zero time. Each point represents the mean ± S.E.M. of 6—10 determinations.

pH 5.8, 7 4 or 8.0 After incubation in pH 5 8 there was a decrease in the fluorescence intensity of the adrenergic nerves and they showed a somewhat fuzzy appearance (micrograph 4) while pH 8.0 and 7 4 had no effect on the fluorescence morphology

The retention of ^{3}H NA taken up at pH 6.0 and pH 8.0 was studied by re-incubation of the atria in isotope-free buffer (pH 7 4) for different periods of time (Fig. 16) There was an increased disappearance of ^{3}H NA previously

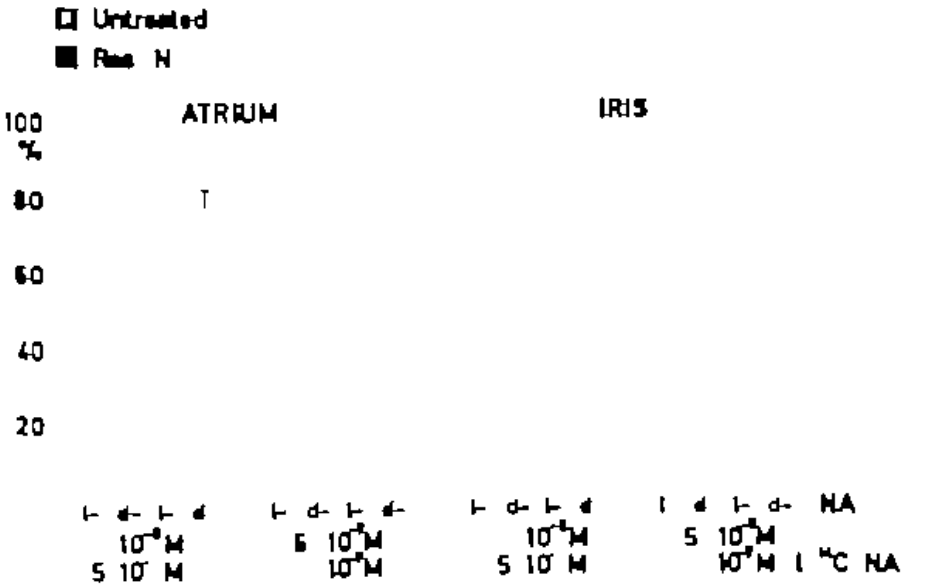

Fig 17 Effect of *d*-NA or *l*-NA (5×10^{-7} or 10^{-6} M) on the uptake of *l*-^{14}C-NA (10^{-7} or 5×10^{-7} M) in mouse atria and rat irides from untreated and reserpine (10 mg/kg i.p. 16 hr) + nialamid (100 mg/kg i.p. 2 hr) pretreated animals. The incubation time was 30 min and no reincubation in fresh buffer was made. The values are expressed as per cent of control tissues. Each column represents the mean ± S.E.M. of 4—6 determinations.

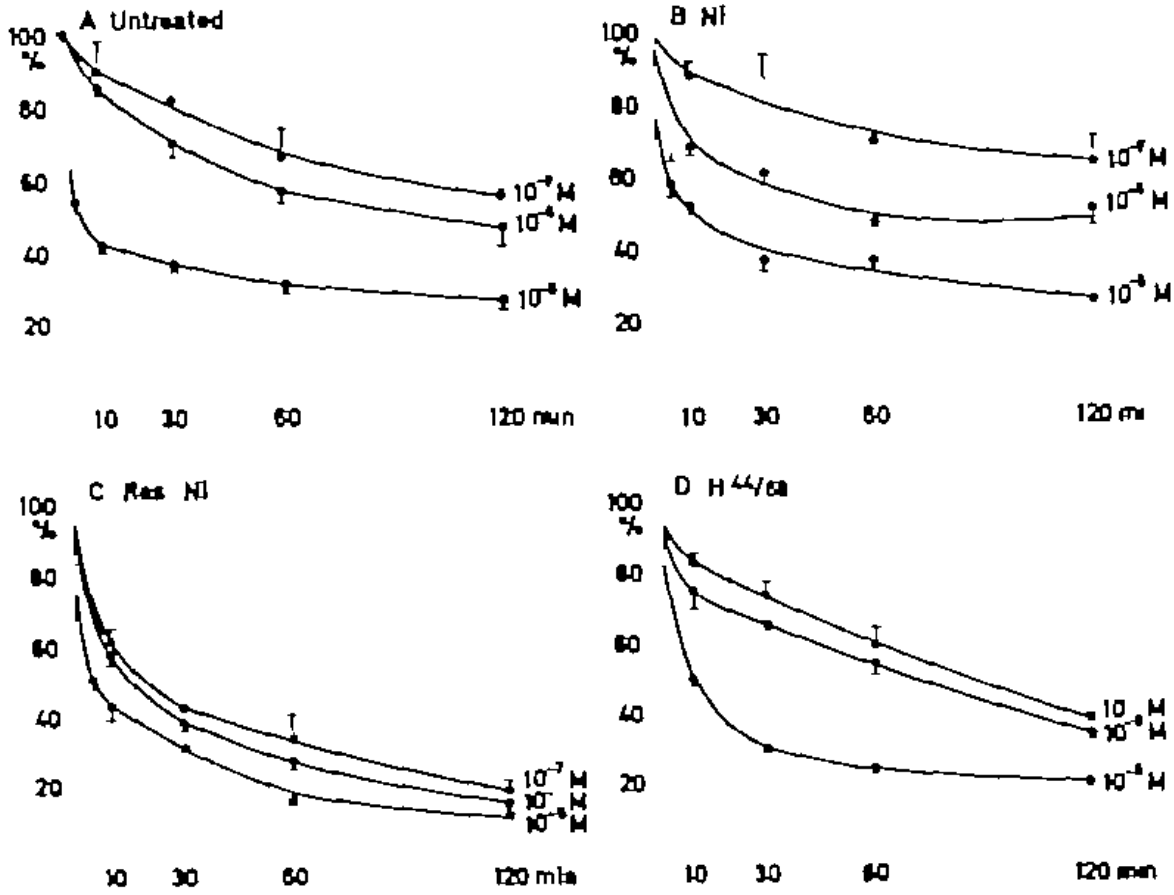

Fig. 18. Time-course of disappearance of H NA previously taken up *in vitro* (10^{-} 10^{-6} or 10^{-6} M, 30 mi) in mouse atria. The tissue was after the incubation transferred to fresh buffer and reincubated for various periods of time. The values are expressed as per cent of the amount present the tissue t zero time. Each point represents the mean ± S.E.M. of 6—14 determinations. The S.E.M. t zero time was ± 5—11 %.

A. untreated
B. nialamide (100 mg/kg *i.p.* 2 hr)
C. reserpine (10 mg/kg *i.p.* 16 hr) + nialamide (100 mg/kg *i.p.* 2 hr)
D. H44/68 (500 mg/kg *i.p.* 16 hr)

taken up at pH 6.0 compared to 7.4 during the whole time period studied. The wash-out curve after pH 8.0 was similar to that after pH 7.4 during the first 30 min, but thereafter showed a more rapid decline (*cf* Fig. 18 A)

Effect of d-or l NA on the uptake and accumulation of l ^{14}C-NA in vitro

The effect of *d* or *l* NA on the uptake of *l* ^{14}C-NA was investigated in mouse atria and rat irides from untreated and reserpine + nialamide pretreated animals (Fig 17) *l* NA caused a slightly more effective inhibition of the *l* ^{14}C-NA

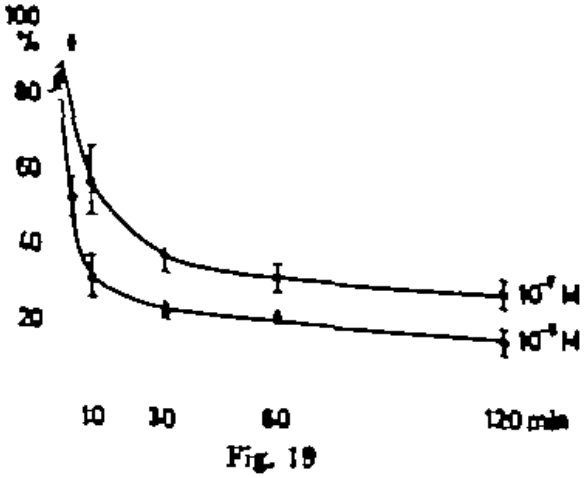

Fig. 19

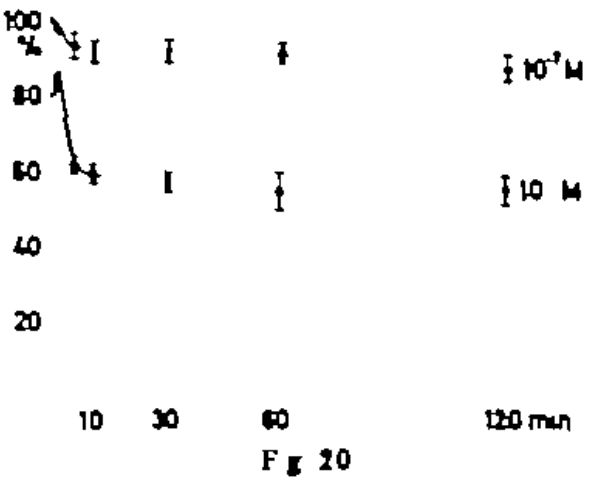

Fig. 20

Fig. 19. Time-course of disappearance of H-NA (10^{-7} or 10^{-6} M) previously taken up in mouse atria during 5 min incubation. The values are expressed as per cent of the amount present in the tissue at zero time. Each point represents the mean ± S.E.M. of 4–6 determinations.

Fig. 20. Time-course of disappearance at 0° C of H-NA (10^{-7} or 10^{-6} M 30 min) previously taken up in atria at 37° C. The tissue was after incubation transferred to fresh buffer of 0° C for reincubation for various periods of time. The values are expressed as per cent of the amount present in the tissue at zero time. Each point represents the mean ± S.E.M. of 8 determinations.

uptake than the *d*-isomer in both atria and atrides from untreated animals. There seemed to be no clear-cut difference, however, between the *d* and *l* isomers after reserpine + nialamide pretreatment.

Disappearance of ^{3}H-NA taken up in vitro

The time-course of disappearance of ^{3}H-NA previously taken up in atria from untreated, nialamide or H44/68 pretreated mice was practically identical (Fig. 18 A, B, D). Reserpine + nialamide pretreatment caused, however, a more pronounced wash-out (Fig. 18 C). The disappearance of ^{3}H-NA taken up was in all cases more rapid with higher concentrations of ^{3}H-NA in the medium.

At the end of an incubation the sorbitol space of atria, in the experimental conditions used in this study, was calculated to contain 4 ng ^{3}H-NA/g atrial tissue when using a medium concentration of 10^{-7} M ^{3}H-NA and 400 ng/g using 10^{-6} M. A 10 min wash-out of atria previously incubated in 10^{-7} M ^{3}H-NA (30 min) caused a disappearance of 8 ng ^{3}H-NA/g atrial tissue, corresponding to a 10 % wash-out of that initially present in the tissue (80 ng/g). Of the amount washed out, 7 ng/g was calculated to originate from extraneuronal sites (including ^{3}H-NA present in the sorbitol space). When using

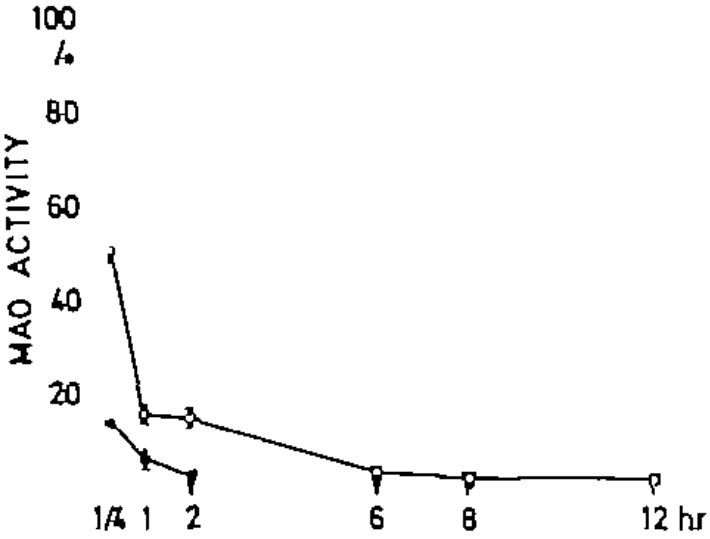

Fig 21 Effect of nialamide (10 mg/kg ○—○—○ or 100 mg/kg ●—●—● i.p.) on MAO activity in atria from mice pretreated with reserpine (10 mg/kg i.p. 16 hr) The values are expressed as per cent of control. Each point represents the mean ± S.E.M. of 6—10 determinations.

10^{-6} M ^{3}H NA (30 min) the disappearance during a 10 min wash-out period was about 910 ng/g (=42.5 % of that present at zero time 1585 ng/g) of which about 650 ng/g came from extraneuronal sites (including ^{3}H NA present in the sorbitol space) These calculations are based on results presented in Figs. 4 6, 9 and 18 A.

The disappearance of ^{3}H NA taken up in atria, previously incubated for 5 min (10^{-7} M or 10^{-6} M) was more pronounced compared to that of atria incubated for 30 min (Fig. 19 *cf* 18 A) Of the amount present at the beginning of the reincubation, 57 % at 10^{-7} M and 31 % at 10^{-6} M remained in the tissue after a 10 min wash-out. On the other hand the disappearance of ^{3}H NA was found to be similar after incubation times of 30 or 60 min.

When the reincubation was performed at 0° C, the disappearance of ^{3}H NA was considerably reduced compared to that at 37 C (Fig. 20)

Effect of MAO activity on the uptake and accumulation of H NA in vitro

The effect of the potent MAO inhibitor nialamide, on the MAO activity in atria from mice pretreated with reserpine was investigated. Injection of 100 mg/kg nialamide *p* caused a reduction of MAO activity to about 14 % of the control value within 15 min After 1—? hr this value was about ? % Ten mg/kg nialamide reduced the MAO activity to about 52 % within 15 min, while after 6 hr the value was 3 % and remained so for 12 hr which was the longest time studied (Fig ?1)

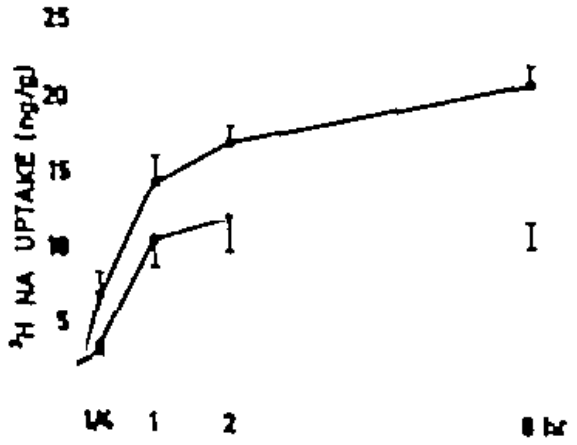

Fig. 22

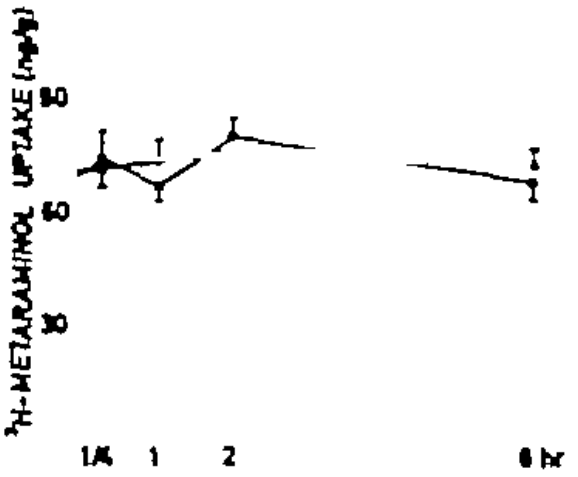

Fig. 23

Fig. 22. Effect of nialamide on the uptake of H NA (10^{-7} M 30 min and 10 min wash-out) in atria from mice pretreated with reserpine (10 mg/kg i.p. 16 hr) The animals were sacrificed t various periods of time after the nialamide injection (10 mg/kg ○——○——○ or 100 mg/kg ● ● ● i.p.) H NA was isolated and determined specifically Each value represents the mean ± S.E.M. from 5–8 determinations.

Fig. 23. Effect of nialamide on the uptake of H metaraminol (10^{-7} M, 30 ml and 10 min wash-out) in atria from mice pretreated with reserpine (10 mg/kg i.p. 16 hr) The animals were sacrificed t various periods of time after the nialamide injection (10 mg/kg ○——○——○ or 100 mg/kg ● ● ● i.p.) Each value represents the mean ± S.E.M. from 8 determinations.

The MAO activity of atria from reserpine pretreated animals was similar to that of normal. The inhibitory effect of nialamide was unchanged after incubation of the atria in buffer alone for 40 min. Atria from untreated mice incubated in buffer for 40 min showed, however a somewhat reduced MAO activity about 20 % compared to that of atria taken directly for determination of the enzyme activity

Uptake and accumulation of ^{3}H NA in atria of reserpine pretreated mice was studied after injection of 10 or 100 mg/kg nialamide i.p. (Fig 22) The ^{3}H NA was determined specifically since the amount of metabolites formed especially the deaminated ones, increases after reserpine treatment (Kopin *et al.* 1962) The ^{3}H NA uptake and accumulation was higher at all points of time studied, using the higher dose of nialamide.

The uptake of ^{3}H metaraminol, an amine which is not metabolized by MAO was studied in an analogously designed experiment. The uptake values were approximately equal after reserpine alone as for 10 and 100 mg/kg nialamide and for all points of time studied (Fig 23)

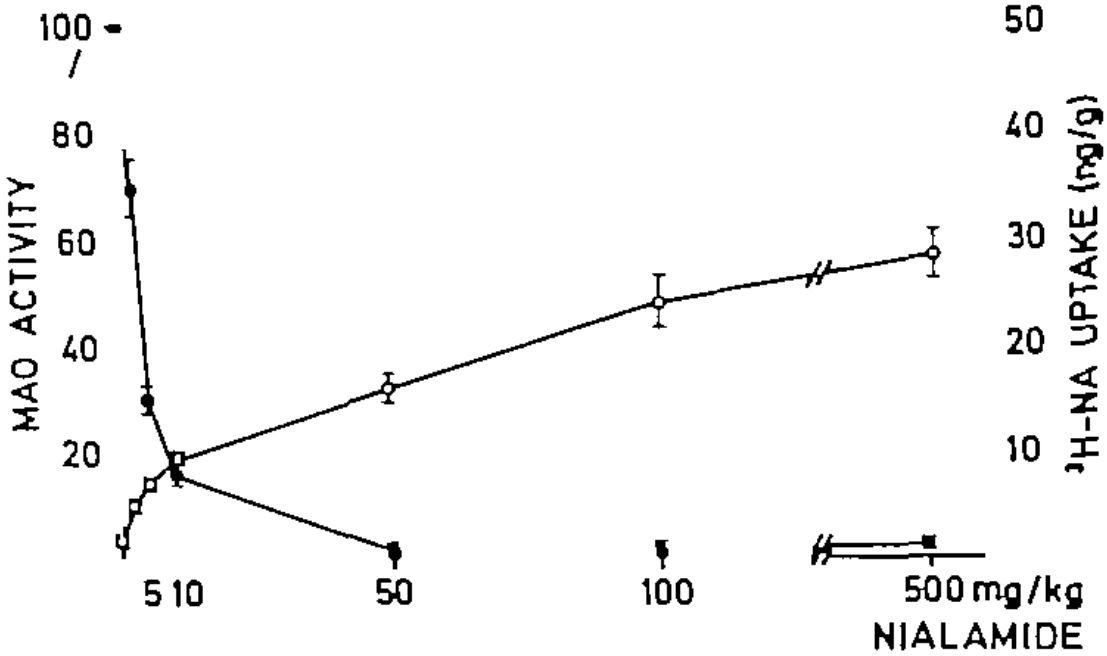

Fig. 24. Effects of various doses of nialamide (injected i.p.) on the MAO activity (● ——— ● ——— ●) and on the uptake of H NA (10^{-7} M, 30 min and a 10 min wash-out) (○ ——— ○ ——— ○) in tria from reserpine (10 mg/kg i.p. 16 hr) pretreated mice. The animals were sacrificed 2 hr after the nialamid injection. H NA was isol ted and deter mined specifically The MAO activity is expressed as per cent of control. Each point represents the mean ± S.E.M. from 4—8 determinations.

Uptake of ^{3}H NA was determined in atria from mice pretreated with reserpine + varying doses of nialamide (Fig 24) After reserpine alone, the uptake and accumulation of ^{3}H NA was very low and was still low after 2 mg/kg nialamide, a dose which caused a 30 % inhibition of MAO activity With increasing dose of nialamide, however the MAO inhibition and the ^{3}H NA uptake increased.

The radioactivity recovered after reserpine alone, consisted of 43 % unchanged ^{3}H NA 17 % ^{3}H NM and 40 % ^{3}H-deaminated metabolites. With increasing dose of nialamide, the relative amount of ^{3}H NA increased being about 81 % after 100 mg/kg nialamide, 2 hr

In control experiments it was observed that nialamide in the incubation medium (50 or 100 μg/ml) increased the uptake and accumulation of ^{3}H NA (10^{-7} M 30 min) 20—30 % of control, both in atria from nialamide pretreated (100 mg/kg i.p. 2 hr) and untreated mice In another experiment it was found that nialamide in the buffer used for wash-out (50 or 100 μg/ml) had no effect on the disappearance of ^{3}H NA previously taken up (10^{-7} M 30 min)

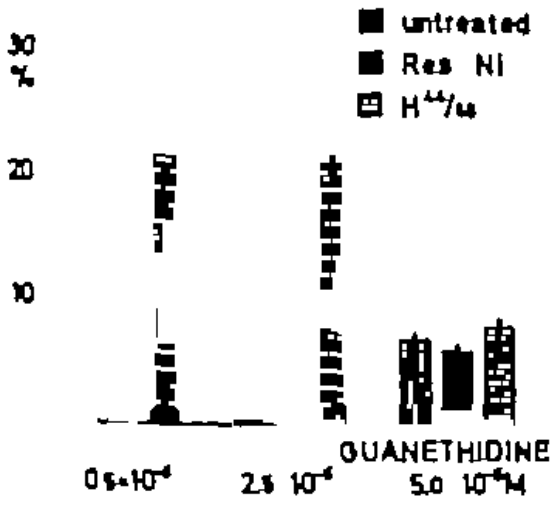

Fig. 25

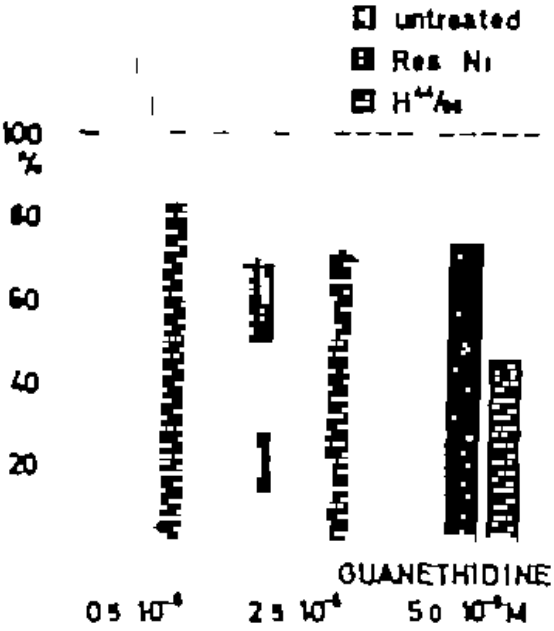

Fig. 26

Fig. 25. Effect of various concentrations of guanethidine *in vitro* on the uptake of H NA (10^{-7} M) in atria of untreated, reserpine (10 mg/kg i.p. 16 hr) + nialamid (100 mg/kg i.p. 2 hr) or H44/68 (500 mg/kg i.p. 16 hr) pretreated mice. The incubation time was 30 min, followed by 10 ml reincubation in fresh buffer. The values are expressed as per cent of the control value for each *in vitro* treatment. Each column represents the mean from 2 determinations.

Fig. 26. Effect of various concentrations of guanethidine *in vitro* on the uptake of H NA in atria of untreated, reserpine (10 mg/kg i.p. 16 hr) + nialamide (100 mg/kg i.p. 2 hr) or H44/68 (500 mg/kg i.p. 16 hr) pretreated mice. The tissue was preincubated with guanethidine for 30 min, followed by 5 min wash-out and hereafter incubated in H NA, 10^{-7} M for 30 min. The values are expressed as per cent of the control value for each *in vitro* treatment. Each column represents the mean ± S.E.M. of 8 determinations.

Effect of guanethidine on the uptake and accumulation of H NA in vitro

Guanethidine *in vitro* caused a reduction of ^{3}H NA uptake, and the inhibitory effect increased with increasing concentration of the drug in the medium. There was, however, no marked difference in the effect of guanethidine on the ^{3}H NA uptake between untreated, reserpine + nialamide or H44/68 pretreated animals (Fig. 25).

In other experiments atria were preincubated with guanethidine (0.5×10^{-6}, 2.5×10^{-6} or 5×10^{-6} M) for 30 min, washed in fresh buffer for 5 min and then incubated in H NA (10^{-7} M, 30 min) (Fig. 26). There was a gradual decrease in ^{3}H NA uptake with increasing concentration of guanethidine in

atria from untreated and H44/68 pretreated mice, whereas in atria from reserpine + nialamide pretreated mice, the inhibitory effect was not observed until the tissue was preincubated in 5×10^{-3} M guanethidine. When using a 15 min wash-out time after the preincubation in guanethidine (5×10^{-3} M) the inhibitory effect observed in the reserpine + nialamide case was, however abolished. The uptake inhibition caused by guanethidine was quantitatively the same in atria from untreated and H44/68 pretreated mice.

No decrease in the NA fluorescence intensity of the adrenergic nerves in atria was observed after incubation for 30 min in 0.5×10^{-6} 2.5×10^{-6} or 5×10^{-3} M guanethidine.

Discussion

The atria of mice consist mainly of the auricles, which are richly adrenergically innervated. A large number of adrenergic nerves is located in the endocardium where they form a two-dimensional network of characteristic varicose nerve terminals (see Jonsson and Sachs 1969 1970a) some of which leave the endocardium and penetrate in between the heart muscle cells. A large number of adrenergic nerves in atria do not seem to be directly related to those innervating the blood vessels (*cf* Nielsen and Owman 1968) A few superficially located clusters of yellow green fluorescent catecholamine containing cells, often with processes, are occasionally present (Jonsson and Sachs 1969) Fluorescence microspectrographic measurements indicate that the dominating catecholamine in these cells is NA (A. Björklund personal communication) and they are probably of a chromaffin" celltype (*cf* Jacobowitz 1967 Nielsen and Owman 1968)

The *in vitro* technique utilized in this study has been successfully used in earlier uptake studies of NA and other amines (see *i.a.* Dengler *et al.* 1962, Giachetti and Shore 1966, Hamberger 1967 and Jonsson *et al.* 1969) It has the advantage of providing controlled experimental conditions, *e.g.* the composition of the medium, amine and drug concentration, temperature and pH. Furthermore, existing differences in circulatory conditions *in vivo* are circumvented. It has been shown that the membrane potentials of neurons in slices of cerebral cortex are maintained for several hours of incubation provided the metabolic requirements, such as good oxygenation and sufficient glucose, are fulfilled (McIlwain and Rodnight 1962) In most of the *in vitro* studies on catecholamine uptake mechanisms referred to above tissue slices have been used. In the present study however whole auricles have been used instead of heart slices, since it was considered that the former preparation would give more intact cells and therefore some disturbances which might be produced by the slicing procedure are eliminated (*cf* Arvill and Ahrén 1966) Mouse atria are also very thin, having a wall thickness of about 0 2—0.5 mm, which is well comparable to that of tissue slices (see Hamberger 1967) Another advantage of mouse atria is that they can be easily prepared as whole mounts for flourescence histochemical studies, which is a simple and highly reproducable technique for the visualization of the adrenergic nerves in their full extent. In addition, mouse atria are as already mentioned richly innervated by adrenergic

13—700081. Scand. Suppl.

nerves and no change in fluorescence morphology of the nerves have been observed even after a two hour incubation *in vitro*. Mouse atrium can thus be considered as a very suitable preparation for catecholamine uptake studies *in vitro*.

Studies on the metabolism of ^{3}H NA during the *in vitro* incubation showed that the amount of metabolites of ^{3}H NA recovered from the tissue was in most cases rather small. This is probably due to the fact that mouse atrium is a very richly innervated organ, and a large part of amine is accumulated in the adrenergic nerves where it is protected from enzymatic degradation. Furthermore, metabolites do not accumulate in the tissue and are easily washed out (see Iversen 1965). Therefore it has been possible to avoid time-consuming analytical procedures and only determine total radioactivity which in most cases mainly represents unchanged ^{3}H NA. There was observed, however, that the proportion of metabolites increased after pretreatment with reserpine or 6-OH DA (see below).

A factor that would interfere with the determination of the tissue uptake of ^{3}H NA, is the amount of ^{3}H NA located in the extracellular space (≈ sorbitol space) *when the tissue is taken for radioactivity analysis (see Iversen 1963)*. The sorbitol space of mouse atrium was estimated to be about 23 % and this space could be efficiently cleared by incubation in isotope free buffer for 10 min, a procedure which has generally been used in this study. The amount of amine present in the sorbitol space must be considered of significance when using short incubation times or high medium concentrations of amine. This follows from the fact that incubation in 10^{-7} M ^{3}H NA for 5 min, the amount present in the sorbitol space constitutes about 14 % of that present in the tissue. This figure is about 34 % when using 10^{-8} M ^{3}H NA and incubation for 30 min.

Extraneuronal uptake

The extraneuronal uptake of NA has attracted great interest since it might be a significant inactivation mechanism for NA. It is also a factor of importance for the evaluation of the neuronal uptake of exogenously administered NA. Extraneuronal uptake has been shown to occur in several organs *e.g.* in pericytes in brain capillaries (Hamberger 1967), certain cells of salivary glands (Hamberger *et al.* 1967), aortic smooth muscle cells (Avakian and Gillespie 1968), special connective tissue cells and muscle cells of rat heart (Farnebo and Malmfors 1969) and muscle cells of rat iris (Jonsson *et al.* 1969).

In this study the extraneuronal uptake was investigated in atria and whole hearts from mice pretreated twice with a high dose of 6-OH DA, a drug which

has been shown to cause within a short time a severe damage of the NA uptake-storage mechanisms (Jonsson and Sachs 1970a) and specific degeneration of the adrenergic nerves (Tranzer and Thoenen 1967, 1968; Malmfors and Sachs 1968b, Thoenen and Tranzer 1968). The ^{3}H NA uptake in atria from mice pretreated with 6-OH DA represents almost exclusively extraneuronal uptake since it was the same as that of atria from immunosympathectomized mice and to judge from histochemical results (Jonsson and Sachs 1970a). After 6-OH DA pretreatment there was a relative increase in the amount of metabolites, recovered from the tissue, especially of NM but also of deaminated ones, although the absolute amounts were practically the same as in normal atria.

The extraneuronal uptake in atria was found to increase with increasing concentration of ^{3}H NA in the medium and with incubation time, although the amount present extraneuronally calculated as per cent of that present in innervated atria identically incubated, was fairly constant using different incubation times.

There was no true accumulation of NA in the atrial tissue, since the uptake ratios were below one. This does not exclude a local accumulation of NA, however but this possibility seems very unlikely since no special fluorescent structures were observed histochemically after administration of NA. A large part of ^{3}H NA taken up extraneuronally is loosely bound since it is easily washed out. The values for extraneuronal uptake presented in this study are obtained after a 10 min wash-out period. During this wash-out period there is, no doubt, an efficient clearing of the sorbitol space thus eliminating this error when evaluating tissue uptake mechanisms, but also a wash-out of NA very loosely bound to the tissue. The present values are evidently too low but when correcting for the NA washed out only small changes of the extraneuronal uptake values are obtained. The value for 10^{-7} M ^{3}H NA, 30 min should thus be 16.5 % instead of 12 % and for 10^{-6} M ^{3}H NA 30 min 37 % instead of 32 %.

The extraneuronal uptake found in the present study *in vitro* was in the same order of magnitude as that found in *in vivo* infusion experiments (*cf* Thoenen and Tranzer 1968).

Results obtained from the perfused rat heart have demonstrated the existence of two different uptake mechanisms for catecholamines: one, Uptake$_1$ working at low (0.01—1 μg/ml) and the other Uptake$_2$ at high amine concentrations (1—40 μg/ml) (Iversen 1965). The former process is efficiently inhibited by metaraminol, while the latter by NM. Both uptake processes have been claimed to be associated with the adrenergic nerves, but recent findings have given evidence for the view that Uptake$_2$ is mainly extraneuronal (Clarke *et al* 1969, Farnebo and Malmfors 1969). The extraneuronal uptake of mouse atria seemed to be of another character than Uptake$_2$ described by Iversen (1965).

since it was not inhibited by NM in a concentration of 5×10^{-8} M and 5×10^{-6} M caused only a slight inhibition of the uptake, both in atria from untreated and 6-OH DA pretreated mice. In the perfused rat heart (Iversen 1965) there was an 85 % inhibition of $Uptake_2$ and 31 % of $Uptake_1$ by 5×10^{-6} M NM. It has to be considered that in Iversen's study no wash-out had been performed, which might in part explain the differences. It might also in part be due to differences in the activity of the catabolic enzymes MAO and COMT (see Lightman and Iversen 1969)

The exact nature of the extraneuronal uptake is still a matter of uncertainty and its physiological relevance is difficult to evaluate. In the present study it was observed that fairly high concentrations of NA were required to obtain a pronounced extraneuronal uptake of NA and furthermore, no true accumulation of NA took place. It has been suggested that high NA concentrations, about 6×10^{-6} M (see Gillespie 1968 see also Hamberger 1967) exist in the adrenergic nerve-effector cell junctions and the extraneuronal uptake might thus locally have a physiological significance.

The importance of extraneuronal uptake as an inactivation mechanism for circulating catecholamines, is difficult to judge, since the exact quantitative aspects of the metabolism of NA extraneuronally is not completely known. This is mainly due to the fact that neither NA nor its metabolites are firmly retained extraneuronally (see Iversen 1965) It has recently been shown by Lightman and Iversen (1969) that $Uptake_2$ is operating also at low concentrations of NA, but the NA taken up is then rapidly metabolized. At higher concentrations the catabolic enzymes are saturated, providing possibilities for uptake of unchanged NA. These authors claim that $Uptake_2$ may prove to have physiological importance in termination of the actions of NA, both circulating catecholamines and after its release from adrenergic nerve terminals.

Uptake and accumulation of NA — effect of reserpine, MAO and tyrosine hydroxylase inhibition

The uptake processes for catecholamines in the adrenergic nerves are considered to be of greatest importance for the function of these nerves. The general opinion regarding catecholamine uptake mechanisms is that there is one located to the axonal membrane of the adrenergic neuron, the so-called membrane pump and one located intraneuronally in the amine storage granules (see *i.a* Kirshner 1962a, b, Carlsson *et al.* 1962, 1963 Euler and Lishajko 1963a, Carlsson 1966a, b Malmfors 1965 1967 Hamberger 1967 Iversen 1967 Lundborg 1967 Hokfelt 1968 1969) Exogenously administered NA is actively taken up by the membrane pump and is thereafter incorporated

into the amine storage granules, mainly by a Mg^{++}-ATP dependent mechanism. The membrane pump is effectively blocked by *e.g.* cocaine and desipramine (Hillarp and Malmfors 1964 Hamberger 1967) while the uptake into amine storage granules is blocked by reserpine (Carlsson *et al.* 1963 Euler and Lishajko 1963c Stjärne 1964 Iversen *et al.* 1965 Lundborg 1967). It has also been shown that there is a small but significant uptake of NA into the granules, which is reserpine-resistant (Stitzel and Lundborg 1967 Jonsson and Sachs 1969). NA is in addition incorporated into the granules via β-hydroxylation of dopamine (Stjärne 1966 Häggendal and Malmfors 1969 Jonsson and Sachs 1970b).

In the present study four different approaches were used in order to elucidate the neuronal uptake mechanisms: untreated, nialamide, reserpine + nialamide and H44/68 pretreatment. As can be concluded from the results on studies on the extraneuronal uptake, most of the ^{3}H NA taken up and accumulated in mouse atria is neuronal, using medium concentration of 10^{-8}—10^{-6} M. The neuronal represents 70—90 % of the total uptake under these conditions. The uptake of ^{3}H NA in atria increased with time and concentration of ^{3}H NA in the medium. The uptake process obeyed Michaelis-Menten kinetics in accordance with the results of several investigators (Dengler *et al.* 1962, Iversen 1963 Jonsson *et al.* 1969). There is a true accumulation of NA from the external environment. The over-all accumulation of ^{3}H NA in atria from *untreated mice* after incubation in 10^{-7} M ^{3}H NA for 30 min was 6-fold a figure which is about 3 times lower than that obtained in rat iris. The over-all accumulation of ^{3}H NA under these conditions in the rat iris varicosity the structure specialized for the synthesis, storage and release of the adrenergic transmitter has been calculated to be as great as 30 000 times (Jonsson *et al.* 1969). This figure is in the same order of magnitude for the varicosity of the adrenergic nerves in mouse atrium, if it is assumed that the NA concentration of an organ reflects the number of nerves and that the number of varicosities per nerve unit' is constant, since rat iris contains about 3—4 times more NA per weight unit than mouse atrium (see Jonsson *et al.* 1969 Jonsson 1969). In view of the extreme efficiency of the neuronal uptake, this process certainly plays a very important role in termination of the actions of NA released at the sympathetic nerve endings, thereby subserving transmitter economy. This is furthermore supported by results obtained from studies on cat nictitating membrane, where it was found that the response to *l*-NA was potentiated about 40-fold when th neuronal uptake was blocked by cocaine (Trendelenburg *et al.* 1962, Langer and Trendelenburg 1969). The neuronal uptake process is in all probability also of great importance for the inactivation of circulating catecholamines, especially in densely innervated tissues and organs.

Nialamide a potent and irreversible inhibitor of MAO (see Pletscher *et al* 1966) caused in a dose of 100 mg/kg i.p 2 hr an almost 100 % inhibition of the MAO activity in mouse atrium, leading to markedly decreased formation of deaminated metabolites and an increase in the endogenous NA level. The uptake and accumulation of ^{3}H NA was somewhat higher than in untreated animals, which is certainly a consequence of the MAO inhibition decreasing the intraneuronal catabolism of the amine taken up in the nerves. The transport of NA over the axon membrane after nialamide is, however the same as that of untreated.

Reserpine is known to be a strong inhibitor of the Mg^{++} ATP dependent uptake mechanism of the amine storage granules, and this effect results in a depletion of the amine stores (Carlsson *et al.* 1962 1963 Kuruhner 1962a, b Euler and Lishajko 1963c, Stjärne 1964 Rutledge and Weiner 1967 Roth and Stone 1968 Sugrue and Shore 1969) The dose of reserpine used in this study reduced the NA content of the heart to about 8 % of untreated and induced a complete disappearance of the fluorescence of the adrenergic nerves in mouse atria, as observed histochemically The ^{3}H NA recovered from atria incubated in ^{3}H NA was very low after reserpine pretreatment and MAO had to be inhibited in order to retain at least some of the NA taken up intraneuronally The low recovery of ^{3}H NA after reserpine alone is a result of the granular blockade caused by reserpine, thereby making ^{3}H NA taken up in the nerves available for degradation by MAO This is also supported by the finding that there was an increased amount of deaminated H-metabolites recovered from the tissue after incubation in ^{3}H NA (Carlsson 1960 Kopin *et al* 196?)

Although many reports on the site of action of reserpine have appeared dur ing the last decade, the question whether reserpine affects the membrane pump is still a matter of controversy Many authors have reported that reserpine leaves the membrane pump unaffected (see i.a. Hamberger *et al* 1964 Lind mair and Muscholl 1964 Iversen *et al.* 1965 Malmfors 1965, Carlsson 1966b Hamberger 1967 Snyder *et al.* 1968 Jonsson *et al.*) although others have concluded that reserpine interferes with the N the axonal membrane (Dengler *et al.* 1961 Brodie and Beaven 1 964 Costa *et al* 1967) The results presented in this paper s *e+niala* mide pretreatment gives a linear initial uptake of which quantitatively the same After 5 min, h ion fr linearity starts and the sured is lower th This wa

Costa (I t. J reserpine does

10

also the case for longer incubation times and for higher concentrations of ^{3}H NA in the medium, even when the values were corrected for an increased wash-out of ^{3}H NA during the 10 min of reincubation in isotope-free medium (see below). The extraneuronal uptake was not affected by reserpine + nialamide pretreatment. The results presented thus, indicate that a dose of 10 *mg/kg i.p.* of reserpine does not cause any inhibition of NA uptake by the membrane pump since the initial rate of uptake is the same as that after no treatment and the reduced uptake values later observed, certainly reflect a decreased retention of the NA taken up, caused by the inhibitory effect of reserpine on the granular uptake storage mechanism (*cf* Kopin *et al.* 1962). The reduced accumulation of ^{3}H NA after reserpine + nialamide may in part also be due to a not complete MAO inhibition (see page 39).

In addition this hypothesis of reserpine not affecting the membrane pump is supported by the observation that reserpine in a concentration of 0.05—5 *μg*/ml in the incubation medium caused no apparent inhibition of ^{3}H NA uptake in atria from reserpine + nialamide pretreated mice. A slight reduction of ^{3}H NA uptake was observed using a reserpine concentration of 25 *μg/ml*. It has to be pointed out, however that this concentration is very high and the effect of reserpine might be unspecific at this concentration.

Tyrosine hydroxylase catalyzes the formation of 3,4-dihydroxyphenylalanine (DOPA) from tyrosine which is considered to be the rate-limiting step in the NA biosynthesis (Levitt *et al.* 1965). A large dose of the *tyrosine hydroxylase inhibitor H44/68* causes a marked depletion of the endogenous NA stores (Andén *et al.* 1966, Corrodi and Hamson 1966). In mouse heart the NA content was about 40 % of normal. This depletion is dependent on nerve impulse activity of the neuron (Andén *et al.* 1966, Corrodi and Malmfors 1966). It was observed histochemically that there was some variation in the degree of NA depletion in atria from different animals and in different neuron systems from the same animal, which might reflect differences in nerve impulse activity. The results presented in this study show that the ^{3}H NA uptake characteristics in atria from H44/68 pretreated animals are practically the same as normal. Subcellular distribution studies have revealed that there is a granular uptake of ^{3}H NA after H44/68 pretreatment which in quality and quantity was approximately the same as normal, after *i.v.* injection of ^{3}H NA and after *in vitro* incubation in ^{3}H NA (Jonsson and Sachs 1969).

Results from fluorescence morphology studies have indicated a granular uptake, since the appearance of the nerves was normal, *i.e.* there were distinct varicosities and weakly fluorescent non-terminal axons. This is in contrast to the reserpine + nialamide case, where the nerves have a smooth appearance and prominent non-terminal axons (Malmfors 1965, Malmfors and Sach

1968a) It has also been shown in iris from H44/68 pretreated rats that ^{3}H NA previously taken up *in vitro* can be released by field stimulation indicating a granular uptake and storage of the administered amine (Farnebo and Hamberger 1970) I s seems that after tyrosine hydroxylase inhibition, both the membrane a e granular uptake mechanisms are operating, although the endogenous res are considerably reduced. H44/68 itself is not a MAO-inhibitor a l ot interfere with the membrane pump mechanism (Jonsson *et al.* 1969 and Hamberger 1970 Jonsson and Sachs 1970b)

The to and accumulation of ^{3}H NA, both *in vitro* and *in vivo* after H4 ıtment was slightly higher than normal (*cf* Laverty and Roberts n ^{3}H NA infusion experiments it was observed, however that the r as 62 % higher after H44/68-pretreatment than the net uptake hereas the exchange with the endogenous NA store was the sam ulated as a percentage. Thus, a larger amount of the ^{3}H NA is incorporated in the granules without being involved in a displacement The NA taken up after H44/68 pretreatment could in no case account for a complete replenishment of the reduced endogenous NA stores, which *consistent with the results of Laverty and Robertson (1967)* Hokfelt (1968) and Jonsson *et al.* (1969) However Spector *et al.* (1965) obtained a more than complete replenishment in guinea pig spleen and heart after i.p injection of 2 mg/kg NA, in animals pretreated with α-methyl-β-tyrosine In the present study however no complete replenishment was obtained in H44/68 pretreated mice with a high dose of NA (1.5 mg/kg i.p.) Some 30 % was lacking compared to untreated when considering the NA present extraneuronally After incubation in 10^{-8} M ^{3}H NA for 2 hours some 25 % was also lacking. An explanation for these results may be a reduced storage capacity of the adrenergic nerves when the endogenous NA has been released. The reduced storage capacity may be caused by losses of enzymes and other protein-complexes of importance for the uptake and storage of amine. It has indeed been shown that β hydroxylase, ATP and some proteins are released by acetylcholine stimulation of the isolated bovine adrenal medulla (Kirshner *et al.* 1966) and by electrical stimulation *in vivo* of the splanchnic nerve (Blaschko *et al.* 1967 de Potter *et al.* 1969 Geffen *et al.* 1969) The incapacity to replenish the emptied stores might also be due to the possibility that the NA taken up may not easily mix with the NA pool or pools (*cf* Iversen 1963 Crout 1964) It has been found however that in rat brain the intraneuronal catecholamine levels reach normal values after a L-dihydroxy phenylalanine injection in animals previously depleted of their catecholamines by H44/68 (Corrodi *et al* 1966) This difference in results may be explained by assuming that a storage pool of the granules are filled in the ordinary

synthetic pathway via a route (*e g* the β-hydroxylation step) which is reached slowly by NA taken up from the external environment (*cf* Stjärne 1966, Haggendal and Malmfors 1969)

It was thought of interest to investigate the uptake of ^{3}H metaraminol in mouse atria, since this compound is a structural analogue to NA, and has been shown to use the membrane pump for transport into the neuron, and is incorporated into amine storage granules (see Lundborg 1967) Furthermore, it is not metabolized by MAO or COMT The ^{3}H metaraminol uptake for each concentration was quite similar in atria from the differently pretreated groups of mice. This is in contrast to the results obtained with ^{3}H NA, where a lower ^{3}H NA uptake and accumulation was observed after reserpine + nialamide pretreatment. The relatively high uptake of ^{3}H metaraminol after reserpine cannot be explained by a higher extraneuronal uptake compared with ^{3}H NA, but rather reflects a high affinity of metaraminol to the reserpine resistant uptake mechanism in the granules (Stitzel and Lundborg 1967)

Stereospecificity of NA uptake

The uptake and retention of *d* NA and *l* NA has been the subject of many investigations. A pronounced stereospecificity for *l* NA in splenic nerve granules (Stjärne and Euler 1965) and in adrenal medullary granules (Carlsson *et al* 1963) has been proposed. An even more pronounced preference for the *l* isomer has been reported for the axon membrane pump (Maickel *et al* 1963) In histochemical fluorescence studies by Malmfors (1965) no difference in the fluorescence of the adrenergic nerves of rat iris was observed after *d* or *l* NA administration in reserpine + nialamide pretreated animals. This treatment would reveal the uptake by the membrane pump alone. When, on the other hand, the endogenous NA was depleted by H44/68 there was a more marked restitution of th nerve fluorescence by *l* NA (Malmfors, personal communication) These data support the view that the stereospecificity of NA uptake by adrenergic nerves is localized to the amine storage granules. Iversen (1968) however could not find any stereospecificity of the overall uptake in the iris cillary body preparation, while the perfused rat heart showed a marked preference for *l*-NA (Iversen 1963)

The results obtained in this study show that there is a small preference for the uptake of the *l* isomer in intact nerves of both mouse atria and rat irides, while blockade of the Mg^{++} ATP dependent uptake mechanism in the storage granules by reserpine seem to abolish this difference. These data taken together would also indicat that the stereospecificity of the NA uptake of adrenergic nerves is associated with the amine storage granules (*cf* Shore *et al.* 1964)

Disappearance of ^{3}H NA

Studies on the disappearance of ^{3}H NA previously taken up and accumulated in atria, disclosed a rapid initial wash-out of ^{3}H NA which was more pronounced when the incubation was performed in higher concentrations of ^{3}H NA. The rapid initial wash-out certainly reflects clearance of the sorbitol space and wash-out of ^{3}H NA from extraneuronal sites, as shown by results from the ^{14}C-sorbitol studies and the disappearance of ^{3}H NA from atria of 6-OH DA pretreated mice. A 10 min wash-out caused a disappearance of ^{3}H NA previously taken up from a medium containing 10^{-7} M ^{3}H NA (30 min) which constituted 10 % of that initially present in the tissue. Of the amount washed out, 87 % was calculated to originate from extraneuronal sites whereas the rest (13 %) represented ^{3}H NA spontaneously released from the adrenergic nerves, corresponding to about 1.5 % of the amount which had been taken up and accumulated in the nerves. When 10^{-6} M ^{3}H NA was used instead 60 % of that present in the tissue after 30 min, disappeared during a 10 min wash-out. In this case, the spontaneous release from the nerves was calculated to be about 40 % of that taken up in the nerves. It has to be pointed out, however that the last figure is relatively uncertain since a small change in the 10 min wash-out value of the denervated atria, will cause a considerable change in the amount of NA calculated to have been released from the nerves. It was also observed that the wash-out of ^{3}H NA taken up during a short time of incubation (5 min) was more pronounced than after a longer incubation time (30 or 60 min) This cannot be solely explained by the fact that the amount of ^{3}H NA in the sorbitol space constitutes a relatively larger proportion when using a short incubation time. The retention is thus in this case poorer which might be due to a less complete incorporation of amine into the granules.

The time-course of wash-out of ^{3}H NA taken up in atria from untreated nialamide and H44/68 pretreated mice was very similar while reserpine+ nialamide pretreatment caused a more rapid disappearance of the amine. These results show that the granular uptake mechanism is of great importance for the retention of the amine intraneuronally

The wash-out at 0 C of ^{3}H NA was rapid during the first 5 min, and probably represents a clearing of ^{3}H NA present in the sorbitol space, since there was no significant loss of ^{3}H NA between 10 and 120 min. The amount of ^{3}H NA washed out in 10 min approximately equals that initially present in the sorbitol space Thus incubation at 0° C seems to inhibit a spontaneous release of neuronal amine

Effect of temperature and pH on the uptake and accumulation of ^{3}H NA

Exogenously administered NA is actively taken up by the membrane pump, which is considered to be an energy dependent carrier mediated process (Dengler *et al.* 1962, Bertl and Shore 1967 Hamberger 1967 Wakade and Furchgott 1968) The NA uptake is considerably reduced at 0 C, which may be due to inhibition of the energy-yielding metabolic processes at this temperature, although it cannot be excluded that this inhibition is also in part due to changes in physical-chemical properties of the membranes.

Studies on H NA uptake at various temperatures and pHs disclosed optima at 37—40 C and pH 7 4 mainly due to effects on the adrenergic nerves, since the extraneuronal uptake was not considerably affected by changes in temperature or pH of the medium. Different temperatures of the incubation medium did not affect the fluorescence morphology of the adrenergic nerves, while it was observed that a low pH (5.8) induced a decreased fluorescence intensity of the nerves which disclosed a somewhat blurred appearance. The latter finding may indicate a damage of the adrenergic nerves, which would explain the low uptake and retention of ^{3}H NA at low pHs. The uptake of ^{3}H NA in atria was lower at pH 8.0 than at pH 7 4 in contrast to results obtained from studies on isolated bovine splenic nerve granules, which had a higher uptake at pH 8.5 than at pH 7 0 (Euler and Lishajko 1963b) This may indicate that the lower uptake in atrial nerves at pH 8.0 is due to an interference with the membrane pump mechanism. The retention of ^{3}H NA taken up at pH 7 4 or pH 8 0 was practically the same after a 30 min wash-out, while a longer wash-out time resulted in an increased disappearance of ^{3}H NA at pH 8.0 pointing to a possible interference also of the amine storage granules. In view of the results presented it is obvious that pH and temperature have to be carefully controlled in studies on NA uptake-storage mechanisms.

Effect of MAO activity on uptake and accumulation of ^{3}H NA

MAO is an enzyme which is located both intra and extraneuronally and in mouse atria the main part is located outside the adrenergic nerves (Jonsson and Sachs 1970a, *cf* Iversen *et al.* 1966) The enzyme is considered to be present in the mitochondria (Laduron and Belpaire 1968 Jarrott and Iversen 1968, Hörtnagl *et al.* 1969) Under normal conditions, when NA is taken up into the nerves very little NA is deaminated by MAO since the amine is rapidly incorporated into the granules. This is supported by the finding that

MAO inhibition leads only to a minor increase of accumulation of endogenous NA. The present studies were made on atria from reserpine pretreated mice, since it provides possibilities to follow experimentally induced changes of intraneuronal MAO activity. After a granular blockade by reserpine the amine accumulates extragranularly where it is readily available for degradation by MAO; therefore the amount of ^{3}H NA recovered from the tissue after reserpine pretreatment is very small and MAO has thus to be inhibited in order to retain NA intraneuronally. The effect of differentiated MAO inhibition, produced by nialamide, on the ^{3}H NA uptake and accumulation in atria from reserpinized mice was investigated in some detail.

The uptake of ^{3}H NA gradually increased with increasing dose of nialamide, whereas the MAO activity was already inhibited almost completely after 50 mg/kg (*i.p.* 2 hr). This may be because a very small fraction of intraneuronal MAO, too small to be measured with accuracy, is sufficient to account for a considerable deamination of NA. If this is correct, then the effect of a higher dose of nialamide than 50 mg/kg should be a reduction of the activity of the small MAO fraction, leading to a subsequent increased accumulation of NA.

Nialamide, 10 or 100 mg/kg, had no effect on the uptake of ^{3}H metaraminol in atria from reserpinized mice. The uptake values were about the same for the two doses used and for all the time periods studied. This can be explained by the fact that metaraminol is not metabolized by MAO.

It has been reported by Carlsson and Waldeck (1967), however, that the optimal dose of nialamide for the *in vivo* uptake of ^{3}H NA in hearts from reserpinized mice was 10 mg/kg. This observation has been confirmed in this laboratory (Sachs, unpublished observations). The findings *in vivo* are thus in contrast to the present results obtained *in vitro*, when the ^{3}H NA uptake and accumulation was in all cases higher after 100 mg/kg than after 10 mg/kg nialamide. Carlsson and Waldeck (1966, 1968) have furthermore reported that nialamide causes an increased disappearance of metaraminol and α-methyl NA taken up *in vivo*. These effects of nialamide obtained *in vivo* were suggested to be mediated by endogenous monoamines accumulating in the adrenergic nerves as a consequence of the MAO-inhibition, leading to a displacement of the amine taken up. The increased disappearance could be abolished by decarboxylase inhibition (Carlsson *et al.* 1968). The discrepancies between the results obtained in this study and those of Carlsson and coworkers, might be due to effects of nialamide observed *in vivo* not being maintained *in vitro*. A possible explanation could be that nialamide in addition to its MAO inhibitory effect also may interefere directly with the uptake and/or releasing processes of NA *in vivo* (*cf.* Besson *et al.* 1969). This is not

likely however since nialamide in a high concentration *in vitro* did not caus any uptake inhibition or any increase in spontaneously released ^{3}H NA pre viously taken up These data taken together indicate that the differences be tween the *in vivo* and the *in vitro* results might be due to a decreased accumu lation of endogenous monoamines *in vitro* after MAO inhibition. Considering these viewpoints it may be suggested that studies using NA uptake for the examination of drugs affecting MAO activity in the adrenergic nerves are preferably performed *in vitro*

Effect of guanethidine on the H NA uptake

The antihypertensive drug, guanethidine has been shown to be taken up by the peripheral adrenergic nerves and is incorporated into the amine storage granules, thereby depleting the tissues of their NA stores. The uptake and accumulation of guanethidine is inhibited by denervation or reserpine pre treatment (Sheppard and Zimmerman 1959 Obianwu *et al.* 1968) It has furthermore been shown that guanethidine can be released upon nerve stimu lation and act as a false transmitter (Boullin *et al.* 1966) Guanethidine in hibits both the membrane pump and the granular uptake-storage mechanisms (Shore and Giachetti 1966 Lundborg and Stutzel 1968, Malmfors and Sachs 1968a)

In the present investigation it was found that the ^{3}H NA uptake decreased with increasing concentration of guanethidine in the medium. When using a concentration of 5×10^{-8} M guanethidine together with ^{3}H NA (10^{-7} M) in the medium the inhibition of ^{3}H NA uptake into the nerves was almost com plete since it was approximately the same as the extraneuronal. The inhibitory effect observed in these experiments, is certainly due to interference with the membrane pump since no difference was observed between reserpine + nialamide pretreated on one hand and untreated or H44/68 pretreated on the other

Preincubation of atria in guanethidine, however followed by a short wash out period (5 min) before the incubation in ^{3}H NA, caused an inhibition of the ^{3}H NA uptake which was considerably less than that caused by incubation with ^{3}H NA and the drug together This was especially pronounced when using a low concentration of guanethidine. Also in these experiments the inhibitory effect of guanethidin increased with increasing medium concentration of the drug, but after reserpine + nialamide pretreatment no uptake inhibition wa observed until a high guanethidine concentration was used. These results are thus consistent with those of Shore and Giachetti (1966) showing that pre incubation in a relatively low concentration of guanethidine results in a prefer

ential inhibition of the granular uptake, while a high concentration leads to an inhibition of both uptake processes.

The results obtained may be explained by guanethidine competing with NA for uptake and storage sites in the adrenergic nerves. When the tissue is incubated with guanethidine and ^{3}H NA together in the medium, the inhibition of NA uptake reflects the action of the drug on the membrane pump. Pre incubation with a low concentration of the drug, however and subsequent washing led to an inhibition of ^{3}H NA uptake in atria from untreated and H44/68 pretreated mice. This is certainly due to a granular blockade caused by a previous uptake and incorporation of guanethidine in the granules. This follows from the observation that no effect on ^{3}H NA uptake was noticed after reserpine + nialamide pretreatment. After preincubation in a high medium concentration of guanethidine an effect on the membrane pump was also obtained, probably in this case due to an insufficient clearing of the drug from *extraneuronal sites*.

Conclusions

In isolated mouse atria there is a rapid and efficient uptake and accumulation of NA *in vitro*. Using NA concentrations of 10^{-8}—10^{-5} M relatively small amounts of NA were recovered from adrenergically denervated atria, corresponding to 9—30 % of the uptake in innervated atria. Thus extraneuronal uptake increases with an increasing medium concentration up to 75 % of innervated atria when the incubation is performed in 10^{-4} M NA. There was no true extraneuronal accumulation of NA compared with the medium. The amine taken up and retained extraneuronally was not observed to be localized in any specific structures, but was evenly distributed in the heart muscle cells and was found to be easily washed out from the tissue.

The neuronal uptake accumulation capacity is very efficient, and the ratio between amine concentration in the vicinity of the adrenergic nerve and the medium has been estimated to be in the order of 30 000 : 1 after incubation in 10^{-7} M NA for 30 min. The neuronal NA uptake is efficiently blocked at 0° C, and exhibits temperature and pH optima of 37—40° C and pH 7.4 respectively. There is a stereospecificity with a small preference for the *l* isomer probably localized to the amine storage granules. It is postulated that the axon membrane pump of the adrenergic neuron is the most important mechanism for the initial uptake of NA. This is supported by the findings that pharmacological modifications of intraneuronal mechanisms, such as the inhibition of MAO or tyrosine hydroxylase or blockade of the Mg^{++} ATP dependent granular uptake did not alter the transport of NA into the neuron. The membrane uptake process obeys Michaelis-Menten kinetics.

To prevent rapid deamination of the NA taken up intraneuronally when the granular uptake is blocked by reserpine MAO has to be inhibited. This inhibition must be very efficient, since a relatively small enzyme activity can cause a substantial decrease in the accumulation of NA.

The reduced accumulation of exogenous NA found after reserpine and MAO inhibition undoubtedly reflects an impaired retention of amine taken up, rather than a direct action of reserpine on the membrane pump. A granular blockade also leads to an increased disappearance of the NA taken up intraneuronally indicating that the amine storage granules are the most important structures for the total uptake and retention of NA.

The uptake and accumulation of ^{3}H NA after tyrosine hydroxylase inhibi-

tion when the endogenous NA content was considerably lowered, were the same as in controls, while the net uptake was markedly increased. Less of the NA taken up was thus involved in a displacement process. In no case could the NA taken up account for a complete replenishment of the NA store. This might be due an incomplete mixing of exogenously administered NA with the endogenous NA pool or pools. It may in part also be due to a reduced storage capacity

CHAPTER I

Introduction

The maintenance of circulatory homeostasis in the organism on the transition from rest to muscular work implies rapid adjustments of cardiac activity and vascular tone. The instantaneous onset of the circulatory events suggests a neurogenic mechanism, which has been described both as a reflex, originating in the active muscles (Alam and Smirk 1937, 1938, Asmussen *et al.* 1943 b, Tuttle and Horvath 1957, Asmussen *et al.* 1963, Humphreys and Lind 1963, Asmussen and Nielsen 1964, Lind *et al.* 1964, Donald *et al.* 1967, Lind *et al.* 1968) as well as a centrally evoked "cortical irradiation" to the vasomotor centers (Krogh and Lindhard 1913). Topical excitation of selected hypothalamic and subthalamic structures in awake animals, which simulated the cardiovascular response to exercise (Rushmer and Smith 1959) supported the concept of a centrally induced cardiovascular drive on the initiation of muscular exercise. Investigations of the "defence reaction" in animals (Hess 1949, Abrahams *et al.* 1964) and other studies of induced behavioral reaction patterns have indicated that somatomotor activity is accompanied by "efferent discharges from the corticohypothalamic centers to lower nerve centers, which affect the cardiovascular system" (Folkow *et al.* 1965). Whether this centrally induced circulatory response is appropriate for the behavioral changes has, however, not been established. Recent experiments suggest that the cardiovascular changes during naturally elicited preparation for fighting are different from those induced by electrical stimulation of the hypothalamus (Adam *et al.* 1968).

In man, circulatory adaptations to muscular exercise have been suggested to occur in anticipation of muscle activation. It has been felt that the magnitude of this mentally induced cardiovascular response should be related to the extent of mental engagement (Folkow *et al.* 1965) and to the amount of intended muscle activity. This circulatory phenomenon is apt to decrease with habituation to the appropriate muscle activation. Thus it has been thought unlikely that voluntary habituated muscle contractions and, especially within restricted muscle groups, should be accompanied by any

significant centrally initiated cardiovascular drive (Folkow *et al* 1965)

From comparisons of voluntary and electrically induced work in humans (Asmussen *et al* 1943 a, b) the similar circulatory and respiratory adjustments to oxygen uptake in the two kinds of work were supposed to be of peripheral nervous rather than of cortical origin The decreased cardiovascular response to a sustained handgrip performed by the affected limb of a patient with syringomyelia (Lind *et al* 1968) was thought to illustrate the earlier documented hypothesis (Lind *et al* 1964 1966) that the circulatory events were initiated by some peripherally evoked reflex.

The concepts of the mechanism initiating the cardiovascular response to muscular work may be summarized as follows

1 Stimuli from motor cortex are conducted to the vasomotor centers, provoking an activation of the cardiovascular system parallelly to that of the somatomotor system The cardiovascular response will be appropriately modulated to the metabolic demands through feedback mechanisms.

2 Receptors in the activated muscles incite afferent discharges to the vasomotor centers which adapt the cardiovascular response. A part of the autonomic response might also be elicited at the level of the spinal cord.

Thus the proposed regulatory mechanisms are seemingly contradictory as was commented on by Horvath and Howell (1964) who wrote "most confusing has been the failure of any theories of regulation to explain adequately the initial events of exercise

The efferent autonomic nervous mediation of the initial circulatory changes at the onset of a voluntary muscle contraction has not been assessed in healthy man. In an attempt to analyze the underlying mechanism it was found that after the administration of a beta adrenergic blocking drug propranolol Macdonald *et al* 1966) a sustained handgrip elicited similar elevations in mean aortic pressure and a greater percentage increase in heart rate *The immediate heart rate acceleration at the onset of mild, dynamic exercise in dogs under beta adrenergic blockade (Smulyan and Eich 1968)* was taken to be largely independent of the beta adrenergic system

In man the effect on heart rate of beta adrenergic, vagal and a combined sympathetic and parasympathetic blockade has been observed during the 5th and 7th minute of dynamic leg exercise (Robinson *et al* 1966) It was concluded that the increase in heart rate with mild exercise was mediated predominantly by a decrease in parasympathetic activity while at higher levels of work sympathetic stimulation also contributed to cardiac acceleration. Corresponding studies of the efferent autonomic activity at the initiation of muscle work have not been found in the literature.

Aim of the present study

As will be evident from this introductory account, the origin of the cardiovascular drive at the onset of muscle activity has not been clearly demonstrated. Furthermore, a differentiated function of the outflow from the autonomic nervous system evoking the initial circulatory response to isometric muscle work has not been established.

In the present study an attempt was therefore made

to study cardiovascular effects at the initiation of voluntary isometric muscle contractions,

to demonstrate the readjustment of the autonomic nervous system provoking the initial circulatory response, and

to establish whether the origin of the cardiovascular drive is central or peripheral.

Dynamic exercise with small muscle groups provokes a higher heart rate and peripheral vascular resistance than exercise with large muscle groups at similar working intensities (Bevegård *et al.* 1966 Freyschuss and Strandell 1968) Isometric work induces more rapid and marked increases of aortic pressures than dynamic work (Tuttle and Horvath 1957) Thus isometric work within small muscle groups was thought to be a preferable stimulus for the cardiovascular effects to be studied.

Through administration of drugs with inhibitory effects on the parasympathetic and the alpha-adrenergic and beta-adrenergic sympathetic nervous system an attempt was made to define the efferent pathways mediating the initial cardiovascular response.

Finally it was supposed that the circulatory changes accompanying an intended contraction in muscle groups with a blocked neuromuscular transmission would elucidate the origin of the cardiovascular drive.

CHAPTER II

General Procedures and Methods

Isometric muscle contraction The various types of isometric contractions will be designated under the attempted movements. The subjects were trained to perform the appropriate, isometric muscle contractions while relaxing non working parts of the body and breathing quietly When a tendency to Valsalva manœuvres was observed, it was mostly prevented by asking the subject to count aloud. Voluntary isometric muscle contractions were performed as flexion of the elbow and as handgrip. During elbow flexion the upper arm was held parallel to the longitudinal axis of the body The forearm was held in a position between pronation and supination and the angle between the upper arm and forearm was 90° The force developed in the contraction was displayed on a dual beam oscilloscope (Model OS 25A, Advance Instrum.) Three to four determinations were made of the maximal force of contraction exerted during 5 sec. Then the position of the other beam on the oscilloscope screen was adjusted to correspond to 50 up to 100 per cent of the highest observed value (100% MVC) and the subjects were told to exert the indicated force of contraction They were informed of both the start and the duration (in general 5—10 sec) of the contractions verbally (Chapter III IV V) or through a visual signal (Chapter III VI—VIII) and they were also trained to monitor their own performances. The muscle contractions were followed by resting periods, which allowed circulatory variables to attain precontraction values. All subjects were investigated in supine position unless otherwise stated in the respective chapters.

Further details concerning the performance of various isometric muscle contractions will be given in the appropriate chapters.

Catheterizations A teflon catheter was inserted percutaneously (Seldinger 1953) into the left brachial artery and under fluoroscopic guidance the tip was positioned in the aortic arch. The catheter was made visible on the X ray screen by introduction of a metal spiral guide, which was withdrawn when the correct position had been obtained. Via a medial cubital vein of

the right arm and by the same technique a teflon catheter was placed in the right atrium or in the superior vena cava. In the study of venomotor reactions a teflon catheter was percutaneously introduced 2—3 cm either upstream or downstream in a forearm vein

For the administration of succinylcholine the right brachial artery was punctured below or at the intercondylar line and a teflon catheter was inserted approximately 10 cm in the proximal direction.

All catheters were made of teflon tubing with external and internal diameters of 1 45 mm and 1 05 mm, respectively The tips of the catheters were adapted during heating to the dimensions of guides with a diameter of 0 8 mm.

Before arterial catheterization the skin and subcutaneous tissue were infiltrated with ca. 1 ml 0.5 per cent mepivacaine solution (Carbocain®)

Venomotor reactions in a resting arm were detected by the occluded limb technique, as described by Wallace (1956) and used by others (Samueloff *et al.* 1966 a, b Zitnik and Lorenz 1969) according to the following procedure.

A teflon catheter within a forearm vein in the resting arm was connected to a pressure transducer (strain gauge) The zero reference level for the venous pressure was the tip of the catheter A pneumatic cuff 12 cm wide was placed around the limb just above the elbow The pressure in the cuff was first raised until the venous pressure in the distal segment was approximately 25 mm Hg The cuff pressure was then rapidly increased to 250—300 mm Hg Around 2 min after the arrest of circulation the venous pressure stabilized and the observations were commenced. The occlusion was maintained for periods up to 10—12 min, during which time only small changes of P_{O_2} P_{CO_2} and pH of the venous blood in the occluded segment have been reported (Samueloff *et al.* 1966 b) A deep inspiration was used as a standard procedure for testing both free pressure transmission and the reactivity of the system. As suggested in a previous report (Samueloff *et al* 1966 b) 5—10 min were allowed for recovery Artefacts due to changes in tension of the muscles in the occluded limb were easily detected as abrupt and irregular pressure oscillations in the otherwise smooth venous pressure record.

Drugs and their administration. Atropine, 1 mg/ml, phentolamine (Regitine®) 10 mg/ml, or propranolol (Inderal®) 1 mg/ml, was rapidly injected intravenously (iv) The initial doses were roughly adapted to body

weight and were for atropine 0 5—1 0 mg, for phentolamine 7.5—10 mg and for propranolol 10 mg The total amount of drug given was dependent on the resulting heart rate and aortic pressures and, for a combined dose of drugs, also on preceding administrations. Further details are given in appropriate chapters.

Succinylcholine (Celocurin klorid®) was diluted in physiologic saline solution to give a concentration of 0 5 mg/ml of the drug The solution was injected intra arterially (ia) in the brachial artery of the limb which had performed hand contractions in the preceding control study As an initial test dose 0 5 mg of succinylcholine was used. The subsequent doses, 0 7—4 mg, were adjusted to the degree and duration of the neuromuscular blockade.

Blood pressures were recorded with Elema differential transformer transducers (EMT 490 A) in the earlier part of the study (Chapters III—V) in the latter part (Chapters VI—VIII) Medec strain gauge transducers (30—145) were used. Both types of transducers had a pressure range of 0—300 mm Hg Mean pressures were obtained after electrical integration (time constant 1 0 sec) The reference point was taken at the midthoracic point of the anteroposterior plane at the insertion of the fourth rib of the sternum.

Respiratory movements were indicated by means of a strain gauge, mounted in a clasp by which the two ends of a piece of rubber tape were held around the thorax. The start and end of the thoracic excursions during respiration were thus indicated and the records allowed a semiquantitative evaluation of the amphtude of the respiratory movements.

The force developed by the contracting muscles was recorded by dynamometers of different designs.

Dynamometer 1 was used during flexion of the elbow and consisted of a rigidly mounted strain gauge transducer to which the exerted force of contraction was transmitted through a strap around the wrist at the level of the styloid process of the radius.

Dynamometer 2 was used during handgrip and had the shape of a rod. It was made up of two metal plates separated by a strain gauge transducer The plates were covered with plexiglass to minimize the effect of temperature of the hand.

The strain gauges were coupled as one arm of a bridge at the input of a chopper amplifier The linearity was ±0 02 per cent within the operative

ranges and the frequency response was estimated to be at least 1 Hz. The forces measured were read directly in kiloponds according to prior calibration.

Muscle action potentials (EMG) were recorded with Ag AgCl surface electrodes (Beckman) and the myopotentials were fed to a differential amplifier (linear frequency response 4 Hz to 10 kHz) In general they were rectified and time averaged to facilitate the estimation of the degree of electromyographic activity

Heart rate was determined from an electrocardiogram (ECG) and was presented both as an ECG and as the inverted value of each R R interval recorded as an analogue signal on the y-axis (see, *e g* Fig 1) on a UV writer The heart rate signal was triggered by the preceding R R interval.

Recording instruments Four to eight variables were simultaneously and continuously recorded on a 8-channel UV writer (0—550 Hz—3dB Oscillofil, Siemens) and four of them were preserved on a FM tape recorder (0—620 Hz±0.5 db model T 3000 Thermionic) allowing further reproductions and changes of scales to facilitate further analyses. ECG and actual blood pressures were also continuously monitored on a 4-channel oscilloscope (model KP-404 ITT) The developed muscular force was displayed as previously described on a double-beam oscilloscope. At times some of the variables were also recorded on a Grass Polygraph DC Driver Amplifier (Grass, Instrument Co)

Statistical methods Statistical calculations were performed according to Snedecor (1959) The following probability (P) levels of significance were used

P <0 001	highly significant	***
P <0 01	significant	**
P <0 05	probably significant	*

Definitions of cardiovascular effects on muscle contractions The heart and aortic pressure response to isometric contractions were measured highest values attained within 3—8 sec from the start of the muscle tion, and so were eventual changes in right atrial or central venous p res. In each individual the measurements have been made prior to and within the same time interval during the contraction F details will be given in the following chapters.

CHAPTER III

Cardiovascular Effects of Voluntary Isometric Muscle Contractions

Subjects

The subjects were 18 healthy male blood donors, aged 22—28 years, and 4 healthy women, aged 26—37 years, belonging to the laboratory staff. Right atrial pressures were recorded in 9 of the subjects, central venous pressure in one. In the study of venomotor reactions two of the females from the laboratory staff and five of the blood donors participated.

Procedure

The procedures for catheterization, for detection of venomotor reactions and for continuous recording of the observed variables (*viz.* heart rate, aortic, right atrial, central and peripheral venous pressures, respiratory movements, integrated EMG and muscular force) are described under General Procedures and Methods.

Voluntary isometric muscle contractions were performed as flexion of the elbow in 6 of the subjects and as handgrip in 21 according to the procedure described in Chapter II.

EMG recorded with surface electrodes over different muscle groups of the shoulder revealed some activity during handgrips of maximal strength, but almost none was observed during contractions of the commonly used lower intensities (*viz.* $\leqq$70 % of MVC). In some instances the EMG output was led through an audio-amplifier and a loudspeaker to make even small amounts of electrical activity from the muscles audible. The subject and the observers were thereby informed of any muscular activity. An attempt was made to remove or minimize such stray activity.

The observed force of contraction during handgrip does not reflect the total muscle activity as stabilizing muscles in the forearm are activated. However, by comparing the recorded force with EMGs from both the flexor and the extensor muscles of the forearm at varying percentage of MVC, a reasonable proportionality was shown to be present between the recorded tension and the myopotentials of both types of muscles.

After determination of the maximal force of contraction (see General Procedures and Methods) the 50—100 per cent of the observed force during MVC was indicated on the oscilloscope.

The changes in heart rate and aortic pressures accompanying the muscle contractions were measured as the highest values attained 3—8 sec from the start of muscle activation. In each individual the measurements have been made within the same time interval after the start of contraction. Contraction periods less than 7 sec were only used in five of the subjects, who performed muscle contractions of intensities higher than 70 % of MVC.

The changes in peripheral venous pressure evoked by muscle contractions or deep inspirations represent data recorded immediately prior to the respective stimuli and at the height of the effects.

All investigations were performed in the supine position, and in five of the subjects also during 60° head-up tilting for a period of 5 to 10 min.

Results

Heart rate and aortic pressures Increments of heart rate and aortic pressures initiated by voluntary isometric muscle contractions in supine position were always obtained. The circulatory effects were similar when the con-

Fig. 1 The circulatory response of subject K. G. on isometric muscle contractions at 70 % of MVC in supine position. Small downward deflections of the respiration record denote expiration. Baseline shifts are due to artefacts. P_{RA} = right atrial mean pressure, mm Hg. (U. Freyschuss, J. appl. Physiol. 1970, in press)

tractions were performed as elbow flexion or handgrip. The cardiovascular response is illustrated by individual cases in Figs 1 2 and 4

At the onset of muscle activity the next R R interval was shortened the pulse pressure of the subsequent beat had decreased, and the systolic and

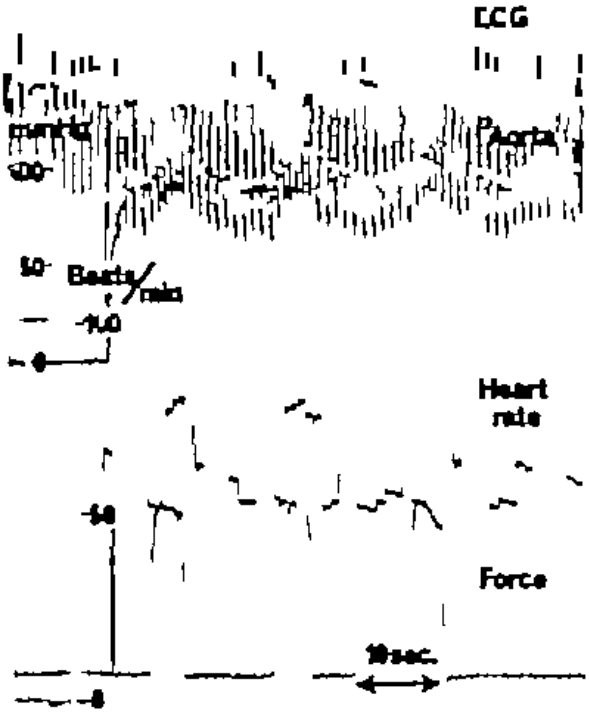

Fig 2. Increases in heart rate and in aortic pressures (subject U F) initiated by muscle contractions at 70 % of MVC in supine position.

diastolic aortic pressures started to rise. For another few beats the pulse pressure remained reduced but thereafter it mostly attained the precontraction amplitude. In general the heart rate increase attained a peak during the contraction while the aortic mean pressure levelled off or demonstrated a continuous rise. The mean increase in heart rate of the group (see Fig 3) was 18 beats/min (SE ±1 6 range 8—35 beats/min, n = 20) and the rise in aortic mean pressure averaged 16 mm Hg (SE ±1 1 range 6—26 mm Hg n = 20) The individual mean values are summarized in Fig 3 and each thin arrow represents data obtained during 3—6 determinations which were made 3—8 sec after the start of contractions and at 50—95% of MVC (average value 73 % of MVC) in each individual the circulatory effect of muscular contraction has been measured at the same muscular force and within the same time interval after the start of contraction. Within the denoted intervals of the relative muscle force (% of MVC) the mean values are ranked, starting with the low values to the left. The SE of the heart rate increase observed within the individuals varied from ±0 7 to ±4 4 beats/min corresponding values for the rise in aortic pressure were ±0 8 and ±6 3 mm Hg

The regression of the mean increments in aortic mean pressure on heart rate was $y = 0\,4890\,x + 6\,9224$ SD $y = 3\,7982$, $r = 0\,69^{***}$

The reproducibility of the cardiovascular effects within an individual is illustrated in Figs 1 and 2. In Fig 1 the SE of the increments in heart rate and aortic pressure were ±1 0 beats/min and 3 0 mm Hg respectively Corresponding values in Fig 2 were ±1 2 beats/min and ±0.3 mm Hg

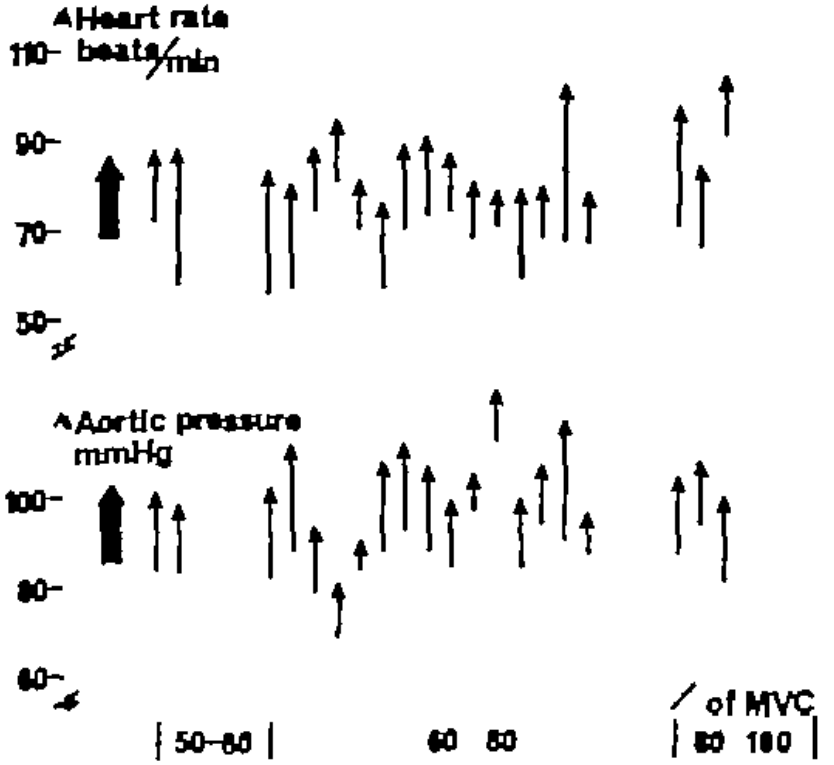

Fig. 3 The effect on heart rate and aortic mean pressure of isometric muscle contraction in supine position. Thin arrows represent individual mean values, while heavy arrows indicate the mean values of th group (n=20) For further information see text.

Right atrial and central venous pressures. The records in Fig 1 indicate that respiration continues during the contractions. The increase in right atrial pressure varied between 4 and 2 mm Hg in Fig 1 in Fig 4 the pressure of the right atrium was 2 mm Hg prior to the contraction and changed to 2.5 and 1 mm Hg during muscle activation. In Fig. 5 right atrial pressure is the same prior to and during the contraction. Changes in right atrial or central venous pressures were not a consistent finding

Venomotor reactions in a resting limb Isometric contractions of the hand initiated an increase in venous pressure in the occluded segment of the contralateral, resting forearm. A typical pattern of response is illustrated in

Fig 5 With the onset of a handgrip at 70 per cent of MVC, venous pressure increased smoothly from 34 mm Hg and reached the peak value, 38 mm Hg 5 sec after the release of contraction. During the following 15 sec the pressure subsequently attained the precontraction level. The pressures of the right atrium, 7 mm Hg and of the artery in the occluded segment 18 mm Hg, were unchanged during the contraction, and the

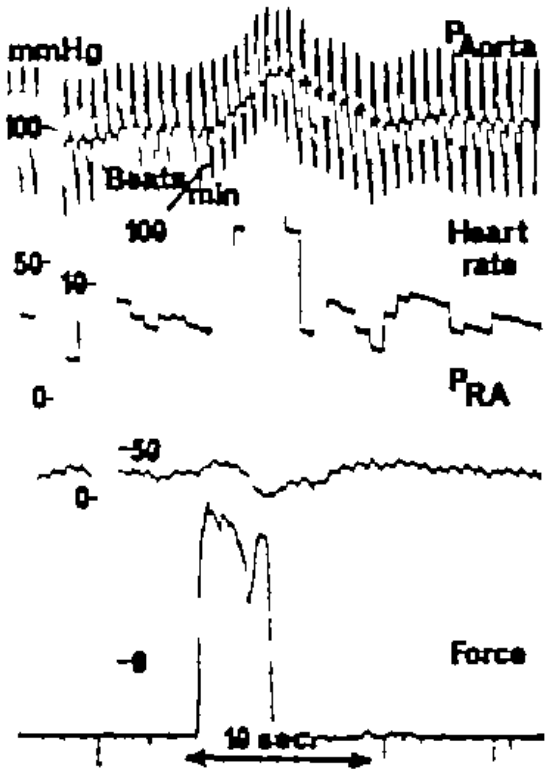

Fig. 4 The circulatory response of subject U A. to an isometric muscle contraction (100 % of MVC) in supine position. Symbols as in Fig. 1 (U Freyschuss, J appl. Physiol. 1970 in press)

depth and frequency of breathing were uninfluenced In the same figure a deep inspiration elicited a similar smooth but greater pressure rise, from 36 to 47 mm Hg

By venous congestion before complete circulatory arrest the equilibrium pressure in the veins was always maintained above that of the arteries in the occluded segment.

Although the rise in venous pressure on muscle activation appeared consistently the amplitude of the pressor response was rather varying In the same subject contractions of the same per cent of MVC induced increases in venous pressure from 3—9 mm Hg during the same period of occlusion Similar variations in response were also noted during deep inspirations.

The average values of venous pressure response to isometric handgrip and to deep inspiration were 3 mm Hg (range 1—6) and 5 mm Hg (range 2—10) respectively

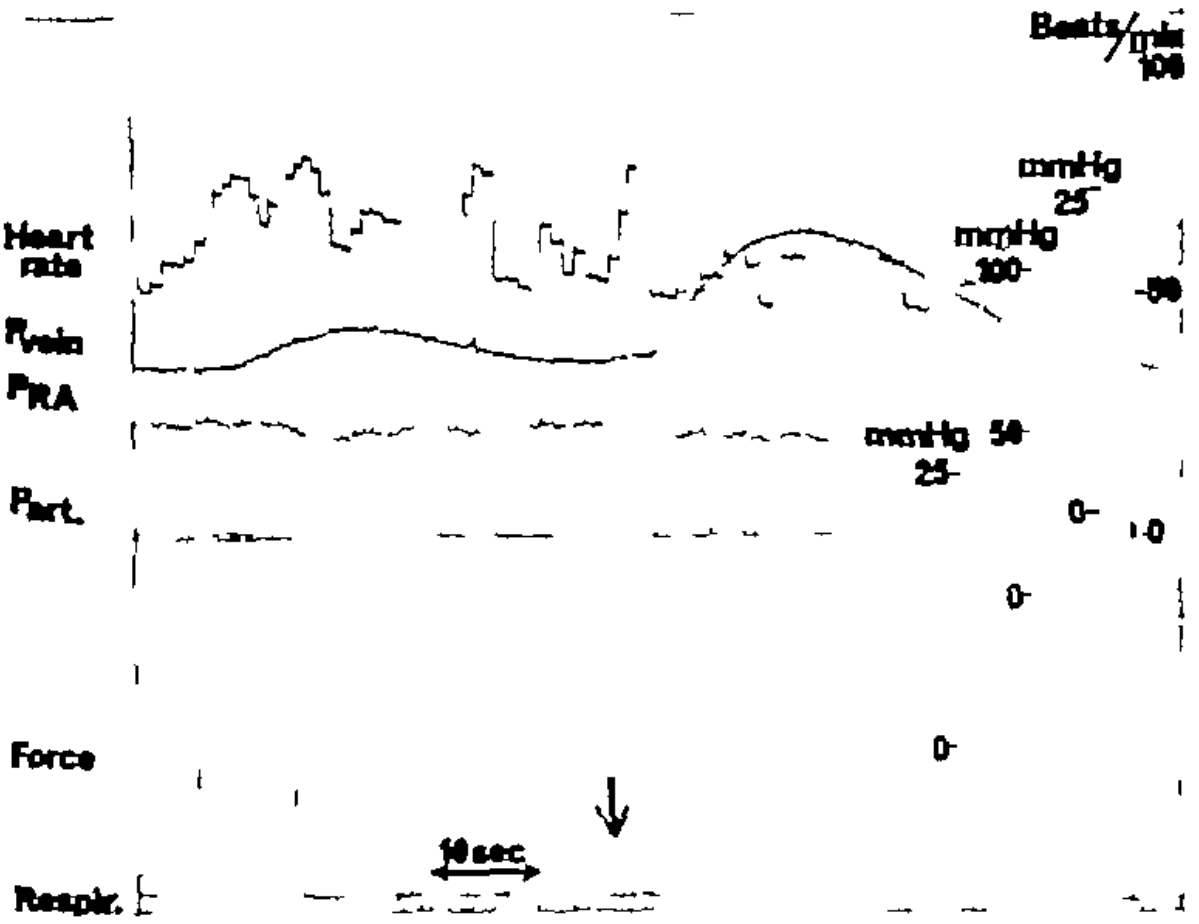

Fig. 5 The cardiovascular effects of an isometric muscle contraction (70 % of MVC) and of a deep inspiration (a downward deflection of the respiration record) denoted by an arrow In subject H. M. P_{v} and P_{art} = venous and brachial artery mean pressures in the occluded limb segment. The reference points for zero and 25 mm Hg refer to (from the left) peripheral venous and right trial pressures (P_{RA}) respec tively

Effect of body position

The 60 head-up tilting did not significantly affect the amplitude of the heart rate blood pressure response to muscle activation in three of the subjects. However in the two others, A.B and L.B. with an orthostatic heart rate reaction upon head-up tilting (heart rate increases from 73 to 115 beats/min and 78 to 114 beats/min, aortic mean pressure elevations from 69 to 72 mm Hg, 78 to 81 mm Hg) a muscle contraction elicited a rise in aortic mean pressure similar to that in the horizontal position although the heart rate response was reduced to some few beats (Fig 6)

Effect of developed muscle force

The rate at which the aortic pressure rose during contraction was roughly related to the exerted force of contraction, i e the difference in time course was discernible between 90 or 100 % of MVC and 50 or 60 % of MVC.

However within the actual range no significant correlation could be assessed between the developed muscle force in per cent of MVC or in absolute values (kilopond) and the magnitude of the heart rate and aortic pressure effects. Both intraindividual and interindividual data demonstrated this discordance.

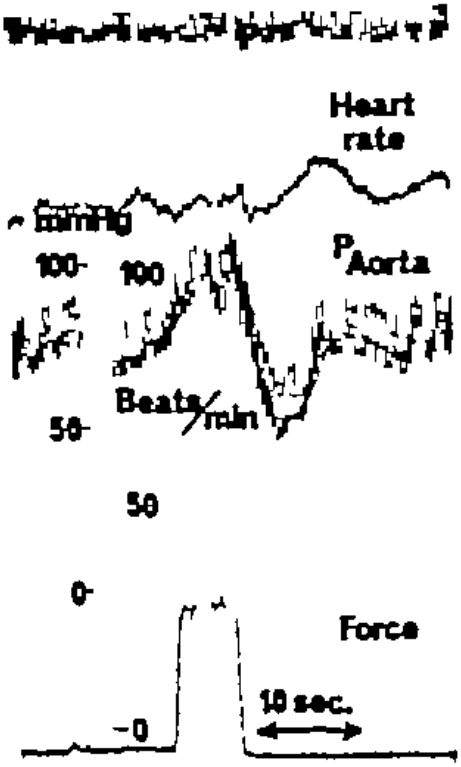

Fig. 6. The effect on heart rate and aortic pressures in subject A. B. of a muscle contraction at 70 % of MVC during 60 head-up tilting. (U Freyschuss, J appl. Physiol 1970, in press)

The upward slope of the EMG record is presumably due to a synchronization of the myo-electric potentials a recruitment of new motor-units might also be involved. (See Fig 1)

Comments

The magnitudes of the heart rate and aortic pressure increments evoked during a voluntary isometric muscle contraction in the present study are in accordance with earlier reported data obtained 10—15 sec after the start of contraction (Tuttle and Horvath 1957 Humphreys and Lind 1963 Lind *et al* 1964 Donald *et al* 1967) However the instantaneous onset of the circulatory events and the fact that their elicitation is independent of changes in respiratory movements and of right atrial pressures have not been previously demonstrated.

The lack of correlation between the magnitude of the pressor response and the relative muscle force developed was also observed by Humphreys

and Lind (1963) during sustained handgrips at tensions varying from 30 to 100 % of MVC and within 10—15 sec from the start of contraction. When the flexion of the hand muscles was sustained for longer periods, *e g* 1—5 min the cardiovascular response appeared to be determined by the relative intensity of the contraction (Lind and McNicol 1967)

A reflex venoconstriction in a resting forearm with arrested circulation has been reported to occur during strong sustained isometric contractions of small muscle groups (Bevegård and Shepherd 1966) but simultaneous respiratory movements or right atrial pressures have not been recorded. Due to the reactivity of venous tone to extraneous stimuli (Merritt and Wessler 1959 Epstein *et al* 1968) such as irregularities in the depth of breathing, special care must be taken to eliminate them. The elicitation by isometric muscle contraction of increases in peripheral venous tone together with an acceleration of the heart and a rise in aortic pressures has not been previously demonstrated From the intra-arterial pressures in the occluded segment it can be concluded that the changes in venous pressure reflect venomotor reactions and not a shift of blood into the veins secondary to a constriction of the precapillary vessels (see Fig 5)

The time course of the central cardiovascular effects and the peripheral venous adjustments to muscle contraction suggests a nervously mediated mechanism. The dissociation of the heart rate and aortic pressure response in the presence of an orthostatic reaction might indicate that the efferent pathways adjusting the heart rate and aortic pressure response emanate from different divisions of the autonomic nervous system. In an attempt to analyze the underlying mechanism the study of Chapter IV was undertaken.

CHAPTER IV

Autonomic Nervous Mediation of the Heart Rate and Blood Pressure Increase on an Isometric Muscle Contraction

The *circulatory effects evoked by a short lasting isometric muscle contraction* suggested a mediation through the autonomic nervous system. In an attempt to investigate the autonomic nervous outflows initiating the cardiovascular response to muscle activation drugs with inhibitory effects on the parasympathetic, on the alpha adrenergic and on the beta adrenergic sympathetic nervous system were administered and their influence on the circulatory response to muscle contraction was studied

Some of the results described in this chapter are obtained from U Freyschuss, J appl. Physiol 1970 in press.

Subjects

Ten healthy male blood donors, aged 22—28 years (average weight 70 1 kg) volunteered for the study One of the subjects was investigated twice

Procedure

Details about catheterizations, drugs and recordings of the observed variables *viz.* heart rate aortic right atrial or central venous pressures, respiratory movements, integrated EMG and muscular force) are given under General Procedures and Methods. Isometric muscle contractions were performed *in supine position as described in Chapters II and III*

When appropriate control data had been obtained, the circulatory response to similar muscle contractions was observed after iv drug administration. Two series of observations were made the first pertained to the effect of a single drug in the second one the effect, in the same subjects, of a combined dose of drugs was studied. Thus atropine (1 0—1 5 mg) was given to five subjects, a beta blocking agent, propranolol (Inderal® 10 mg) to one subject, phentolamine (Regitine® 7.5—10 mg) to six, and to seven of the subjects both atropine (0 5—2.0 mg) and phentolamine (5 0—10 mg were administered This composite dose was injected on an

average 9 min after the injection of the first drug In four investigations of three subjects the combined dose of drugs could not be given due to technical defects of the recording systems. The circulatory effect of muscular contraction has in each individual been measured as the highest value attained within the same time interval from the start of the muscle activa

[illegible] whereby each individual serves as his

[illegible] of atropine (1 mg) or phentolamine (7.5—[illegible] and dose of both atropine (0 5—1 5 mg) and phen[illegible] are presented in Table 1 These data were obtained within [illegible] of the iv administration when the circulatory variables on the continuous records demonstrated a temporary stationary level. No figures are available of the phentolamine effect in one subject due to technical error The changes in right atrial pressures are not listed, since the number of observations is incomplete. Atropine as well as phentolamine induced decreases in right atrial pressure which averaged 1.5 (n=3) and 3 0 mm Hg (n=4) respectively When both drugs were given together the mean decrease was 2 mm Hg (n=5) The effects of atropine are in accordance with previous reports (Wessler *et al* 1957 Berry *et al* 1959) and so are the cardiovascular adjustments to phentolamine (Taylor *et al* 1965 a, b) The predrug observations prior to the second injection do not fulfil control criteria, as an influence of the previously given drug might be or was obviously present.

Propranolol 10 mg, was given iv 65 min after the administration of 1 mg of atropine and induced a decrease of heart rate from 73 to 62 beats/min aortic mean pressure did not significantly change.

Results

Common to the single-dose injections of drugs in the present study are their relatively short lasting effects as judged from the observed circulatory variables. In general the magnitude of the initial circulatory response to muscle contraction successively started to attain predrug values approximately 5 min after the administration. A second dose of the same compound was at times necessary The data presented below were obtained within a period when the precontraction circulatory values were similar to the drug effects at rest.

Effect of atropine Fig 7 section A, and data in Table 2 demonstrate the anticholinergic effect on the change of heart rate and aortic pressure elicited on muscle activation. The mean heart rate increase of the group 104 to 107 beats/min was 17 beats/min less ($P<0.01$) than in the predrug study A concomitant but less marked ($P<0.05$) decrease (6 mm Hg) in the pressor response was recorded.

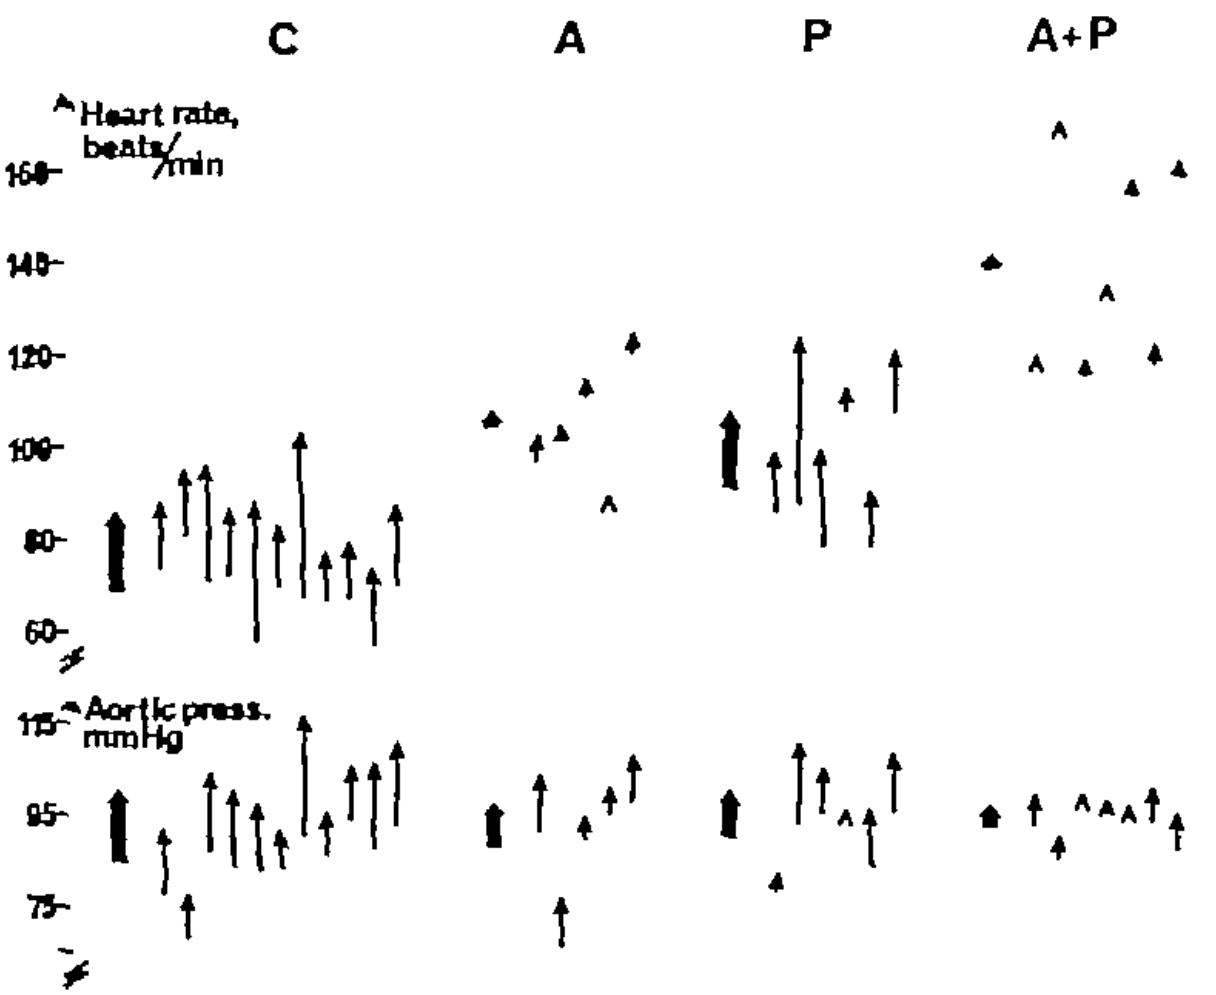

Fig. 7 The effect on heart rate and aortic mean pressure of isometric muscle contraction in C) control studies, and under the influence of A) atropine, P) phentolamine, A+P) atropine and phentolamine. Thin arrows represent individual mean values while heavy arrows indicate the mean values of the group. The first five mean values in section C represent control data for the atropine study and the remaining six mean values the control data for the phentolamine study. Of the mean values in section A+P nos. 1 and 2, should be compared with nos. 4 and 5 in section C the remaining five in section A+P should be compared with the last five in section C. (U. Freyschuss, J. appl. Physiol. 1970, in press)

Effect of propranolol. Under the influence of a beta-blocking agent the circulatory effects initiated by a muscle contraction were similar to those in the predrug, control period. The mean increments in heart rate and in aortic mean pressure were 15 beats/min and 16 mm Hg.

Effect of phentolamine. When phentolamine was given as the first drug, the mean increase in heart rate of the group, 17 beats/min, was similar to that in the control studies (Figs. 7 and 8 and Table 2) although the individual mean heart rates at the initiation of muscle activation after drug

TABLE 2. Difference ($\bar{d}$) in the heart rate increase (ΔHR) beats/min, and the aortic mean pressure rise (ΔP_{Ao}) mm Hg, elicited on a muscle contraction prior to and after drug administration. C—A, C—Ph, C—A+Ph predrug data minus those attained after atropine, phentolamine, and atropine plus phentolamine, respectively. Degrees of freedom (df) and t-test values (t) are given. P values are for paired comparisons between individual means.

	C — A		C — Ph		C — A+Ph	
	ΔHR	ΔP_{Ao}	ΔHR	ΔP_{Ao}	ΔHR	ΔP_{Ao}
$\bar{d}$	16.7	6.0	0.6	4.7	18.0	11.8

administration were on an average 20 beats/min higher (Fig. 7). The rise in aortic pressure was less marked, the mean value of the group being 5 mm Hg ($P < 0.05$) lower than in the control situation (Fig. 7 and Table 2).

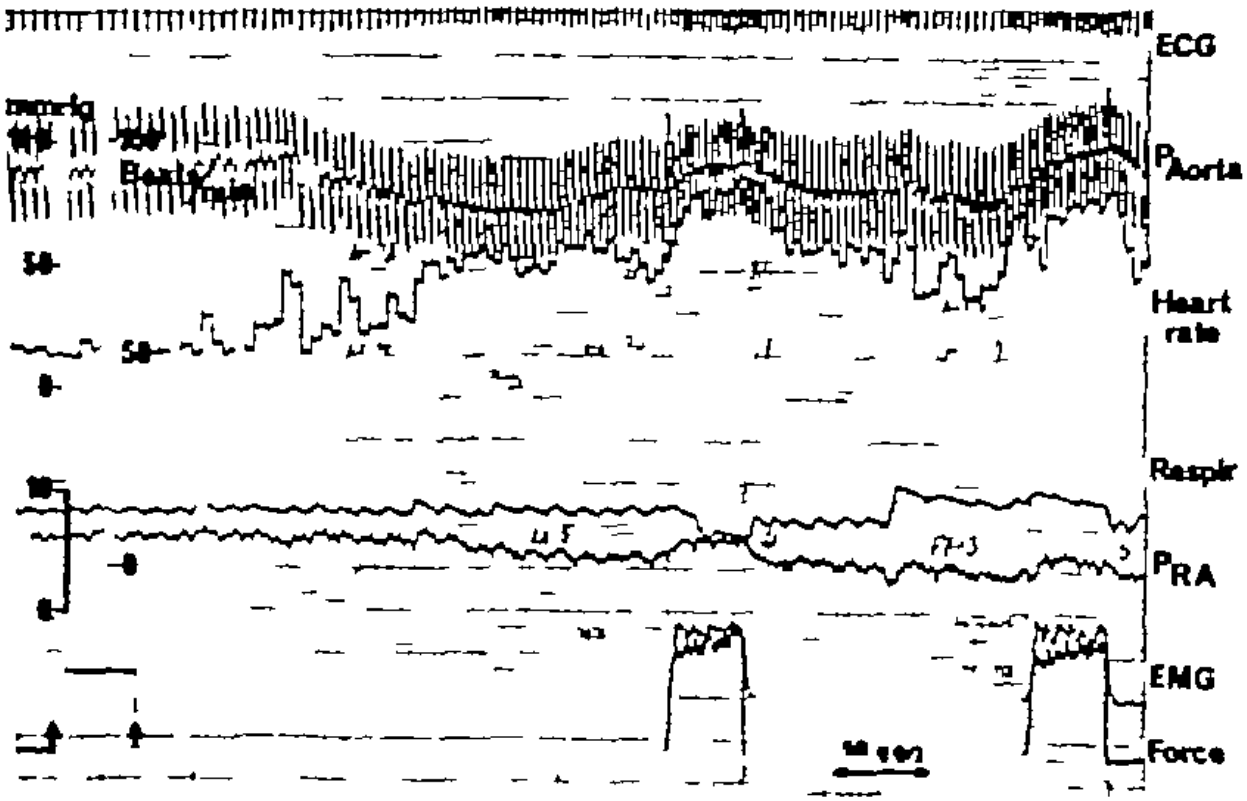

Fig. 8. The circulatory effects in subject K. G. of iv injection of phentolamine (10 mg) denoted by arrows, and of muscle contractions at 70 % of MVC. Subject and symbols as in Fig. 1, Chapter III. (U. Freyschuss, J. appl. Physiol. 1970, in press)

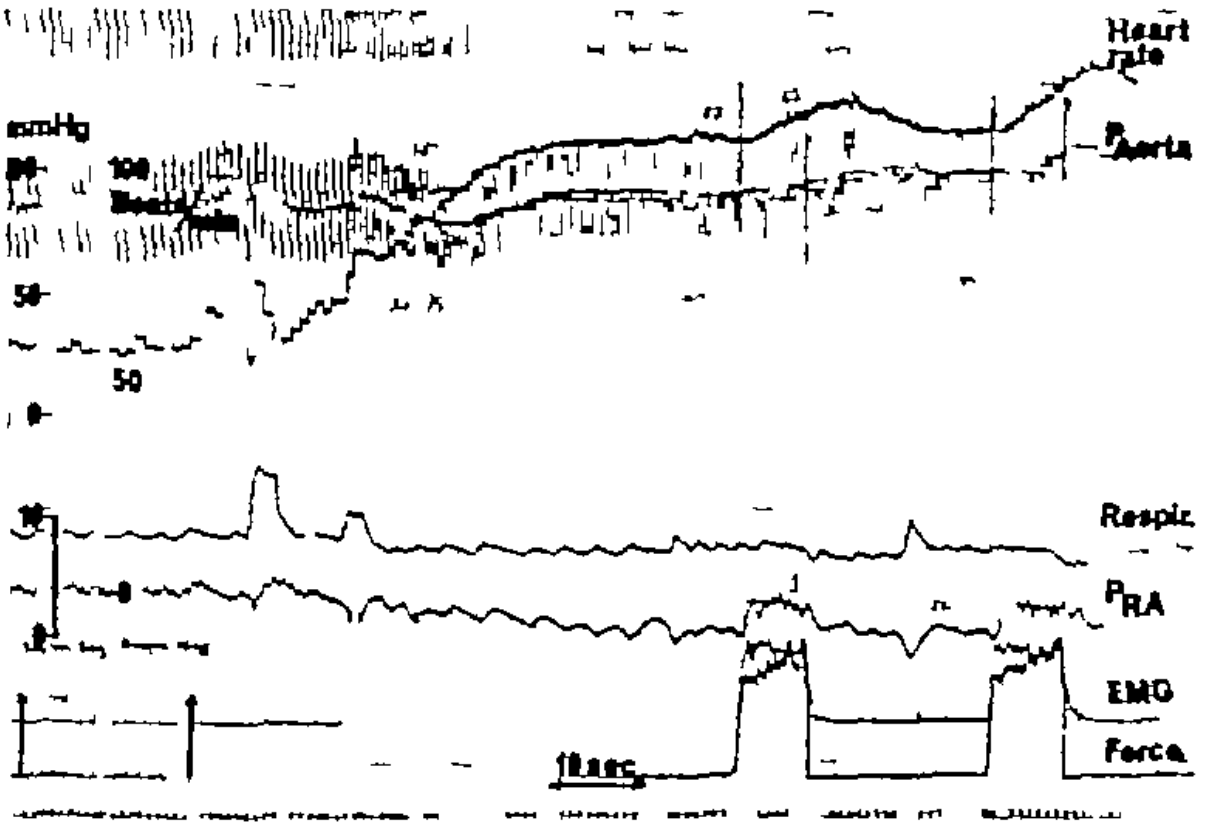

Fig 9 The circulatory effects of v injection of 5 mg phentolamine and 1.5 mg atropine (within the arrows) and of subsequent muscle contractions at 70 % of MVC. Symbols and subject are the same as in Figs 1 and 8.

Effect of atropine and phentolamine Under the influence of both drugs (Figs 7 9 10 and Table 2) the acceleration of heart rate evoked by muscle contraction was significantly ($P < 0.01$) inhibited and in many instances completely abolished The average rise in aortic pressure, 5 mm Hg, was 12 mm Hg lower ($P < 0.01$) than the corresponding control value

Effect of orthostatic reaction As commented on in Chapter III an orthostatic reaction upon head-up tilting greatly reduced the heart rate acceleration evoked by the muscle activity but did not affect the amplitude of the pressor response.

Comments

According to the design of the study an attempt was made to abolish the heart rate acceleration initiated by the muscle contraction, thus permitting observations of changes in aortic pressure response. In the earlier study by Macdonald *et al* (1966) on the cardiovascular effects of handgrips, 30 % of MVC, sustained for 5 min, it appeared that under the influence of

Fig 10. The cardiovascular response to muscle contractions (70 % of MVC) at 1 min 20 sec, 2 min and 4 min after a second iv injection of the combined dose of 5 mg phentolamine + 0.5 mg atropine in the same experiment as in Fig. 9 (U Freyschuss, J appl. Physiol. 1970 in press)

10 mg iv of a beta adrenergic blocking agent propranolol, the percentage increase of heart rate was greater but the rise in aortic pressure unchanged. In their records of the individual heart rate accelerations it can be observed that the rate of increase during the first minute of contraction is higher than in the control study. In keeping with this observation are the data of Smulyan and Eich (1968) concerning the effect of beta-sympathetic blockade on the initial hemodynamic response of dogs to treadmill exercise.

In the single investigation in the present study of the effect of propranolol 10 mg iv the circulatory response to isometric muscle contractions was not affected. The deviation from the findings of Macdonald *et al* (1966) might be explained by the fact that the data emanate from different time intervals from the start of contraction, 7 sec and 60 sec, respectively.

With the administration of atropine the heart rate acceleration evoked by muscle activation was inhibited to a degree which was dependent on the amount given. During head-up tilting of the orthostatic subjects in the control study the heart rate reaction on muscle contraction was likewise diminished. These findings suggest that the heart rate modulation during

the initial part of voluntary isometric muscle contraction is predominantly elicited by a withdrawal of vagal tone.

A significant pressure response was maintained both during the cholinergic block and during tilting. The pressure rise evoked by muscle activation can consequently not be ascribed solely to a heart rate acceleration. The time course of this circulatory reaction seems to preclude a humoral mechanism.

When phentolamine was given as the first drug muscle contraction elicited a less marked rise in aortic pressure although the increment in heart rate was the same as in the control study. Phentolamine is known as a moderate effective adrenergic blocking drug (Goodman and Gilman 1965) which prevents responses to circulating adrenergic mediators more readily than those to sympathetic nerve impulses. Recently the drug has been ascribed a beta adrenergic stimulating action (Zahir and Gould 1968, Gould 1969, Gould *et al* 1969). However the latter effect seems rather to be indirect, due to a neurotransmitter overflow (Iversen 1967). In the present study no effects of an indirect beta adrenergic stimulation are discernible when phentolamine is given alone. It might be hypothesized that, under the influence of both atropine and phentolamine, the high heart rates above the level of vagal dominance and the small but remaining heart rate acceleration during muscle contraction would reflect a lowering of the threshold for beta receptor stimulation.

The maintained pressure effect on the withdrawal of vagal tone presupposes an increased peripheral vascular resistance. The inhibition of the blood pressure response under the influence of phentolamine suggests that the pressure rise is partly mediated by alpha-adrenergic receptors.

The pressor response to an isometric muscle contraction could thus be ascribed both to the heart rate acceleration and to an effect on the systemic vascular resistance mediated by sympathetic constrictor nerves.

Further if the observed increase in venomotor tone reflects a more general effect on the capacity vessels, an increase of venous return would be provoked, which should compensate for the greater outflow and maintain the stroke volume. Thus, the heart rate acceleration, the increase of the systemic vascular resistance and the venomotor effect would contribute to an enhanced perfusion of the activated muscle groups.

CHAPTER V

Autonomic Nervous Mediation of the Heart Rate Acceleration on an Isometric Muscle Contraction in Tetraplegic Men

Some data from a study of the cardiovascular control in men with transverse cervical cord lesions (a preliminary report has appeared, see Freyschuss and Knutsson 1969) might further elucidate the autonomic nervous mediation of the circulatory response to isometric muscle contractions.

Subjects

The subjects were eight tetraplegic men, 21—42 years of age, with a complete transverse spinal syndrome below segments C_5—C_7 one of the subjects (no. 4) was investigated twice. Clinical tests of sensory and motor functions had indicated a complete loss of functional continuity at the appropriate cervical levels. All lesions were traumatic and 1—5 years had elapsed since the accident. None of the subjects gave any history of previous neurological or cardiovascular diseases. They had passed courses of physical training and rehabilitation

Procedure

The catheterizations and recordings of the observed variables (*viz.* heart rate aortic right atrial or central venous pressures, respiratory movements, EMG and muscular force) are described under General Procedures and Methods. Isometric muscle contractions were performed according to the descriptions in Chapters II and III The circulatory reaction upon head-up tilting 30—60 above the horizontal plane during 2—10 min was tested in all subjects. The drug influence on the blood pressure control during tilting was investigated after the administration of 1 mg of atropine in two of the subjects, of 7 5 mg f phentolamine in two other subjects and finally after the injection of the composite dose (0 5—1 mg atropine plus 10 mg phentolamine) in another two ubjects. Observations of the cardiovascular response to isometric muscle contractions were also made after the iv administration of atropine 1 0 mg in three subjects, of phentolamine (5 mg) in

one subject and in three subjects once again after an iv dose containing both drugs (atropine 0.5—1.5 mg and phentolamine 5—10 mg) The circulatory effect of muscle contraction has in each individual been measured as the highest value attained within the same interval from the start of the muscle activation and at the same muscular force, whereby each individual serves as his own control.

Results

The increments of heart rate and aortic pressures evoked by isometric muscle contractions demonstrated the same rapid onset as in healthy individuals (see Fig 11) The individual mean values of the increments in heart

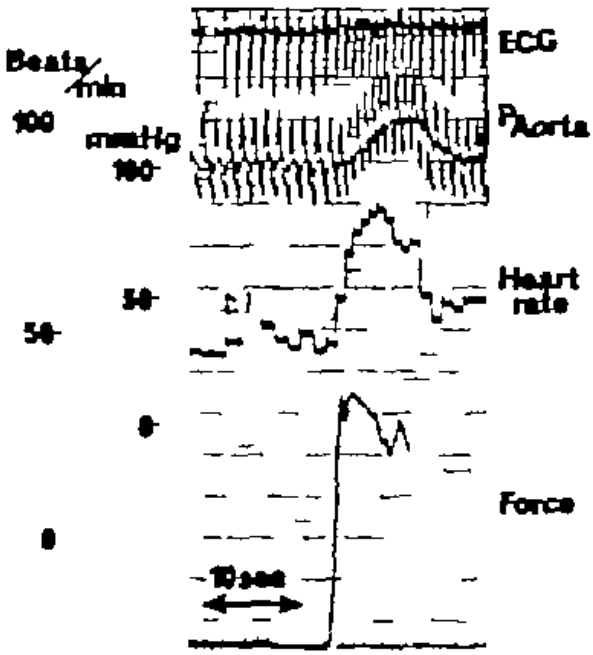

Fig. 11 Increments in heart rate, beats/min, and aortic pressures, mm Hg, initiated by an isometric muscle contraction at 90 % of MVC in a tetraplegic patient (subject 4)

rate and aortic pressures are summarized in Fig 12, where each thin arrow represents data obtained during 2—7 determinations at the same muscular force. More numerous observations of the heart rate blood pressure response were made within the same individual but at various per cent of MVC. The circulatory effect was a consistent finding The mean value of the heart rate increase among the tetraplegic men did not differ significantly from that among healthy individuals ($t = 0.2521$ degrees of freedom 22) Several data of the heart rate blood pressure response to muscle contraction, especially in subjects 4 and 6 had to be excluded due to the well-known phenomenon in patients with high spinal lesions associated with profuse sweating, a marked rise in blood pressure and bradycardia. The mean value of the heart rate increment of the group (see Fig 12) was 17 beats/min (SE ±3.8 range 8—23 beats/min $n = 4$) in supine position. The in

dividual mean heart rate at the initiation of muscle contraction was 63 beats/min. The rise in aortic pressures in supine position averaged 12 mm Hg (SE ± 2.3 range 7—18 mm Hg, n=4)

The circulatory effects of head up tilting (see Table 3) 30—60° above the horizontal plane revealed an incapacity to maintain an effective blood

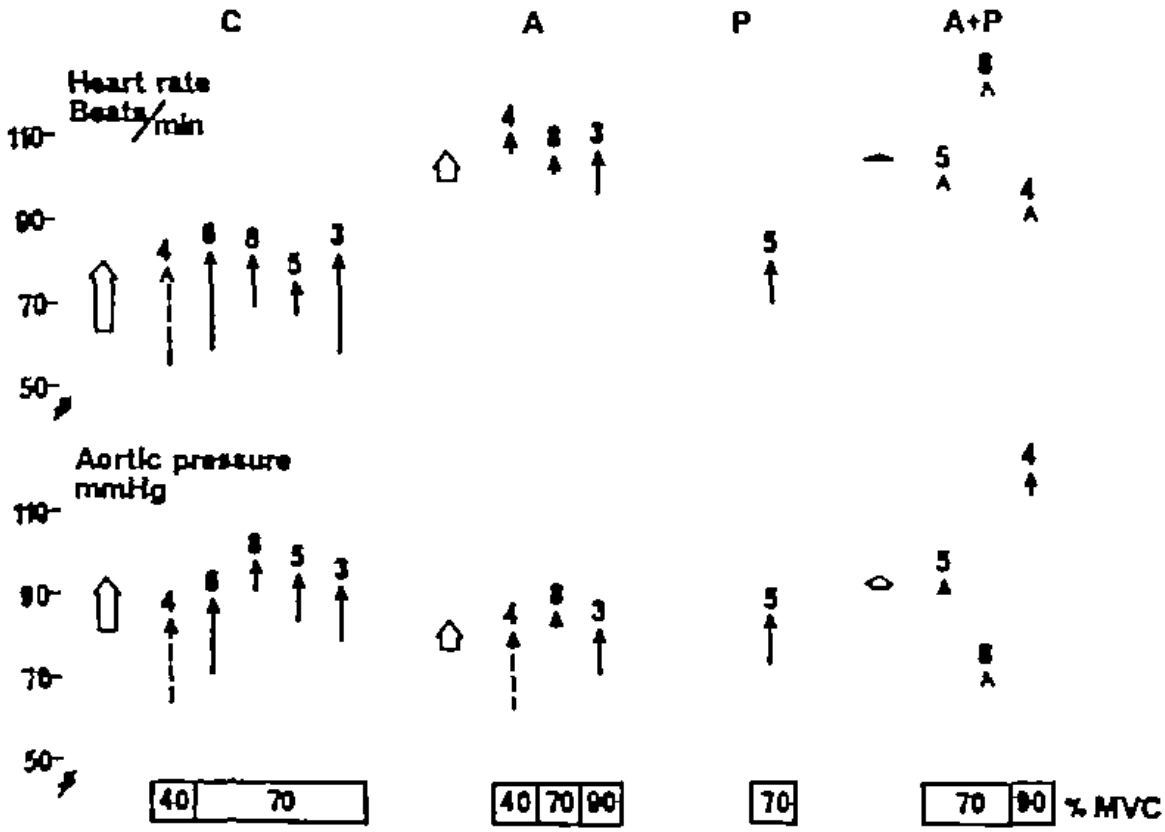

Fig 12 The increments in heart rate, beats/min, and in aortic mean pressure, mm Hg, evoked by isometric muscle contractions in supine position. Thin arrows represent individual mean values, while heavy arrows denote the mean values of the group. A broken arrow indicates that the observations were made during 60° head-up tilting The data were obtained prior to drug administration (C) after iv injections of atropine (A) or phentolamine (P) and of both drugs (A+P)

pressure. In one subject the tilting had to be interrupted due to a continuous decrease in aortic pressure In two other subjects a similar tendency was stopped by decreasing the angle of tilting

Under the influence of atropine or phentolamine a rapid decline in aortic pressure necessitated an interruption of the tilt test in five of six investigations.

The heart rate acceleration initiated by muscle contraction was inhibited (see Fig 12) or in some instances completely abolished after the iv injec

tion of atropine. The inhibition was more marked in tilted position (see Fig 13) and under the influence of both atropine and phentolamine (Figs 12 and 14)

Comments

There is no physiological evidence for a sympathetic nervous outflow from the cervical region of the spinal cord (Hillarp 1960) It might thus be

expected that patients with a transverse cord lesion at cervical levels should be deprived of centrally controlled sympathetic nervous discharges to the heart. The cardiac adjustment elicited in the vasomotor centers would consequently be mediated by changes of the vagal tone only. The maximal

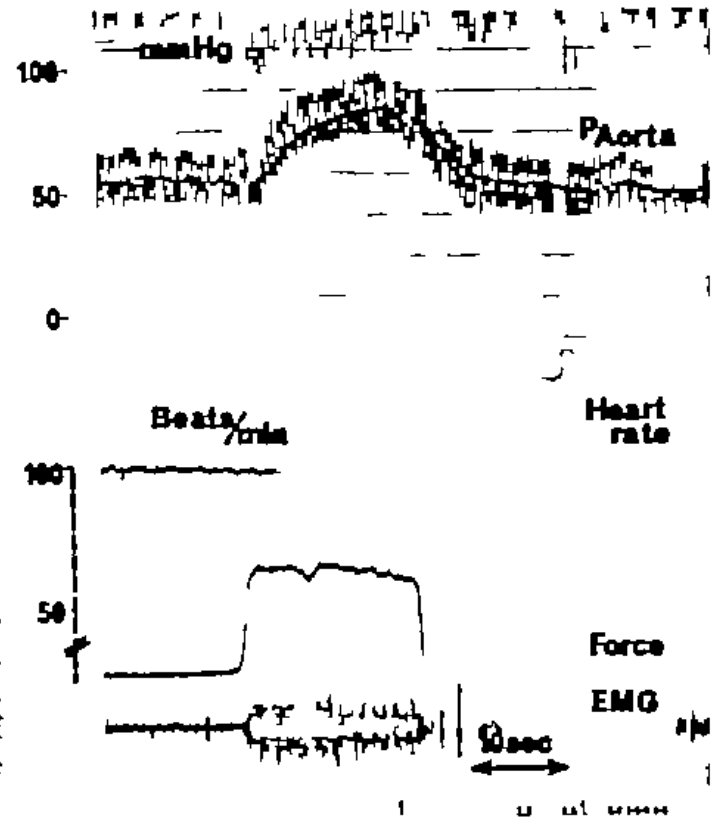

Fig. 13. Effect of 1 mg of atropine i. and of head-up tilting on the circulatory response to a muscle contraction at 40% of MVC, exerted during 20 sec. The same subject as in Fig. 11.

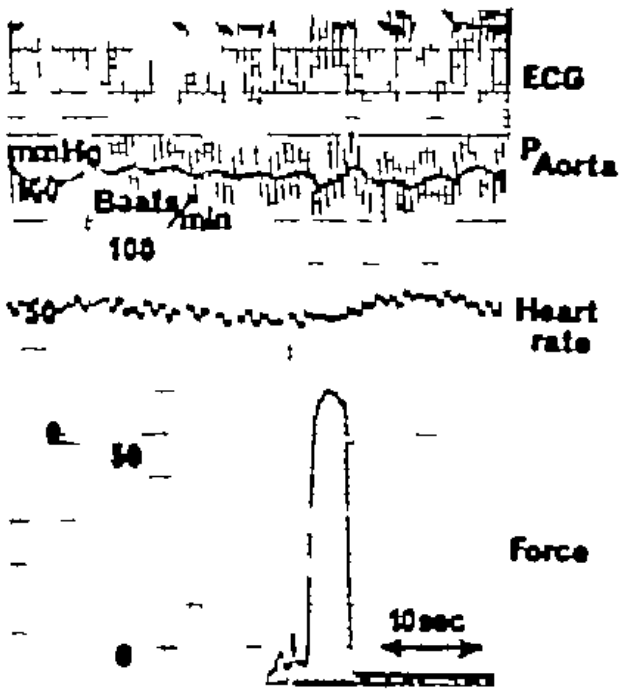

Fig. 14. Effect of a muscle contraction at 90 % of MVC after the administration of a combined dose of drugs (0.5 mg of atropine and 5 mg of phentolamine). The same subject as in Figs. 11 and 13.

heart rates confined to the range of vagal influence and the insufficient circulatory adaptation to postural changes are in accordance with the proposed mechanism

An inadequate blood pressure control during head-up tilt has been reported in earlier studies of patients with cervical spinal syndromes (*e g Guttman et al 1963 Gilliat et al. 1948 Cole et al. 1967*)

When vagal tone was diminished as after the administration of atropine or phentolamine, five of six subjects were unable to maintain the blood pressure in tilted position. This seems to indicate a loss of the integrative cardioaccelerating function of the efferent sympathetic nervous part of the baroreceptor reflex loop.

The magnitude of the heart rate response to isometric muscle contractions, mean 17 beats/min, was similar to the value (mean 18 beats/min) observed in healthy individuals. The highest value measured during a contraction under the influence of atropine in the present study 113 beats/min, was never attained by the healthy subjects prior to drug administration. As in healthy controls, atropine diminished or abolished the heart rate response to muscle contraction. When both atropine and phentolamine were given the heart rate during an isometric contraction was maximally 127 beats/min among the tetraplegics, while higher values were observed among the healthy volunteers in corresponding drug study (see Fig 7 Chapter IV)

The pathways mediating the pressor response to muscle contraction in tetraplegic men remain obscure and possible mechanisms will not be discussed here. It should only be noted briefly that the muscles activated during the contractions were innervated from segments of the spinal cord located both above and below the level of the functional discontinuity

The similar heart rate response to isometric muscle contractions observed both in healthy individuals, and in tetraplegic men with an apparent loss of the cardioaccelerator function mediated through the sympathetic nerves of the baroreceptor reflex loop indicates a common mechanism. The inhibited heart rate response under the influence of atropine in both materials supports the earlier (Chapter IV) proposed interpretation that the heart rate modulation during the initial part of a voluntary isometric muscle contraction is elicited by a withdrawal of vagal tone.

It might also be assumed that the high heart rates observed during contraction in healty individuals but not in tetraplegic men after the administration of the combined dose of drugs might indicate that, depending on the adjustment of the prevailing autonomic tone, a cardioacceleration due to muscle activation could also be initiated by a stimulation of beta adrenergic receptors.

CHAPTER VI

Cardiovascular Response to Intended Muscle Contraction during Neuromuscular Blockade

The origin of the nervous activity provoking the circulatory response at the onset of muscular work has been disputed. The basis for the main concepts of a "centrally" or peripherally" initiated neurogenic drive provoking the cardiovascular changes might be exemplified as follows.

The cardiovascular effects induced in animal experiments, whether behavioural or concerned with electrical stimulation of diencephalic structures in the fields of Forel (Rushmer and Smith 1959) have provided deductive evidence of a "centrally" initiated cardiovascular reaction in parallel to somatomotor activation

In human subjects the similarity of the circulatory adjustments to voluntional and electrically induced exercise (Asmussen *et al* 1943 b) has been taken to be the result of a neurogenic drive emanating from the periphery

In the present study an attempt was made to test whether the hypothesis of a centrally initiated autonomic drive might be valid in man. It was thought that the mechanism might be elucidated by observations of the cardiovascular response to intended muscle contractions within restricted paralyzed muscle groups. Hence stimulation due to mechanical and peripheral metabolic events could be eliminated.

Subjects

Six healthy male blood donors (24—29 years of age) volunteered for the study The right atrium was catheterized in three of the subjects.

Procedure

The procedures for catheterization are described under General Procedures and Methods. Methods of recording of the observed variables, *viz.* heart rate aortic and right atrial pressures and muscular force are presented in the same chapter

A local neuromuscular blockade in the forearm and hand was induced

by an intraarterial injection of a depolarizing agent, succinylcholine (Celocurin klorid®) via a catheter in the brachial artery. The tip of the catheter was localized ca. 10 cm above the elbow. Successively increasing doses (0.5 to 4 mg) were given until an apparently total neuromuscular blockade was obtained. For indication of the degree of blockade as well as the time of its onset and the time when it starts to disappear the muscle action potentials of the M. flexor carpi ulnaris in response to electrical stimulation of the ulnar nerve were recorded. The stimulation was made with felt skin electrodes placed over the nerve at the elbow. A Grass stimulator (type S 8) delivered the electrical stimuli which were square wave impulses of 0.1 sec duration at a frequency of 1 imp/sec and of just supramaximal strength. The muscle action potentials were recorded with two skin electrodes (Beckman) placed over the distal end of M. flexor carpi ulnaris and the signals were fed to a differential a.c. amplifier (Grass type P 9). The amplification was chosen so that even a minimal activity during the neuromuscular blockade would be detected. The action potentials were monitored on an oscilloscope (type 502 Tektronix Inc.) for direct observations of alternations in the response thus facilitating timing of the intended contractions to periods of blockade. The signals were also fed to the UV writer used for concomitant recordings of the cardiovascular variables, but were then passed through a high-frequency filter to avoid recording of a capacitive stimulus artefact that could not be differentiated from the myopotentials at the time scale used.

The criteria of neuromuscular blockade were as follows:

no discernible muscular movement or muscle action potentials in response to electrical stimulation of N. ulnaris,

no discernable muscle activation or EMG activity in response to intended handgrip.

Control data of the cardiovascular response to voluntary isometric handgrips were obtained according to the description in Chapter II. During neuromuscular blockade the subjects were told to act volitionally within the periods of intended contraction as during the previously performed handgrips. In order to reduce extraneous stimuli, the surroundings were kept quiet and the subjects were always informed by a visual signal of the start and duration of the performed or intended contraction. Indications of lighting and extinction of the visual signal were made by a test signal in the dynamometer record. These signals thus denote the duration of the intended handgrip with a slight fault due to the response time of the individuals.

Activation of muscles proximal to the blockade cannot be totally excluded, but EMG records from various positions over the shoulder revealed no

activity and inspections and palpations were made to check that other parts of the body were relaxed.

The effect on heart rate and aortic mean pressure has in each individual been measured as the highest value attained within 7 sec from the start of an isometric handgrip performed at 70 % of MVC and within the same time interval from the start of an intended handgrip in the same, paralyzed arm.

Results

Effect of succinylcholine at rest In some of the subjects the injection of the drug induced a short-lasting feeling of increased pressure in the vessel causing discomfort or pain during the subsequent 5—15 seconds. In two of the subjects the effect was reproduced with every injection of succinylcholine

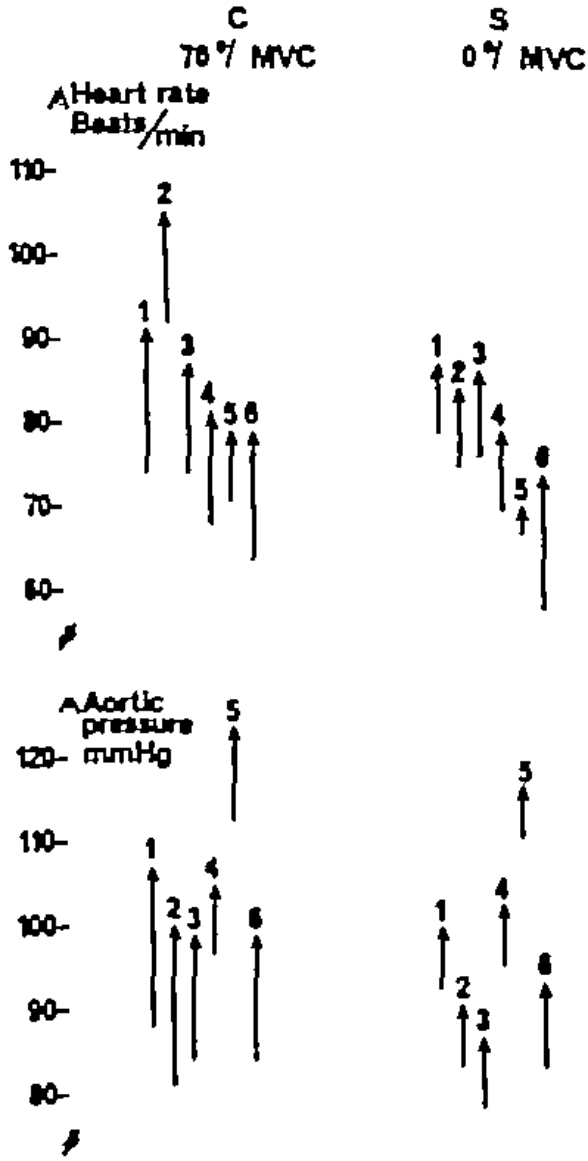

Fig 15 Individual mean values of the increments in heart rate, beats/min, and in aortic mean pressure, mm Hg initiated by performed (C, at 70 % of MVC) and intended (S) muscle contractions.

in the others it was not a consistent finding When pain was induced a short-lasting increase in heart rate and aortic pressures was recorded otherwise no circulatory changes were initiated by the drug administration.

With the initial test dose, 0.5 mg complete neuromuscular blockade was usually not obtained. With higher doses, 1—4 mg of succinylcholine, criteria of blocked neuromuscular transmission were fulfilled within 5 sec from the start of the injection. Muscle fasciculation was never observed during the onset of the blockade. The duration of the depolarization block was dependent on the amount of drug given, but interindividual variations were noted. In general, single doses of 1—4 mg of the drug induced a neuromuscular blockade during 1—4 min. The rapid restoration of motor function relieved the volunteer from anxiety about the unfamiliar situation of paralysis.

No symptoms or signs appeared of drug influence on other muscle groups than those perfused by the arterial blood distally to the catheter tip

Cardiovascular response to intended muscle contraction Individual mean values of the increments in heart rate and aortic mean pressure during performed and intended isometric handgrips are summarized in Fig. 15 and represent data obtained during 3 to 19 determinations in each subject.

The mean heart rate increase of the group (n=6) during performed handgrip was 14 beats/min (SE ±1 8 range 8—21 beats/min) The SE observed within the individuals varied from ±0 7 to ±1 7 beats/min. The mean value for the rise in aortic mean pressure was 15 mm Hg (SE ±1 8, range 8—19 mm Hg) and corresponding intraindividual values of SE varied from ±0 8 to ±3 8 mm Hg

Intended handgrips in the muscle groups with a blocked neuromuscular transmission elicited increments in heart rate and aortic mean pressure which averaged 9 beats/min (SE ±1 6 range 4—16 beats/min) and 8 mm Hg (SE ±0 6 range 6—10 mm Hg) among the individuals (n=6) The SE range of the intraindividual mean values for the heart rate increment was ±0.3 to ±1 0 beats/mm and corresponding values for the aortic pressure rise varied from ±0 6 to ±1 7 mm Hg

The heart rate increase initiated by intended handgrips among the individuals (n=6) was on the average 64 per cent (range 47—76 %) of the value observed during performed muscle contractions. The corresponding mean value of the aortic pressure rise was 55 per cent (range 37—75 %) of control data.

The cardiovascular response to performed and intended muscle contractions is illustrated in Figs 16 and 17 During the isometric handgrip in

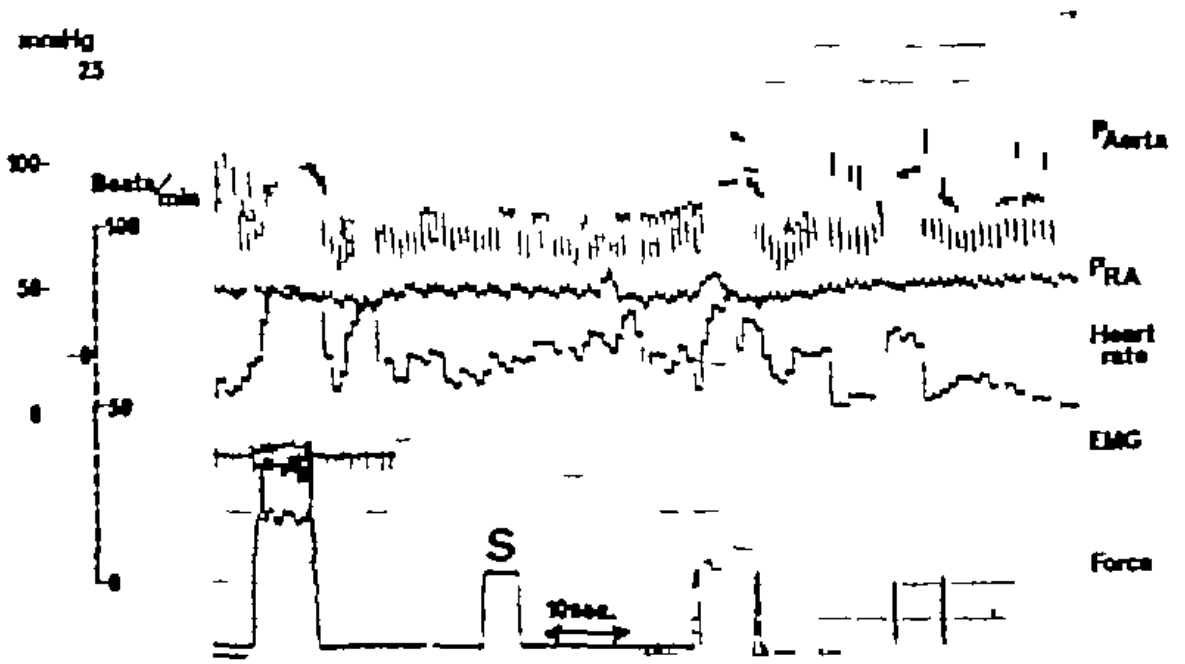

Fig. 16. The cardiovascular effects in subject no. 6 of an isometric muscle contraction at 0 ° of MVC and of intended muscle contractions after an i.a. administration of 2 mg succinylcholine (denoted by S). Periods for intended muscle contractions are indicated by test signals on the force record. The EMG demonstrates myopotentials evoked both by volitional muscle activity and by electrical stimulation (1 imp/sec) of the ulnar nerve. P_{RA} = right atrial mean pressure. Further information is given in the text.

Fig. 16 the heart rate increased from 64 to 84 beats/min, the aortic mean pressure rose from 83 to 101 mm Hg while the right atrial pressure remained unchanged, 7 mm Hg. A subsequent intraarterial injection of 2 mg of succinylcholine denoted by S induced a short-lasting pain and a heart rate acceleration during the subsequent 20 sec up to maximally 76 beats/min. The contractions of the hand and fingers induced by the ulnar nerve stimulation were abolished within a few seconds. During the two subsequent visually ordered contractions with start and end denoted by the test signals the heart rate increased by 20 and 15 beats/min, respectively and aortic mean pressures by 11 and 17 mm Hg respectively. In the account of the experiment the technician had noted a delay of the second "on-signal". During the first intended contraction the right atrial pressure rose by 1.6 mm Hg probably due to a slight Valsalva manoeuvre. During the second intended contraction the right atrial pressure was unchanged and the amplitude of the aortic pressure elevation was greater. Fig. 17 illustrates the cardiovascular response in the same subject to a performed handgrip with increases in heart rate from 68 to 87 beats/min and in aortic mean pressure from 82 to 107 mm Hg and the effect of a second intraarterial injection of 2 mg succinylcholine. Within the subsequent periods of intended contrac

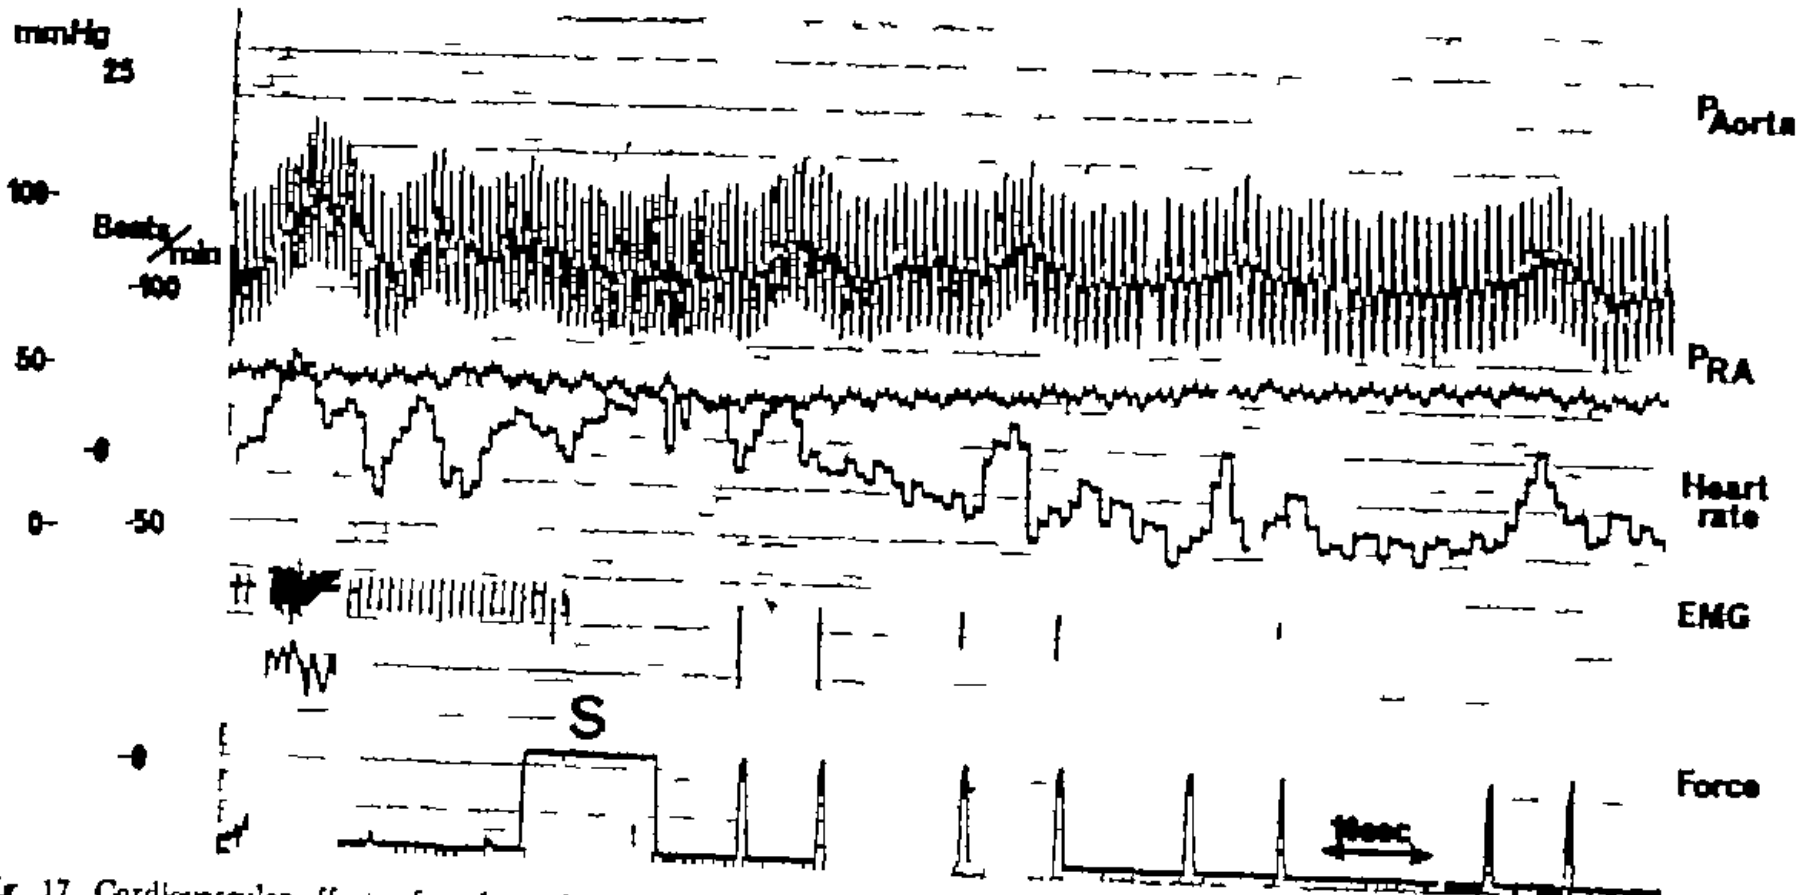

Fig. 17 Cardiovascular effects of perf rmed and intended muscle contractions during neuromuscular blockade. Symbols and subject as in Fig 16.

tions, consistent increments in heart rate and aortic mean pressures appear The aortic pressure elevation within the third intended contraction, 6 mm Hg, was the lowest value observed in the investigation of that volunteer (subject no 6)

Fig 18 illustrates the effects on heart rate and aortic mean pressure at the initiation of handgrips in the period of successive restitution of the neuromuscular transmission. In the same individual (no. 6) similar changes in heart rate and blood pressure were observed during total neuromuscular blockade and no correlation could be obtained between the circulatory variables and the exerted muscular force.

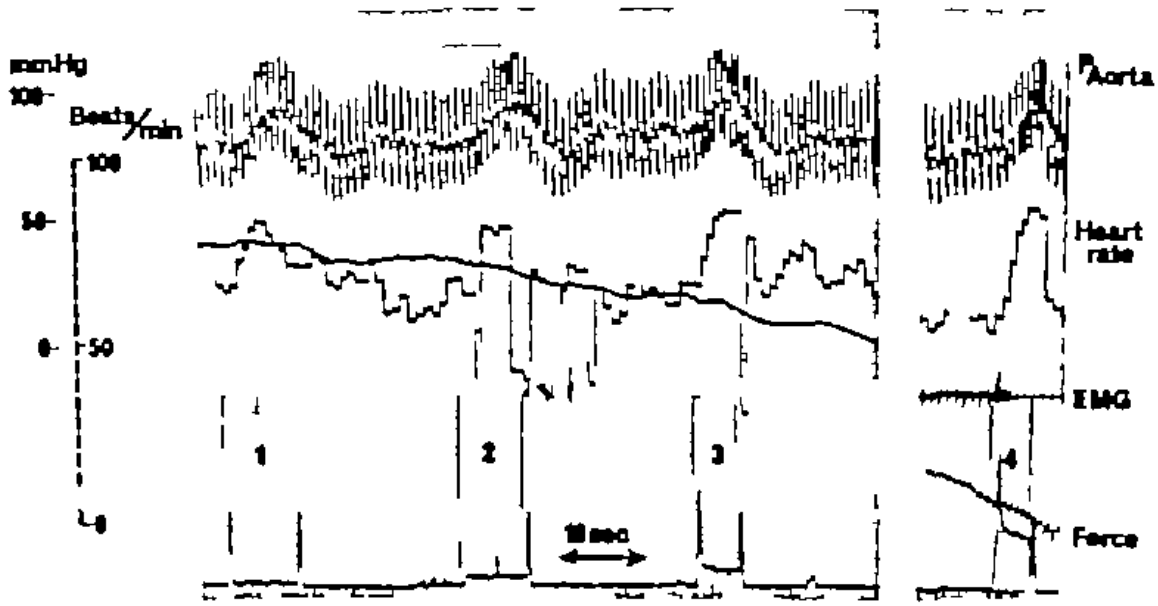

Fig 18 Effects on heart rate and aortic pressures of muscle contractions in the phase of successive restitution of the neuromuscular transmission (after blockade) The eighth trial record is disturbed by a technical fault. During the contractions (nos. 1—4) the last force exerted was ca. 2 %, 5 %, 10 % and 30 % of MVC, respectively Symbols and subjects as in Figs. 16 and 17

When the same subject performed isometric handgrips at similar or higher per cent of MVC, when not under the influence of succinylcholine, the observed circulatory effects were definitely less marked (see Fig 19) This finding was pertinent to all subjects.

Comments

Observations of the heart rate—aortic pressure response to intended contractions in muscle groups with a complete depolarization block have not been found in the literature Earlier investigations (Ochwadt *et al* 1959

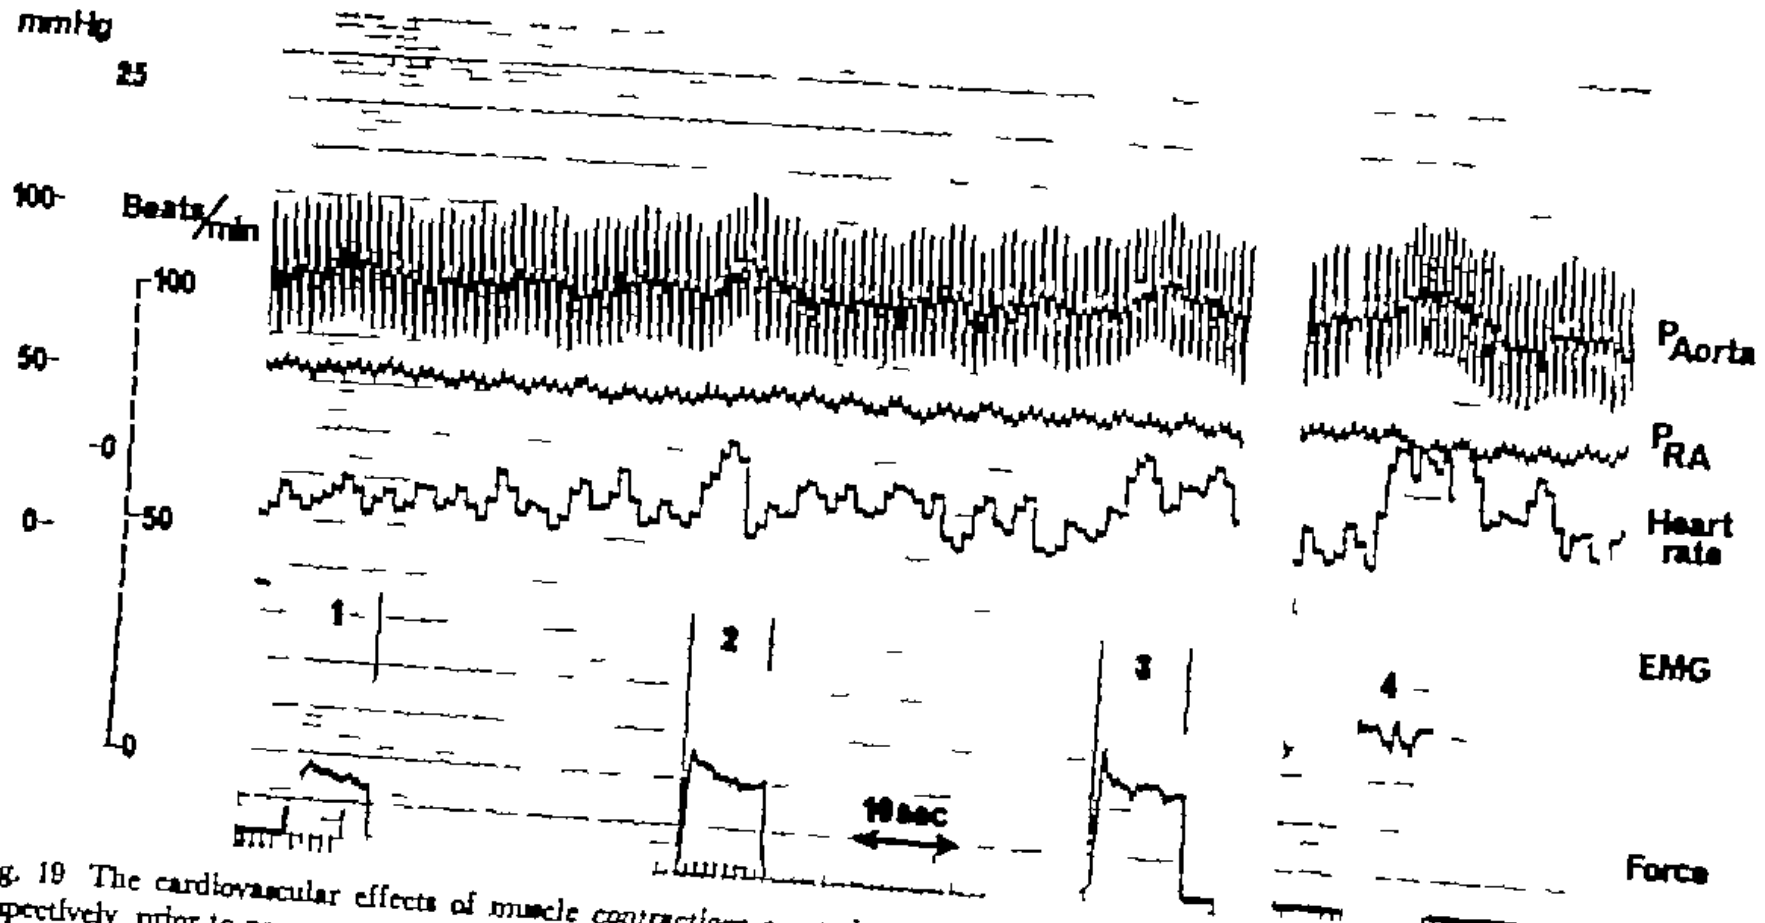

Fig. 19 The cardiovascular effects of muscle contractions exerted at (nos. 1 to 4) 25 % 35 %, 40 % and 70 % of MVC, respectively prior to neuromuscular blockade. Symbols and subjects as in Figs 16—18. EMG record is shut off.

Asmussen *et al* 1963 and 1965) have been concerned with respiratory and circulatory effects of exercise performed after iv injections of (+) tubocurarine, a non-depolarizing neuromuscular blocking agent. Owing to the route of administration the neuromuscular transmission within the dynamically working leg muscles could only be partially blocked, and effects on other muscle groups were noted. Finally the induced hyperventilation could not provide basal conditions at the observations of the circulatory changes evoked by muscle exercise in the state of partial curarization. Thus the cited data do not allow comparisons with the present results.

In the actual experiments, possible extraneous cardiovascular stimuli, occurring simultaneously with the intended muscle activation were scrutinized. From experience it was learnt that two kinds of artefacts might appear *viz* breathholding with a more or less marked tendency to a Valsalva manœuvre and activation of muscles proximal to the paralyzed limb segment. Inspections were therefore made to check that breathing was unrestricted, which was confirmed by records of the right atrial pressure. EMG s from various muscles of the shoulder revealed no appreciable activity although irrelevant muscle activation could never be totally excluded. However in order to provoke circulatory effects of the magnitude observed during the depolarization block, the exerted muscular force must attain so high a fraction of MVC (see Fig 19) that such activity cannot possibly remain undetected. This will further be elucidated by the investigation presented in Chapter VII

Thus the cardiovascular effects on intended muscle contraction indicate that the increments of heart rate and blood pressure at the initiation of somatomotor activity are elicited by an autonomic nervous drive of central origin.

The lower amplitude of the cardiovascular response to intended muscle contraction might be the result of a less marked central excitatory drive. Alternatively provided this drive was of the same intensity as in the control study the lower values attained during an intended handgrip would indicate that peripheral feedback mechanisms operate within 7 sec from the start of a developed contraction Comparisons of heart rate increments from rest to voluntary muscular exercise and from rest to passive movements of the same amplitude and speed have been made The results have indicated that a proprioceptive stimulus accounts for a part of the cardiac acceleration Dejours *et al* 1956)

CHAPTER VII

The Relationship between Cardiovascular Response and Extent of Muscle Activation

The present study was undertaken to evaluate whether the size of the activated muscle groups might influence the heart rate and the aortic pressure response to muscle contraction. Further the cardiovascular effects of contraction intensities within a wide range of exerted relative force will be discussed.

Subjects

Ten of the male blood donors, 24—29 years of age, participated in the investigation.

Procedure

Details of the catheterization and recording of the observed variables, *viz.* heart rate, aortic pressure and muscle force are given in Chapter II Six of the subjects performed isometric contractions in the form of handgrips and elbow flexions at the same per cent of MVC and according to descriptions in Chapters II and III In four of the subjects isometric handgrips were performed at 70 per cent of the maximal force observed for the right hand as described in the same chapters. In randomized order isometric handgrips were exerted with the left hand, the right hand and both. When handgrip was performed simultaneously with both hands, the left hand contracted over a rod of the same diameter as the dynamometer The subjects were told to exert the muscle force indicated (on the oscilloscope) and to contract both hands at similar intensities.

Results

Paired comparisons of the individual increases in heart rate and aortic mean pressure revealed no differences in the circulatory response to any of the three types of handgrip The differences calculated from paired comparisons of the individual mean increments of heart rate and aortic mean pressure were likewise non-significant (see Table 4) As commented

TABLE 4 Difference ($\bar{d}$) in the heart rate increase (Δ HR) beats/min, and the aortic mean pressure rise (ΔP_{Ao}) mm Hg, elicited on a muscle contraction performed with right hand (R) left hand (L) or with both (B) Degrees of freedom (df) and t-test values (t) are given. P values are for paired comparisons between individual means. (ns = not significant)

	R — L		R — B		L — B	
	ΔHR	ΔP_{Ao}	ΔHR	ΔP_{Ao}	ΔHR	ΔP_{Ao}
$\bar{d}$	1.5	3.8	0.5	1.8	—1.0	—2.0
df	3	3	3	3	3	3
t	0.5508	2.7699	0.3216	0.8197	—0.3572	—1.4771
P	ns	ns	ns	ns	ns	ns

on in Chapter III the individual circulatory responses to isometric hand grips and to elbow flexions were similar The mean differences ($\bar{d}$) between the increments in heart rate and blood pressure observed during elbow flexion and the values observed during handgrip were $\bar{d}$ -0 7 beats/min t = -0 4822 df = 4 and $\bar{d}$ 1 2 mm Hg, t = 1 2335 df = 4 respectively

As demonstrated in Fig 19 Chapter VI and in accordance with the observations in other subjects during the procedure for selecting a suitable per cent of MVC, the circulatory response to muscle contractions less than one fourth of the value observed during maximal contraction was non-significant. According to Fig 19 there seems to be a rough direct correlation between the exerted relative muscle force and the circulatory effects. However in the study of Chapter III no correlation could be obtained between the increments in heart rate and aortic pressure and the fractions of maximal force of contraction from 50 to 100 per cent of MVC. Thus a relation between the force of contraction and the initial cardiovascular effect seems to be discernible only within ranges of 25 and 70 per cent of MVC It has been beyond the scope of the investigation to make a more thorough analysis of any quantitative relationship

Comments

The lack of additive effect on the circulatory response when one or two muscle groups contracted at the same relative tension is in keeping with the findings of Lind and McNicol (1967) They observed similar increments in heart rate and blood pressure when two or more muscle groups contracted separately or together Yet the latter data were obtained during contractions sustained for 1 to 3 minutes.

No correlation could be obtained between the magnitude of the heart

rate — blood pressure response and the degree of somatomotor activity expressed as relative muscle force developed within the range of 50—100 per cent of MVC. Similar results concerning the pressor response within the first 10—15 sec of contractions at varying intensities were observed by Humphreys and Lind (1963) The circulatory response to rather small fractions of MVC (see Fig 19) was of lower magnitude than the circulatory effects evoked by even lower total developed strength of contraction (intended to be higher) in the period immediately following total neuromuscular blockade (see Fig 18) This is in accordance with the assumption that the evoked cardiovascular effects are related to the degree of intended muscle activation rather than to the total muscular activity developed.

Thus the initial circulatory effects of isometric contractions are not determined by the size of the activated muscle groups considered. The circulatory response seems to be related to the intensity of voluntary motor innervation.

taps, the foot being kept in position by the tension recording device and thus involuntary tension changes in the Achilles tendon were also recorded for control purposes (Knutsson and Mattsson 1970) The elicited muscle contractions were recorded by this device, i e a rigidly mounted strain gauge transducer displaying the pressure exerted by the sole of the foot during the plantar flexion. The strain gauge constituted one arm of a bridge at the input of a chopper amplifier The amplitude of the contrac tions was recorded on a Grass Polygraph ink writer with a linear fre quency response at frequencies below 100 Hz. In the female subject the contractions were simultaneously recorded on the UV writer

Recordings of the muscle action potentials over M triceps surae were made with Ag AgCl surface electrodes (Beckman) After amplification the potentials were displayed on an oscilloscope screen (type 502, Tektronix Inc) and photographed. In the female subject (see Figs 20 and 21)

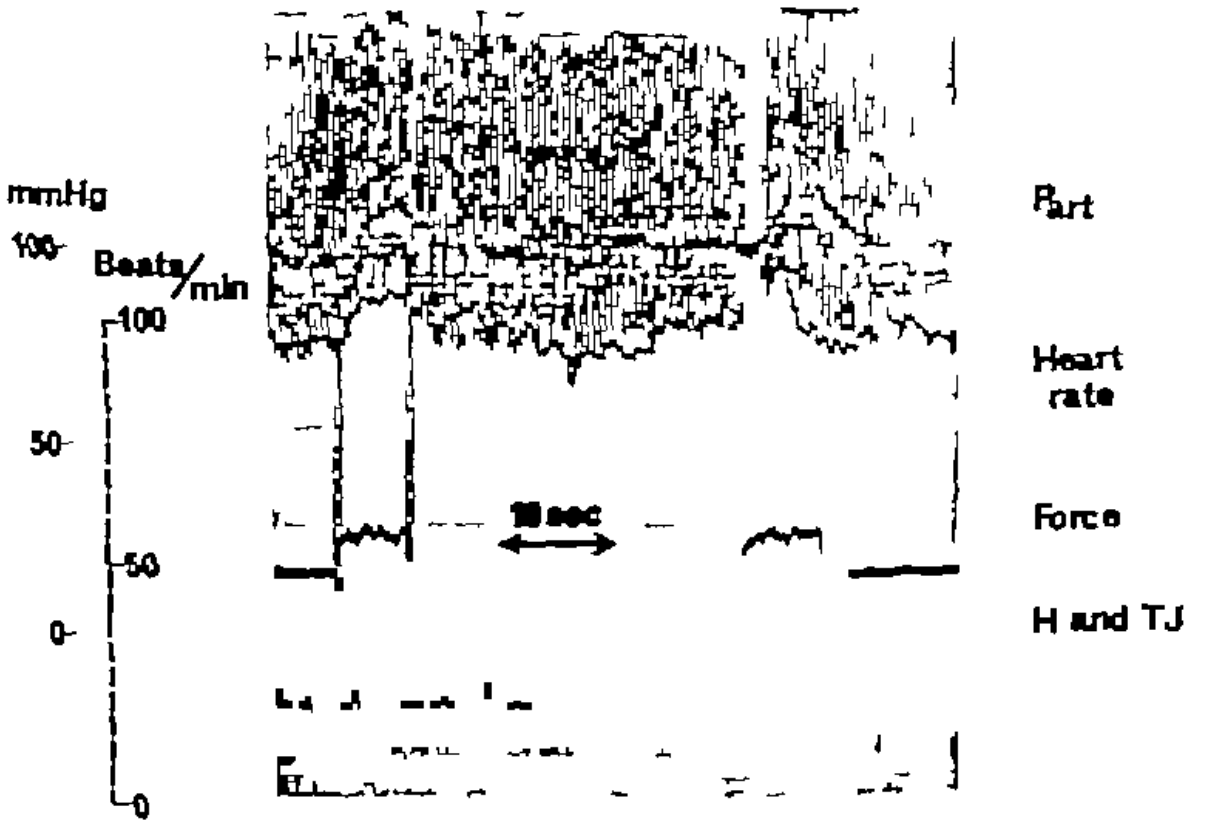

Fig. 20. Subject M. B.. Effects on heart rate, arterial pressures (P_{art}) and on triceps surae tendon jerk (H and TJ) of isometric handgrips performed at 70 per cent of MVC. In the record of H and TJ each deflection gives th amplitude of the force exerted during a plantar flexion. Triceps surae jerks were elicited by alternate tendon (TJ) taps (the smaller deflections) and electrical (H) stimulation (the bigger deflections) of the posterior tibial nerve. In the EMG records from M.carpi ulnaris and M.triceps sura electrical stimuli artef cts were packed p fo the sake of clearness the simultaneous tracings were omitted in Figs 20 and 21

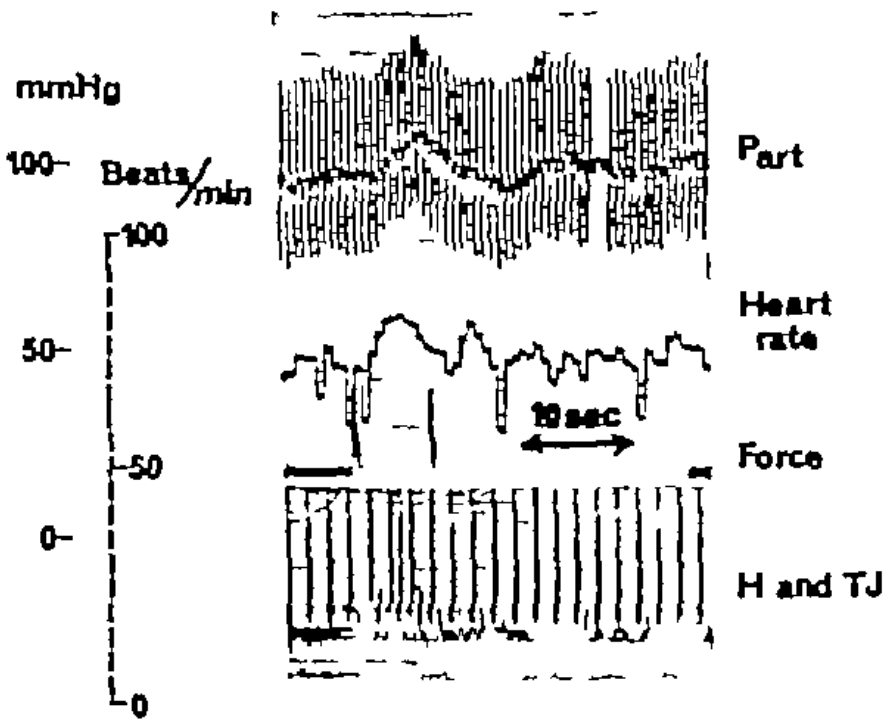
H reflexes, *i e* monosynaptic reflex responses elicited by stimulation of Group I afferent fibres proximal to the muscle spindles, were elicited by electrical stimulation of the posterior tibial nerve, but the results will not be discussed in the present investigation.

Due to technical faults, arterial pressure and heart rate could be recorded in only two of the subjects.

Results

Isometric handgrips at 70 per cent of MVC initiated increases in heart rate of 12 (SE ±1 8 n = 10) beats/min in subject M B. and 23 (SE ±2.3 n=5) beats/min in subject J R. Corresponding values for the rise in arterial mean pressure were 13 (SE ±0 8 n=10) mm Hg and 19 (SE ±2.4 n=5) mm Hg respectively During handgrip all subjects demonstrated the well-known reinforcement of the tendon jerk associated with a Jendrassik's manœuvre (see Figs 20 22a and 23a)

Intended handgrips in the muscles with total neuromuscular blockade initiated increments in heart rate of 16 (SE ±2 0 n = 9) beats/min in subject M B and 11 (SE ±1 8 n=3) beats/min in subject J R. Arterial mean pressure rose by 10 (SE ±1 7 n=7) mm Hg and 9 (SE ±1 2 n=3) mm Hg, respectively



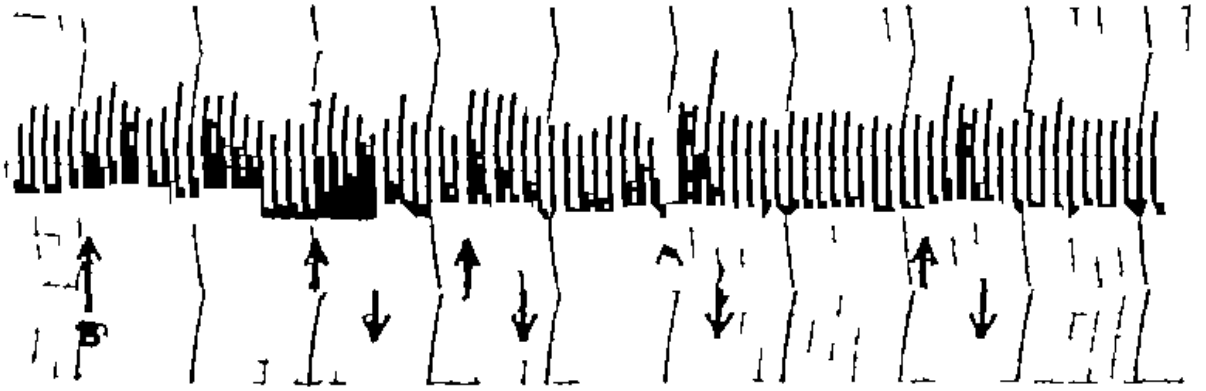


Fig. 21 Effect on heart rate arterial pressures and on triceps sura jerk of intended handgrip during neuromuscular blockade Symbols and subjects are the same as in Fig 20.

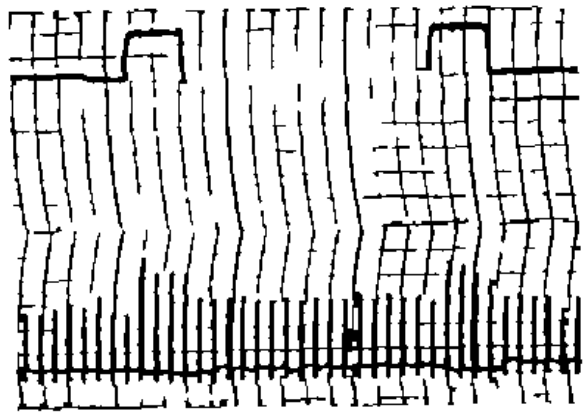
Fig. 22. a) Effects of isometric handgrips at 70 per cent of MVC (within the arrows) on triceps surae jerks elicited by alternate tendon taps (the smaller deflections) and electrical stimulation (the bigger deflections) of the posterior tibial nerve. Each square = 3 sec. Same subject as in Figs 20 and 21

b) Effects of succinylcholine (S) and intended handgrips (within the arrows) during neuromuscular blockade. Same recording procedure and subject as in a)

At the time of and during the subsequent ca. 20 sec after the injection of succinylcholine a consistent finding was an enhancement of the tendon jerks. Similar changes were observed during instruction of or other communications with the subjects. However prior to the first intended contraction during blockade, the reinforcement of the reflex response had been deleted (see Figs 22 b and 23b)

During intended handgrips in the periods of neuromuscular blockade the tendon jerks were augmented in all subjects. This finding pertained both to the electromyographically recorded responses (see Fig 24) and to the recorded plantar flexions (see Figs 21 22b and 23b) elicited by the tendon taps. In Fig 23b the mean maximal force of plantar flexion increased by ca. 45 and 30 per cent when compared with an equal number of tendon jerks preceding the intended contraction. In Fig 23a the same subject demonstrated a corresponding increase of 55 and 37 per cent, respectively



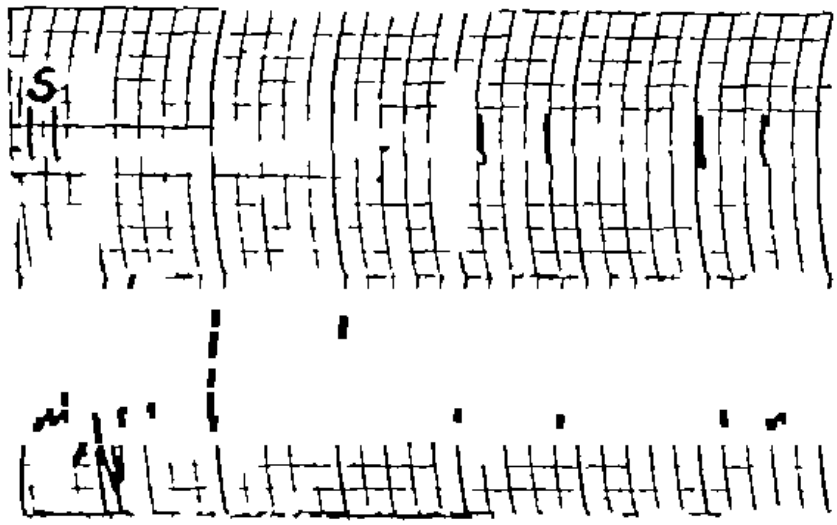


Fig. 23. a) The effect of isometric handgrip (upper record) at 70 per cent of MVC on the force of plantar reflexion (lower record) elicited by Achilles tendon tap in subject J. R. Each square = 3 sec.

b) Effects of succinylcholine (S) and intended handgrips (upper record) during neuromuscular blockad on the force of plantar reflexion (lower record) elicited by tendon tap. Recording and subject as in a)

Comments

The increments in heart rate and arterial mean pressure both on performed and intended muscle contraction during blockade were similar to those observed in Chapters III and VI where blood pressure was measured in the aorta.

It has been reported that the augmentation of the quadriceps jerk is lost if the Jendrassik's manoeuvre is continued for more than 1 sec (Clarke 1967) but others (Buller and Dornhorst 1957) have found that reinforcement has persisted at least up to 6 sec. The present data are in accordance with the latter results.

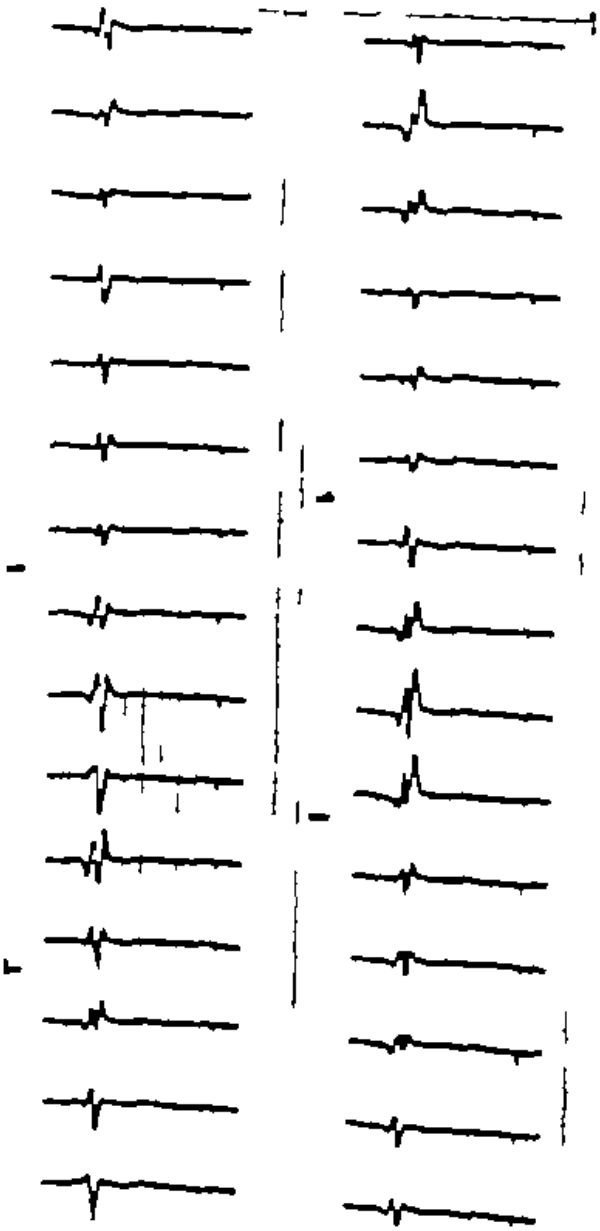

Fig. 24. Muscle action potentials of M.triceps surae elicited by tendon taps. The tracings within brackets were obtained during the same periods of intended handgrips as illustrated in Fig 23.b)

The enhancing effect on the tendon jerk during performed or intended handgrips cannot be quantified, since at the stimulation frequency used a slight high-frequency depression (Magladery *et al* 1952) of the tendon jerk might be present. Due to the short lasting periods of the neuromuscular blockade and also to the short-lasting duration of intended handgrips it would have been inconvenient to use stimulations at lower frequencies.

Granit and Kaada (1952) demonstrated that gamma efferent activity (to the muscle spindles) was facilitated by reticular stimulation at strengths considerably below those which would elicit a discharge of the large skeletal-muscle (alpha) motoneurons. It might be hypothesized that the reinforcement of a spinal reflex on intended somatomotor activity is an analo-

gous phenomenon.

A non-hypothalamic route for influencing somatomotor and autonomic function was defined by Rossi and Brodal (1956) They found corticofugal fibres passing from cortex to the reticular formation of the pons and medulla, with the motor area as the chief contributor Thus the mechanism proposed by Landau (1953) concerning the facilitation of activity patterns, which are essentially determined at spinal and peripheral levels, might be substantiated.

However the purpose of the presentation was merely to demonstrate the parallel appearance of a cardiovascular response and an enhancement of a spinal reflex on intended somatomotor activity

CHAPTER IX

General Discussion

The present study was incited by observations on the central and peripheral circulatory adjustment to exercise with small and large muscle groups. A further analysis demanded a differentiation of the regulatory factors involved and prompted a simplified model of work. Therefore muscular exercise was substituted for a single, isometric muscle contraction and studies of steady state circulatory conditions were replaced by continuous observations during the first 3 to 8 sec of the initial cardiovascular response on muscle activation. In the selected period a modulation of the circulatory effects to mechanical and peripheral metabolic factors would be less marked.

In Chapters IV and V it was demonstrated that the heart rate acceleration at the onset of muscle contraction was predominantly elicited by a withdrawal of vagal tone, but depending on the prevailing autonomic balance a stimulation of beta-adrenergic receptors might also contribute. The mediation of the heart rate acceleration through a decrease of parasympathetic activity at the onset of muscular work has been anticipated in studies demonstrating that, in the presence of a beta-adrenergic blockade, rapid and marked increments in heart rate occurred during isometric handgrips (Macdonald *et al* 1966) or treadmill exercise (Smulyan and Eich 1968)

The effects on heart rate during supine leg exercise of either atropine, propranolol or both drugs were studied in human subjects by Robinson *et al* (1966) They observed that the heart rate increase during mild exercise (oxygen uptake $\leq$ 500 ml/min) was primarily associated with a decrease in parasympathetic activity while at higher working intensities sympathetic stimulation also contributed to cardiac acceleration.

The aortic pressure response to muscle activation, demonstrated in Chapters III and IV was ascribed both to the heart rate acceleration and to an effect on systemic vascular resistance mediated by alpha-adrenergic receptors. In addition, an increase of venomotor tone was initiated on muscle contraction. All three circulatory effects contribute to an enhanced perfusion of activated muscle groups.

In Chapter VI cardiovascular effects were revealed during intended contractions within restricted paralyzed muscle groups. An accompanying facilitation of spinal reflexes was demonstrated in Chapter VIII Thus the conditions may exist for a central nervous excitatory drive evoking the observed cardiovascular effects and the facilitation of somatomotor activity as proposed by Landau (1953) The influence on somatomotor and autonomic function might be exerted both via a non-hypothalamic (Landau 1953 Rosa and Brodal 1956) and a hypothalamic route.

The relation between the cardiovascular response and the baroreceptor mechanism might be considered as follows

Is a counterregulation via the baroreceptors elicited by the cardiovascular response to somatomotor activity or is a simultaneous centrifugal inhibition of the baroreceptor function induced?

The tetraplegic men (Chapter V) were deprived of the integrative cardioaccelerating function of the efferent sympathetic nervous part of the baroreceptor reflex loop Still, the heart rate response to muscle activation was the same as that in healthy subjects. This indicates that normally the baroreceptor function is superseded during muscle contraction. This is furthermore confirmed by the highly significant direct relation found between the increments in blood pressure and heart rate (see Chapter III) An interference between the studied mechanism and the baroreceptor function would have resulted in an inverted relation between the two circulatory variables.

In keeping with such a mechanism are studies reporting that the baroreceptor reflexes are suppressed during isometric work (Lind *et al* 1964) and that hypothalamic stimulation (Hilton 1963) and corticohypothalamic impulse discharges to medullary neurons (Follow *et al.* 1965) can supersede the mechanoreceptor reflexes.

Further it has recently been demonstrated (Gebber and Snyder 1970) that the tachycardia associated with the pressor effect evoked by electrical hypothalamic stimulation was the result not only of increased cardiac sympathetic activity (Pitts *et al* 1941) but also of inhibition of baroreceptor induced vagal activation Assuming a similar mechanism in intact man, the rapid changes in heart rate would correspond to the time course of a discontinued vagal stimulation (Warner and Cox 1962)

Thus from the presented arguments and from the absence of a counterregulation via the baroreceptors it might be assumed that the cardiovascular response to muscle activation is the result of a simultaneous somatomotor and autonomic nervous activity and an inhibition of the baroreceptor reflexes.

It might be expected that the cardiovascular adjustments during dynamic muscular exercise from its start up to a steady state level would appear far more complex. From an unpublished investigation made by the author of the cardiovascular effects of rhythmically repeated isometric handgrips at a frequency from 6 to 40 c/min a summation of the cardiovascular responses to single muscle contractions is discerned. Consequently it seems possible through extended studies to evaluate the effect of the described pattern of reaction on the circulatory adjustment to dynamic muscular exercise.

In Chapter VI cardiovascular effects were revealed during intended contractions within restricted paralyzed muscle groups. An accompanying facilitation of spinal reflexes was demonstrated in Chapter VIII. Thus the conditions may exist for a central nervous excitatory drive evoking the observed cardiovascular effects and the facilitation of somatomotor activity as proposed by Landau (1953). The influence on somatomotor and autonomic function might be exerted both via a non-hypothalamic (Landau 1953, Rossi and Brodal 1956) and a hypothalamic route.

The relation between the cardiovascular response and the baroreceptor mechanism might be considered as follows:

Is a counterregulation via the baroreceptors elicited by the cardiovascular response to somatomotor activity, or is a simultaneous centrifugal inhibition of the baroreceptor function induced?

The tetraplegic men (Chapter V) were deprived of the integrative cardioaccelerating function of the efferent sympathetic nervous part of the baroreceptor reflex loop. Still the heart rate response to muscle activation was the same as that in healthy subjects. This indicates that normally the baroreceptor function is superseded during muscle contraction. This is furthermore confirmed by the highly significant direct relation found between the increments in blood pressure and heart rate (see Chapter III). An interference between the studied mechanism and the baroreceptor function would have resulted in an inverted relation between the two circulatory variables.

In keeping with such a mechanism are studies reporting that the baroreceptor reflexes are suppressed during isometric work (Lind *et al* 1964) and that hypothalamic stimulation (Hilton 1963) and corticohypothalamic impulse discharges to medullary neurons (Folkow *et al* 1965) can supersede the mechanoreceptor reflexes.

Further, it has recently been demonstrated (Gebber and Snyder 1970) that the tachycardia associated with the pressor effect evoked by electrical hypothalamic stimulation was the result not only of increased cardiac sympathetic activity (Pitts *et al* 1941) but also of inhibition of baroreceptor-induced vagal activation. Assuming a similar mechanism in intact man, the rapid changes in heart rate would correspond to the time course of a discontinued vagal stimulation (Warner and Cox 1962).

Thus from the presented arguments and from the absence of a counter regulation via the baroreceptors, it might be assumed that the cardiovascular response to muscle activation is the result of a simultaneous somatomotor and autonomic nervous activity and an inhibition of the baroreceptor reflexes.

a cardioacceleration might be initiated by a stimulation of beta-adrenergic receptors. The pressure rise could be ascribed both to the heart rate acceleration and to an effect on systemic vascular resistance mediated by alpha-adrenergic receptors.

3 A study of similar experimental design to that previously described was performed in tetraplegic men with a complete transverse spinal syndrome below segments C_6-C_7. Interest was focused on the heart rate response to muscle activation. Evidence suggested that due to the spinal cord lesion at cervical levels the patients were deprived of centrally controlled sympathetic nervous discharges to the heart. The cardiac adjustment elicited in the vasomotor centres was consequently mediated by changes of vagal tone only. The increments of heart rate and aortic pressures evoked by isometric elbow flexion or handgrips exhibited the same rapid onset as in healthy individuals, and the magnitude of the heart rate response did not differ significantly from that of healthy men. Atropine diminished or abolished the heart rate acceleration initiated by muscle contraction. When both atropine and phentolamine were given the heart rate during an isometric contraction was maximally 127 beats/min, while higher values were observed among the healthy individuals.

It was concluded that the heart rate acceleration at the initiation of a muscle contraction was elicited by a mechanism similar to that in healthy men, *viz.* by a withdrawal of vagal tone.

4 Injection of succinylcholine in the brachial artery induced a total neuromuscular blockade in the muscle groups which were activated during handgrips. Intention to perform handgrips in the paralyzed forearm elicited increments in heart rate and aortic pressures which were on an average 64 and 55 per cent, respectively, of appropriate control data. The absence of irrelevant stimuli, such as breathholding with a tendency to Valsalva manoeuvres or activation of muscles proximal to the paralyzed segment, was controlled by inspection, recording of right atrial pressure and EMG records over various muscles of the shoulder.

It was concluded that the increments of heart rate and blood pressure at the initiation of somatomotor activity were at least partly elicited by an autonomic nervous drive of central origin.

5 Similar cardiovascular effects were elicited when one or both hands contracted at the same relative force or when the isometric contraction was performed as elbow flexion. When the same muscle groups contracted at various fractions of maximal force (MVC) there seemed to be a relation between the initial cardiovascular response and the relative force of contraction, so that circulatory data obtained while exerting one

fourth of MVC were lower than those at three fourths of MVC In the phase of restitution of the neuromuscular transmission following blockade, the circulatory effects evoked by small fractions of developed MVC (intended to be higher) were of higher amplitude than contractions performed at higher MVC prior to the blockade.

The results indicated that the initial circulatory effects of isometric contractions were related to the intensity of motor innervation and not to the size of activated muscle groups.

6 Intended muscle contractions during neuromuscular blockade were accompanied by an enhancement of the triceps surae tendon jerk. It was suggested that the cardiovascular response and the reinforcement of spinal reflexes were integral parts of a centrally initiated pattern of reaction.

7 The absence of a counterregulation via the baroreceptor reflexes, indicates a simultaneous inhibition of the baroreceptor function at the initiation of somatomotor nervous activity

Acknowledgements

To my teacher Professor Torgny Sjöstrand, who inspired me to enjoy the challenge of scientific work, and under whose stimulating guidance I had the privilege of working I wish to express my gratitude for advice and important suggestions.

To Docent Evert Knutsson for his invaluable collaboration and stimulating criticism.

To the entire staff of the Department of Clinical Physiology Karolinska sjukhuset, for their kind interest and collaboration.

I am especially grateful to Mrs. Gertrud Grünfarb and Miss Ulla Oswaldsson for their excellent help in visualization of the results, which has greatly facilitated my work.

I am deeply indebted to all the volunteers, who willingly underwent the experiments.

The investigation was carried out during 1968—1970 at the Department of Clinical Physiology Karolinska sjukhuset Stockholm, and has been supported by grants from the Förenade Liv insurance Company

INTRODUCTION

This study is primarily concerned with a comparison between patients with hypertension, predominantly of the essential type, and normotensive controls with respect to the pheripheral hemodynamics. Special interest has been devoted to the hemodynamic effects of an increased wall/lumen rano in the resistance vessels. In order to illustrate these effects two series of animal experiments have also been performed.

PREVIOUS STUDIES

Cardiac output in hypertensive disease

Today most authors agree that cardiac output at rest, in patients with established high blood pressure, is within normal limits (Goldring and Chasis 1944 p 39 Pickering 1968 pp 179—180) This means that the blood pressure in most hypertensive patients at rest is elevated because of an increased peripheral resistance rather than an increased cardiac output. This increase in resistance seems to be distributed rather uniformly over the various systemic circuits, possibly being somewhat less pronounced in the skeletal muscle and more intense in the kidneys (Pickering 1968 pp 185—186)

Peripheral resistance in hypertensive disease

Blood viscosity

Pickering (1968 pp 179—180) considers blood viscosity to be within normal limits in essential hypertension. Tibblin *et al.* (1966) on the other hand found about twenty per cent higher values for whole blood viscosity *in vitro* in a small number of hypertensive patients compared with normotensive persons but only slight changes in hematocrit and plasma viscosity

Animal studies indicate, however that viscosity as measured *in vitro* might sometimes be an unreliable indicator of the viscosity *in vivo* (Djojosugito *et al* 1970) These investigators observed fairly large differences in the viscosity *in vitro* of blood from different cats, while the *in vivo* values were similar Furthermore, the viscosity *in vitro* was usually about twice as high as that *in vivo* at corresponding shear rates.

Sympathetic nerves

There is little evidence of an increased vasoconstrictor nerve activity to peripheral vessels of hypertensive subjects during rest (Pickering 1936 Prinzmetal and Wilson 1936, Freis 1960 Pickering 1968 pp 186—187) However this by no means excludes that there may often be an increase during daily life perhaps in the form of intermittent bouts of sympathetic discharge to both heart and blood vessels in hypertensive patients (Hinman, Engel and Bickford 1962, Bevan Honour and Stott 1969)

Humoral vasoconstrictor agents

Increased amounts of circulating substances which may directly or indirectly cause hypertension have been found in some special forms of hypertensive disease *e g* noradrenaline in phaeochromocytoma, corticoids in Cushing's syndrome and Conn's disease, and renin-angiotensin in renal and malignant hypertension In patients with uncomplicated essential (primary) hypertension, however increased amounts of circulating pressor substances have not been convincingly demonstrated.

Electrolytes

Changes in the electrolyte balance of a nature that may lead to an increased smooth muscle tone or increased vascular reactivity have been much discussed, but according to Freis (1960) "cations in the extracellular fluid are normal in uncomplicated essential hypertension" and evidence is lacking for a change in intracellular concentrations" However Pickering (1968, p 191) considers it possible that "a change in the extra/intracellular fluxes of Na and K in the small arteries and arterioles" might be a final common path leading to an increased peripheral resistance in DCA hypertension hypertension due to renal artery stenosis and perhaps also in essential hypertension. An increased amount of water and electrolytes in the vascular wall, "water logging" that reduces the lumen of the vessel, was first proposed by Tobian and Binion (1952) However in their monograph about renal hypertension Page and McCubbin (1968 p 209) summarize that at present there is no firm evidence concerning the importance of water logging" It has been questioned whether "water logging" might simply be another aspect of the morphological changes seen in the vessels of hypertensive subjects (Pickering 1968 p 191)

Increased vascular reactivity or sensitivity to constrictor agents

Terms like increased "sensitivity" or "reactivity" are often used in the studies that will be discussed below As a rule, the authors have used these terms without exact definition, in the general meaning of an increased response to a given stimulus, the definitions used in this study are given below on page 17

There are many papers on this topic, often with contradictory results. Reflex increases of blood pressure, as a result of cold exposure of the hand, were studied by *e g* Hines and Brown (1933) Pickering and Kissin (1936) Alam and Smirk (1938) and Harlan, Osborne and Graybiel (1964) Enhanced responses to cold were found in essential hypertension by Hines and Brown and by Alam and Smirk, but these observations could not be

verified by Pickering and Kissin In their extensive follow up study Harlan, Osborne and Graybiel could not verify the idea proposed by Hines and Brown that the cold pressor test could be used for the diagnosis of prehypertension.

However the explanation of an increased response in such experiments must not necessarily involve an increased vascular reactivity Hines and Brown believed that the cause of the large response in hypertensive patients was an increased reactivity" in the vasomotor centres.

In some studies the change in blood pressure (Clough 1920 Jensen 1930 Gordon and Levitt 1935 Fatherree and Hines 1938 Goldenberg *et al* 1948 Judson *et al.* 1950 a, Judson, Epstein and Wilkins 1950 b Gombos *et al* 1962) or in total peripheral resistance (Goldenberg *et al* 1948) was measured when standard doses of a pressor substance were given intravenously or subcutaneously Most of these studies were performed with adrenaline as the only pressor agent used. The increase in systolic pressure produced by this drug, however is due to an increased cardiac output, and in the doses used it usually reduces overall systemic resistance (Jensen 1930 Goldenberg *et al* 1948) Many of the studies discussed above are therefore of little relevance for the question of vascular reactivity to vasoconstrictors.

Among studies utilizing noradrenaline or some other purely vasoconstrictor drug the one performed by Goldenberg *et al* (1948) indicated increased pressor responses in patients with essential hypertension. However this finding could not be verified by Judson, Epstein and Wilkins (1950 b) nor did Gombos *et al* (1962) observe any increased vascular reactivity in experiments of this type. Furthermore, in studies where blood pressure changes are measured, as well as in those where changes in regional blood flow or flow resistance (Gombos *et al* 1962) are determined during intravenous or subcutaneous drug administration, the results may be considerably modified by secondary reflex adjustments as elicited by *e g* the baroreceptors. The disadvantage of such a type of drug administration to the general circulation can be reduced somewhat by regional or generalized sympathetic nerve blockade, *e g* by means of ganglion blocking drugs (Doyle and Black 1955) application of local anesthetics to regional sympathetic nerves (Bárány and James 1959 Bárány 1963) or for the skin vessels, by indirect heating (Mendlowitz and Naftchi 1958) The studies maid with these techniques have indicated an increased vascular reactivity to noradrenaline in essential hypertension

In many of the studies discussed above changes in blood pressure were given in absolute figures (*e g* Goldenberg *et al* 1948 Doyle and Black

1955) As pointed out by Pickering (1936) and Gombos *et al.* (1962) however it seems more correct to compare relative changes rather than absolute changes.

The most reliable information concerning vascular reactivity is probably obtained if vasoactive substances are given directly into the artery which supplies the tissue or organ studied (Duff 1957 Doyle, Fraser and Marshall 1959 Scroop and Whelan 1968) According to Doyle, Fraser and Marshall (1959) vascular reactivity seems to be unspecifically increased in essential hypertension for many different drugs, *e g* noradrenaline, 5 HT and angiotensin. This is in good agreement with the results reported by Duff (1957) which indicated an increased vascular reactivity for adrenaline. Scroop and Whelan (1968) could, however not confirm these findings

In his review Mendlowitz (1967) summarized "The weight of evidence indicates that there is increased systemic vascular reactivity in essential hypertension" However as discussed above the experimental results reported in the literature, though extensive, are often contradictory and difficult to interpret.

Morphological changes in the arterioles of patients with high blood pressure

The existence of morphological changes in the systemic vascular bed of patients with high blood pressure is well known. In 1868 Johnson reported hypertrophy of the arteriolar walls in the kidney intestine, skeletal muscle, pia mater and skin in Bright's disease. He interpreted the hypertrophy as being a result of "long continued overactivity of the vessels

Moritz and Oldt (1937) in their extensive study gave the following description of arteriolar morphological changes in hypertensive patients. *Intimal hyalinization* is characterised by a subendothelial accumulation of homogeneous acidophilic material. *Medial hypertrophy* implies an increased size (and number) of smooth muscle cells. *Medial degeneration* means an increase of intercellular collagen, which in some cases is associated with atrophy rather than hypertrophy of smooth muscle cells. A fourth type of vascular change, *endothelial hyperplasia (intimal hyperplasia)* was also discussed. All these vascular changes were also seen more or less frequently in healthy persons with normal blood pressure, and in patients with diseases other than high blood pressure. However as a rule, these changes were more severe and frequent in hypertensive patients. Furthermore the occurrence of such arteriolar changes differed from one organ to another *Acute arteriolar lesions* arteriolonecrosis or fibrinoid necrosis, were often superimposed upon the more chronic changes.

In their biopsy study Sommers, Relman and Smithwick (1958) observed smooth muscle swelling and hypertrophy as well as an increased amount of PAS-positive substances in the vascular wall in the early benign cases of hypertension (arteriolar sclerosis, grade I and II) Degenerative changes were found predominantly in the more severe and long standing cases (grade III) "It was inferred" they wrote, "that the sequence of events was spastic arterial contraction intramural vascular edema, muscular overgrowth, replacement of the degenerated muscle by pooled ground substance and ultimately collagenization and hyalinization" Other workers have suggested that the hyaline and fibrinoid deposition in the vascular wall has a hematogenous origin and results from deposition of fibrin and in fact there is considerable evidence to support this opinion (Giese 1966 Page and McCubbin 1968 pp 378—384)

Smooth muscle hypertrophy intimal hyperplasia and hyalinization would tend to increase the wall thickness. Such changes are probably responsible for the increased wall/lumen ratio in the arterioles of hypertensive patients, which has often been reported (*e g* Kernohan, Anderson and Keith 1929 Morlock 1939) The determinations of wall/lumen ratio, however are open to criticism, because it is difficult to decide, if the increased ratio is due to a truly increased wall tissue mass, or simply to a vascular contraction present at the moment of fixation (Andrus 1936) On the other hand, Moritz and Oldt (1937) who also found an increased wall/lumen ratio in the resistance vessels of hypertensive patients, claimed that experimentally induced changes of smooth muscle tone, produced immediately before the animal was killed, did not alter the wall/lumen ratio as observed in a histological section. Changes in the preparation technique were also without effect on this ratio However there are probably situations where differences in *e g* intravascular pressure and in wall distensibility in the arterioles may greatly affect morphological estimations of vascular design.

Short and co-workers claimed (Short and Thomson 1959 Short 1966) that the increased wall/lumen ratio in arterioles from patients with high blood pressure is due to what they called a vascular "contracture rather than to a wall thickening. They proposed that prolonged arteriolar constriction from any cause leads to persistent shortening of the circular muscle They determined the cross-sectional area of the vascular wall in what they considered to be corresponding arterioles in hypertensive and normotensive persons and stated that this was equal. However at the same time the lumen was smaller and the wall/lumen ratio was larger in the vessels of hypertensive patients compared with those in normotensive persons. According to them the wall surface area would better reflect

vascular smooth muscle hypertrophy or hyperplasia than a measure of arteriolar wall/lumen ratio However this almost borders on a semantic problem, and it is a matter of the definition of wall hypertrophy In hollow organs, like the heart and the vessels, the only useful meaning of the term "wall hypertrophy" at least in terms of function of such hollow organs, is an increased wall thickness in relation to the lumen, since the force against which the smooth muscles in the wall act is to a great extent determined by the size of the lumen, according to Laplace s law If then the result of vascular rebuilding in hypertension is that branches of the same generation in the vascular tree are generally decreased in luminal size but have an increased wall/lumen ratio due to an undiminished wall mass, as suggested by Short, one may still define this as wall "hypertrophy' from the functional, hemodynamical point of view The reason is that such a vessel has available for the control of its particular lumen, a relatively greater mass of contractile tissue.

Barrett (1963) studying arteries, found good correlation between the heart weight and the cross-sectional area of the wall in the five largest branches of the superior mesenteric artery in a series of 100 cases of normotensive and hypertensive subjects, where all other causes of cardiac hyper trophy except hypertension were excluded.

Naeye (1967) related the total area of the arteriolar smooth muscle cells to the total area of the nuclei of the endothelial cells in arteriolar cross sections. The size of these nuclei was thought to be a good reference for the estimation of the size of the vessel. He claimed that, in hypertensive patients, arterioles situated proximally to sclerotic obstructions of the vessels, in which the intravascular pressure could be supposed to be higher than normal, showed media hypertrophy and hyperplasia, while those placed distally to such obstructions, where pressure is lower exhibited decreased media muscle mass. He found, like many other authors, that the vascular changes in hypertensive patients varied considerably from one arteriole to another and also within the same arteriole and artery For a more complete discussion of structural vascular changes in hypertension see Giese (1966)

There are surprisingly few physiological studies performed concerning the hemodynamic consequences of these morphological vascular changes. Prinzmetal and Wilson (1936) and Pickering (1936) simultaneously published two rather similar papers, in which the ability for skin and muscle vessels to dilate was compared in normotensive and hypertensive subjects. They found that skin blood flow was the same in the two groups after sympathetic nerve blockade as well as after indirect heating. This means

that flow resistance in the hypertensives was still increased above that in normotensive subjects after elimination of the vasoconstrictor influence, and this increase would therefore have another background than an increased vasomotor activity It was furthermore shown that muscle blood flow was almost equal at rest in normotensive and hypertensive subjects, and increased to about the same level in the two groups after 5—10 minutes of arterial occlusion. This finding was, apparently not only taken as an argument against rigid sclerotic vascular changes, but also against morphological vascular changes of any kind (Prinzmetal and Wilson 1936) These authors suggested that the increased flow resistance in hypertensives, at rest as well during dilatation might be due to some kind of circulating pressor substance that was resistant to ischemia

Stead and Kunkel (1940) made similar observations on hand and foot blood flow after direct and indirect heating and on forearm blood flow after ischemic work. The blood flow in all three tissues reached about the same values in hypertensive and normotensive subjects. These authors also presented evidence indicating that blood flow resistance in the brain could not be lowered to the same level in hypertensive patients as in controls by inducing cerebral anoxia. They discussed both structural factors and humoral vasoconstrictor agents as the cause of the increased resistance in hypertension. Novack *et al* (1953) found that cerebral blood flow could increase in both hypertensive and normotensive persons on 5 % CO_2-breathing, reaching about the same values in the two groups. Flow resistance during vasodilatation was therefore increased in the hypertensive group in proportion to the elevation in blood pressure.

Pickering (1955 p 144) summarized "There would seem little doubt that these organic changes, which encroach on the lumen of small arteries and arterioles, must contribute to the increased peripheral resistance. But the consensus of current opinion is opposed to their being entirely responsible for the increased peripheral resistance, for two reasons which may now be examined. The first reason given is that the increased peripheral resistance in hypertension may be diminished by certain vasodilator agents The second and more formidable reason is that these structural lesions are too slight and too inconstant to constitute the whole abnormality in vascular behaviour which is observed"

Folkow and co-workers (Folkow 1956 Folkow Grimby and Thulesius 1958) have expressed another opinion They demonstrated in principle that for any given degree of smooth muscle shortening the change in flow resistance would always be larger in a vessel with increased wall/lumen ratio than in one with a normal ratio. This might be one, or even the main,

explanation for the increased vascular reactivity to constrictor agents often found in hypertensive patients, and it would eliminate the first of Pickerings two arguments against the hemodynamic importance of morphological vascular changes. They also found an increased flow resistance in forearm vessels at maximal vasodilatation, suggesting that the proposed increase of vascular wall mass had encroached upon the lumen of the resistance vessels also at complete relaxation of the smooth muscles. If these findings reflected a generalized change of the systemic resistance vessels this would eliminated also the second of Pickerings arguments. These findings were fully confirmed in an extensive study of the forearm vessels in hypertensive patients by Conway (1963) The present work is a further analysis of this conception, including its hemodynamic consequences.

HEMODYNAMIC CONSEQUENCES OF AN INCREASED WALL/LUMEN RATIO IN THE RESISTANCE VESSELS

Folkow and co-workers have previously pointed out the hemodynamic effects of an increased wall/lumen ratio in the resistance vessels (Folkow 1956 Folkow Grimby and Thulesius 1958) They conclude on the basis of mathematical deductions that the presence of a wall thickening which practically always implies an increased wall/lumen ratio, in the resistance vessels might affect the flow resistance in two principally different ways

1 By potentially influencing *flow resistance already at maximal vasodilatation* by changing the morphologically set dimensions of the vascular bed

a) *if the wall "grows inwards" flow resistance at maximal dilatation will* increase (Fig 1 H and 2 H_a)

b) if the vascular wall grows in such a way that the outer diameter increases to the same extent as the wall thickness, the result will be an unchanged inner radius and resistance at maximal dilatation (Fig 1 H_b);

c) if finally the wall "grows outwards" to the extent that the outer diameter increases more than the wall thickness, the flow resistance at maximal vasodilatation will be decreased (Fig 1 H_c)

2 By changing the *relation between the degree of vascular smooth muscle contraction and flow resistance* The changed vascular architecture behind an increased wall/lumen ratio in the resistance vessels, with an increased wall mass situated inside the "line of force" of the smooth muscle ring, will lead to exaggerated luminal reductions for given degrees of vascular smooth muscle shortening (Fig. 1 and 2) Now suppose that the smooth muscle cells for any degree of excitation (*e g* sympathetic nerve stimulation or intraarterial noradrenaline infusion) show a perfectly normal per cent decrease in length. In such vessels with thickened walls this would produce a *steeper dose-response relation* between sympathetic nerve stimulation (or intraarterial noradrenaline administration) and flow resistance than in normal vessels. The slope would be increased also if resistance were given in *relative* units, *e g* as a fraction of basal resistance, as in the present study (for definitions see below p. 29) This difference in slope

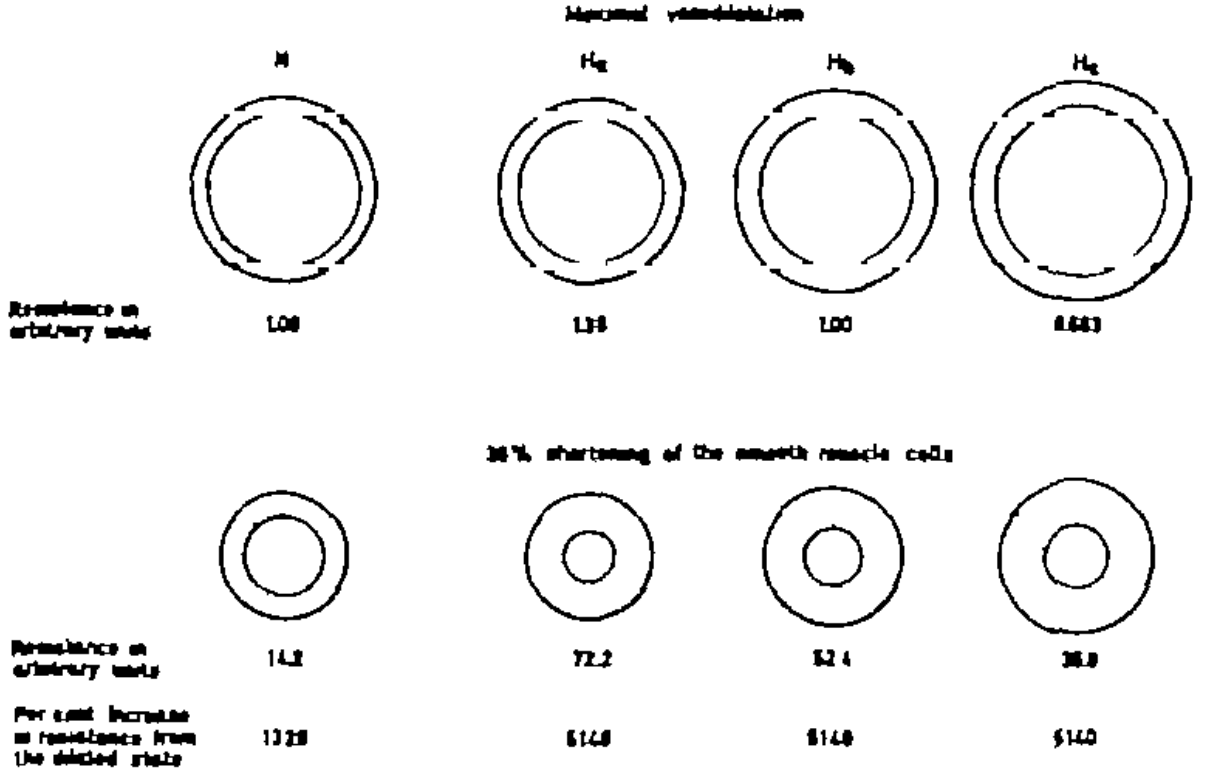

Fig. 1 Illustration of the hemodynamic effects of an increased wall/lumen ratio in the resistance vessels (Folkow 1956, Folkow Grimby and Thulesius 1958).

N represents a normal vessel which at maximal dilatation has a flow resistance of one unit and a wall/lumen ratio of 0.2. All the vessels represented by H have wall/lumen ratios of 0.3 at maximal dilatation, 50 per cent larger than in the normal vessel. H_a has an increased, H_b an unchanged and H_c a decreased resistance at maximal vasodilatation compared with the normal vessel. In the upper series all the vessels are maximally dilated. In the series below the "line of force" in the smooth muscle sheath, represented by the outer circumference, is shortened by 30 per cent. Due to the larger wall mass situated inside this line in the vessels denoted H, the ensuing increase in resistance is much larger in these vessels than in the normal vessel. It should also be observed that the percentual increase in resistance produced by the vascular contraction is the same in all three vessels denoted H because their wall/lumen ratios are equal.

might be one explanation of the potentiated vasoconstrictor response often seen in patients with high blood pressure.

If the intention is to separate the effect of an increased wall/lumen ratio *per se* on the slope of the dose-response curve from that of an increased resistance at maximal dilatation it is important to calculate the slopes from dose-response curves where the resistance is given in *relative* units, either related to the resistance at maximal dilatation or to the basal resistance, if this is proportional to the resistance at maximal dilatation, which is the case in the present study This is important because slopes calculated from curves, where resistance is given in *absolute* values, will depend on the level of the resistance at maximal dilatation (Fig 3) If the resistance at maximal

HEMODYNAMIC CONSEQUENCES OF AN INCREASED WALL/LUMEN RATIO IN THE RESISTANCE VESSELS

Folkow and co-workers have previously pointed out the hemodynamic effects of an increased wall/lumen ratio in the resistance vessels (Folkow 1956 Folkow Grimby and Thulesius 1958) They conclude on the basis of mathematical deductions that the presence of a wall thickening, which practically always implies an increased wall/lumen ratio in the resistance vessels might affect the flow resistance in two principally different ways: 1 By potentially influencing *flow resistance already at maximal vasodilatation* by changing the morphologically set dimensions of the vascular bed

a) if the wall "grows inwards" flow resistance at maximal dilatation will increase (Fig. 1 H_a and 2, H_a)

b) if the vascular wall grows in such a way that the outer diameter increases to the same extent as the wall thickness, the result will be an unchanged inner radius and resistance at maximal dilatation (Fig 1 H_b)

c) if finally the wall "grows outwards" to the extent that the outer diameter increases more than the wall thickness, the flow resistance at maximal vasodilatation will be decreased (Fig 1 H_c)

2 By changing the *relation between the degree of vascular smooth muscle contraction and flow resistance* The changed vascular architecture behind an increased wall/lumen ratio in the resistance vessels, with an increased wall mass situated inside the "line of force of the smooth muscle ring, will lead to exaggerated luminal reductions for given degrees of vascular smooth muscle shortening (Fig 1 and 2) Now suppose that the smooth muscle cells for any degree of excitation (*e g* sympathetic nerve stimulation or intraarterial noradrenaline infusion) show a perfectly normal per cent decrease in length. In such vessels with thickened walls this would produce a *steeper dose-response relation* between sympathetic nerve stimulation (or intraarterial noradrenaline administration) and flow resistance than in normal vessels. The slope would be increased also if resistance were given in *relative* units, *e g* as a fraction of basal resistance, as in the present study (for definitions see below p 29) This difference in slope

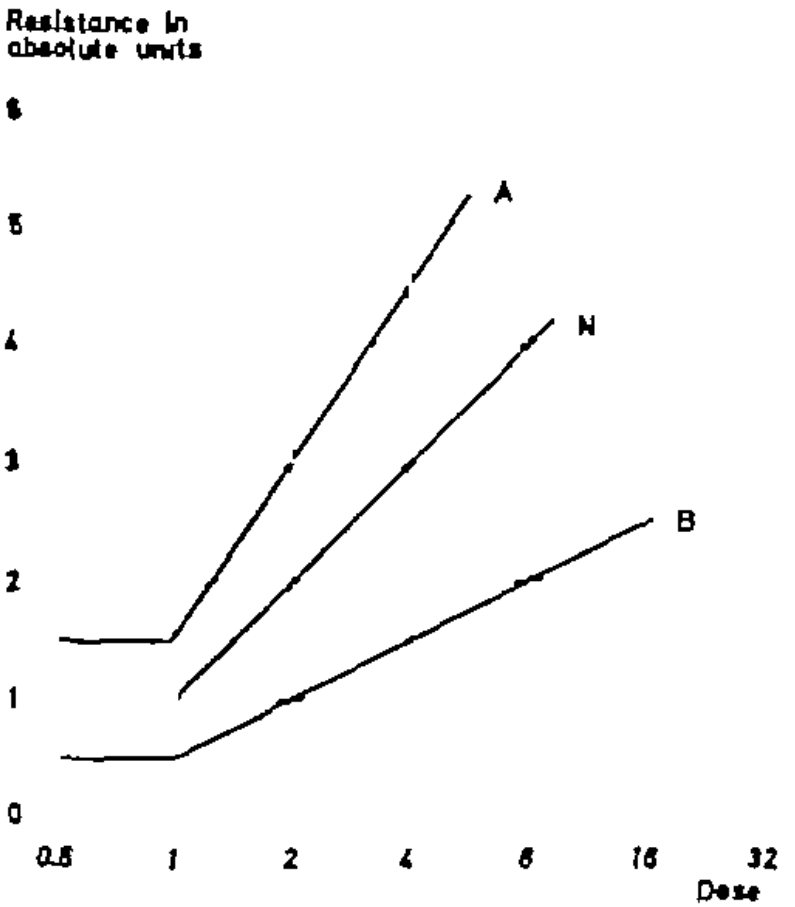

Fig. 3 Hypothetical dose-response curves showing the effect of an increased resistance at maximal dilatation on the slope of the curves when resistance is given in *absolute* values. In all cases the wall/lumen ratio is thought to be the same.
N: Normal resistance at maximal dilatation.
A: 50 per cent increased resistance at maximal dilatation.
B: 50 per cent decreased resistance at maximal dilatation.

wall/lumen ratio and one due to an *increased smooth muscle sensitivity* to noradrenaline. Usually these two different factors are not distinguished in previous studies. The terminology used in the literature to describe these and similar aspects often differs from one author to the other.

By *increased sensitivity* it will here be meant that a normal response is obtained within the entire dose spectrum for any dose which constitutes the same fraction (say one tenth) of that normally needed for this response (see e g Trendelenburg 1963). In other words, if a dose-response curve is plotted with the logarithm for the dose on the abscissa and the response on the ordinate an increased sensitivity will according to this definition, move the curve to the left in a *parallel* fashion, implying a *decreased threshold with unchanged steepness* as is schematically illustrated in Fig. 4 A. A wellknown example of a sensitization in this meaning is that seen after

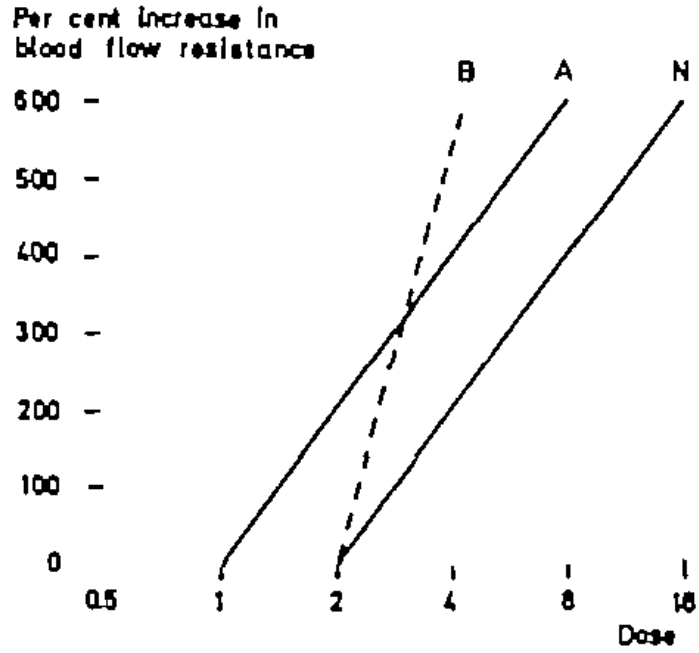

Fig. 4 Schematic illustration of the effect of an increased sensitivity of the vascular smooth muscle cells for noradrenaline (A) and an increased wall/lumen ratio in the resistance vessels (B) on the dose-response curve. N refers to the normal situation.

denervation (Cannon and Rosenblueth 1949) During competitive interaction the dose-response curve is moved to the right in a parallel fashion.

An *increased wall/lumen ratio* in the resistance vessels, on the other hand, will give an *unchanged threshold* but a *steeper dose-response curve* (see Fig 4 B) An increased ability of the smooth muscle sheath to develop contraction force as a consequence of smooth muscle hypertrophy (or hyperplasia) may affect the shape of the dose-response curve. Smooth muscle hypertrophy or hyperplasia is almost inevitably combined with an increased wall/lumen ratio in the resistance vessels, since the media normally makes out the greater part of the wall in these vessels. Such changes appear to be common in hypertension, and the increased contractile strength, which is a consequence of the increased muscle mass as related to the lumen will here be included in a somewhat widened concept of an increased wall/lumen ratio

By *increased vascular reactivity* it is here meant that an exaggerated luminal change is obtained when a standard dose of a vasoconstrictor drug is given. This expression thus includes a lowered threshold as well as an increased slope.

It should be observed that there are other theoretically possible explanations of a raised flow resistance at maximal vasodilatation than an increased wall/lumen ratio of the resistance vessels. These vessels may simply be

symmetrically decreased in size both in lumen and in wall thickness they may be *elongated* there may be *fewer vessels per tissue volume* or the *viscosity* of the blood may be increased. None of these factors would however lead to an increased steepness of the dose-response curve, if the response is measured in relative units.

A steeper slope of the dose-response curve relating flow resistance to vasoconstriction stimulus need not necessarily imply an increased wall/lumen ratio of the resistance vessels. It could also be achieved by other types of changes, but none of these alternatives could explain an increased resistance to flow at maximal vascular relaxation. Thus, a steeper slope of the dose-response curve might be due to an *increased degree of shortening of the smooth muscle cells* for the same stimulation intensity without any change of vascular structures. One example, the only one known to the author where a given drug increased the slope of the dose-response curve of the smooth muscle cell itself (membrana nictitans) to both sympathetic nerve stimulation and intravenous adrenaline administration, is discussed by Cannon and Rosenblueth (1949 p 15) After thyroxine administration the response was increased by about 50 per cent at every stimulation intensity An increased slope could also be explained by a *decreased vascular reactivity to vasodilator metabolites* which accumulate during vasoconstriction. Furthermore, where several effectors are involved, a dose-response curve may at least to some extent, be looked upon as a *cumulative frequency-distribution curve* which provides another possibility to explain a difference in slope between two curves. Suppose that the individual vessel in a vascular bed reacts in an all-or none fashion, changing from maximal relaxation to complete closure, whenever the threshold for vasoconstriction is surpassed. In such a hypothetical situation a shift in threshold within a population of parallel-coupled resistance vessels might change the slope of the curve comprised of the response of the entire vessel population of the tissue. If the difference between the highest and lowest threshold were large a flat curve would be obtained, if it were small a steep curve would ensue. It is, however very unlikely that resistance vessels exposed to physiological stimuli would react in such an all-or none fashion (see *e g* Van Citters 1966) but it is probable that the slope of the dose-response curve to some extent is due to differences in reactivity between the individual vessels in a vascular bed

PRESENT STUDIES

Animal experiments

In order to test the hypothesis discussed above, that an increased wall/lumen ratio in the resistance vessels will increase the slope of the dose-response curve without changing the threshold, the two following series of animal experiments were performed

I. A hemodynamic study on cutaneous A V shunts in cats

Two cutaneous vascular beds with different proportions of thermo-regulatory arterio-venous shunts and of "nutritional resistance vessels were compared. Cutaneous A—V shunts normally display a higher wall/lumen ratio than the regular resistance vessels (Clara 1956 p 18) and possibly but not necessarily their smooth muscles are more sensitive to noradrenaline As both sets of vessels are located in the skin of the cat s paw the local chemical environment of their smooth muscle cells may be expected to be fairly similar

Methods

In 19 anesthetized cats the large saphenous vein was cannulated at the ankle and the total venous effluent from the paw directed to this vein by means of a moderately tight rubber string around the ankle, allowing for a recording of the blood flow in the paw (for details see Paper I) It is known from many animal species that the cutaneous A—V shunts are mainly located in the pads and toes (Clara 1956 pp 25—28) By studying the paw blood flow with the pads and toes included and excluded, respectively it was possible to compare the responses of two parallel-coupled vascular circuits which differ in wall/lumen ratio From these data the blood flow in the pads and toes could be calculated separately and thus the response of their vessels, dominated by the A—V anastomoses evaluated. Blood flow from the cat s hind paw was thus recorded during direct stimulation of the lumbar sympathetic nerve trunk with stepwise increases of frequency and also during intraarterial and intravenous infusion of noradrenaline (Nor-exadrin® Astra) with stepwise increases of dosage. Intraarterial blood pressure was simultaneously recorded with a mercury

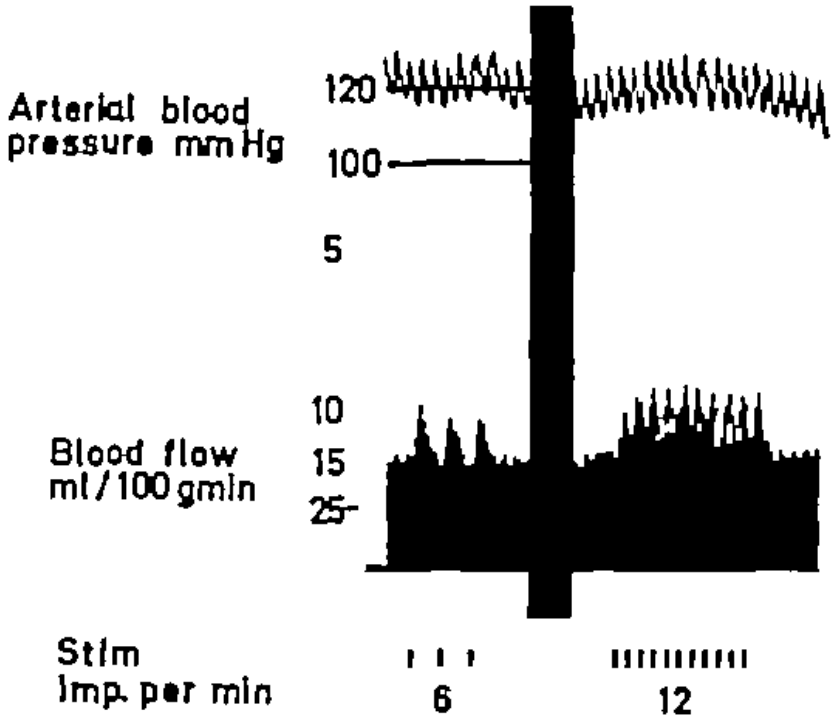

Fig. 5 Blood flow from the cat's hind paw during low frequency vasomotor nerve stimulation.

manometer From these data dose-response curves for sympathetic nerve stimulation and for noradrenaline infusion could be deduced for the paw blood flow resistance, with pads and toes excluded ("skin ') with pads and toes included ("skin + pad") and for pads and toes alone ("pad")

Critical aspects of the methods

With respect to nerve stimulation no distinct threshold in the dose-response correlation could be obtained, simply because even a single impulse produced a clearcut response (Fig 5) Therefore the sensitivity of the acutely denervated vascular smooth muscle had to be judged from the nor adrenaline infusion experiments.

In some of the infusion experiments noradrenaline was given into the femoral artery When a drug is given in this way "close intraarterially there is a risk for incomplete mixture between the drug and the blood stream, causing an uneven distribution of the drug to the tissues. In order to determine whether this factor affected the results significantly some experiments were performed where noradrenaline was administered intra venously which ensures a complete mixture between drug and blood in the heart and lungs. There was little difference in the results, whether nor adrenaline was infused intraarterially or intravenously

For intraarterial infusions a solution of noradrenaline (0.5μg/ml) dis-

solved in 0 9 per cent saline was administered into the femoral artery By changing the speed of infusion different amounts of noradrenaline could be administered per time unit. The highest infusion rates used in the experimentes were often between 0.2 and 0.5 ml per min, but sometimes 1 ml per minute was given This relatively high infusion rate no doubt changed the hematocrit and blood viscosity in the limb vessels to some extent, especially as blood flow to the limb was maximally reduced when this infusion was given. However the changes in hematocrit and blood viscosity which depend on the amount of saline infused per min in relation to the entire blood supply to the hind limb of the cat, must be supposed to be largely the same whether the pads and toes were included or not. Thus, this factor will not significantly affect the comparison of the two vascular circuits studied.

The infusion and stimulation experiments were as a rule first performed with the pads and toes included and then repeated with these parts excluded. It could therefore be argued that the decrease in slope of the dose-response curve, occurring after ligation of the pads and toes, might be due to the fact that one vascular bed was examined isolated after such a long time that a deterioration of the vascular responses might have occurred. However as the pads and toes were excluded only by rubber strings, which left their vessels and nerves relatively undamaged, they could again be included into the perfusion system after a period of exclusion This was done in some experiments and brought about a considerable increase in slope of the dose-response curve. The slopes, however did not quite reach the initial values, which may be due to slight injuries to the vessels, caused by the procedure for exclusion. In any case, this control indicates that the difference between paw vessels with pads and toes included and with these organs excluded could not be entirely explained by the fact that the skin" vessels were studied later in the day than the former but reflected a true difference in the relationship between dosage and resistance response of the two types of vessels.

Results and comments

In the experiments where noradrenaline was infused intravenously or intraarterially there was no difference in threshold when pads and toes were included or excluded. However once the dose surpassed the threshold the vascular bed which included pads and toes usually exhibited more pronounced constrictor responses than the other one. This means that the vascular bed where the vessels displayed the highest mean wall/lumen ratio also showed the steepest dose-response curve (see Fig. 1 in Paper I)

In the experiments where the sympathetic vasoconstrictor fibres were stimulated the vascular bed that was rich in A—V shunts also exhibited the steeper dose-response curve (Fig. 2 in Paper I). However as discussed above (p. 21) it is not possible to evaluate the sensitivity to sympathetic nerve stimulation in this way as no distinct threshold could be recorded.

From these results it is evident that there is no significant difference in sensitivity to noradrenaline between "skin" resistance vessels and the A—V shunts of the pads. However once the threshold is surpassed the "pad" vessels constrict more powerfully than the "skin" vessels. This increased reactivity characterized by a steeper dose-response curve but by an unchanged noradrenaline threshold, is what would be expected from vessels with a higher wall/lumen ratio other things being equal.

In addition, the relatively high reactivity of the A—V shunts to sympathetic stimulation may to some extent be due to a more dense adrenergic nerve supply to these vessels (Celander and Folkow 1953). Such a factor alone, however cannot explain all the findings: there was also, for example, a distinct difference in the slope of the dose-response curve to noradrenaline infusion. Neither does it fully explain the results of the sympathetic nerve stimulation experiments. If the only difference were an increased number of nerve endings in the smooth muscle cells one would expect a tendency of the frequency response curve to move in a parallel fashion to the left without any appreciable change in its slope.

The possibility of an increased strength of smooth muscle contraction, despite an unchanged morphology (p. 19) cannot be *a priori* excluded as an explanation of the steeper dose-response curve in the "skin+pad" vascular bed. Were this the case one might then expect more powerful responses also at noradrenaline concentrations close to the threshold (p. 19). The second alternative explanation discussed above (p. 19) that the "nutritional" skin vessels might be more reactive to vasodilator metabolites accumulated during vasoconstriction, seems unlikely because the cutaneous vessels in general react very little to such factors, and the flow of the skin in relation to its metabolism is high. As "skin+pad" consists of more different types of vessels than "skin" with "pads" excluded, it is likely that the former vascular bed is more heterogeneous with respect to the reactivity of its individual vessels. This would give a less steep curve in "skin+pad" than in "skin" instead of the steeper one observed. Therefore the finding of a steeper curve in the bed rich in A—V shunts can hardly be explained as the effect of a changed frequency distribution curve — the third alternative discussed on p. 19.

II Adaptive changes in wall/lumen ratio and reactivity in cat blood vessels exposed to a reduced transmural pressure

The presence of a high wall/lumen ratio in the resistance vessels of patients with hypertension is usually considered to reflect an adaptation to an increased load on the vessels produced by the high blood pressure. If this is true, the reverse would also occur *i e* prolonged hypotension would lead to some reduction in wall/lumen ratio. In this series of animal experiments a unilateral arterial occlusion was produced in one hind limb of the cats to test whether after some weeks the consequent hypotension caused an adaptive decrease in arterial and arteriolar wall/lumen ratio of that leg. After this time the reactions of the two legs were compared in acute experiments.

Methods

Under ether anesthesia the superficial and deep femoral arteries and the inferior epigastric artery were ligated unilaterally in the cat. This initially decreased the mean arterial blood pressure in the leg to about one third of the normal but the blood supply still proved to be sufficient at rest. Due to widening and growth of collaterals the arterial pressure distal to the occlusion successively rose to about two thirds of the normal value.

After 3—5 weeks the two hind limbs were compared in an acute experiment, in which an isolated calf muscle preparation was arranged on each side (for details see Paper II) so that the only intact communications to the calf besides the femur were the popliteal artery and vein and the sciatic nerve. After heparinisation a normal arterial blood pressure was reestablished on the occluded side ("test limb") by a tube connecting the common iliac artery with the popliteal portion of the femoral artery. In series with this tube a drop recorder operating an ordinate writer was inserted, allowing a continuous measurement of the arterial inflow to the calf. An identical arrangement was made in the "normal limb" so that both had identical arterial supply routes. Arterial blood pressure was continuously measured.

In some experiments, when intraarterial infusions of drugs were given to the limbs, the arterial blood had first to pass a common drop chamber before entering the two femoral arteries. This established a "mixing chamber" where the infused substance was thoroughly mixed with the arterial inflow to the two limbs. In these experiments venous outflow from the two calves was recorded by the drop chamber technique instead of the arterial inflow.

The lumbar sympathetic trunks as well as the intact sciatic nerves could be directly stimulated on both sides so that separate and graded excitations of the vasoconstrictor fibres and the somatomotor fibres to the calf muscles, respectively could be performed. In one series of 13 experiments the relation between increasing rates of constrictor fibre stimulation and flow resistance was investigated. In another series of 12 experiments dose-response curves were determined, relating stepwise increases in rate of noradrenaline infusion (2.5 and 10 μg/ml) to the ensuing resistance responses.

In order to allow the neurohumoral constrictor influences to affect the resistance vessels over the "middle physiological" range of smooth muscle tone, the motor fibres to the calf muscles were continuously and selectively stimulated at an impulse frequency of 1 per sec. Under these conditions the resistance vessels were moderately dilated to start with. As a rule the "basal flow", *i. e.* the flow level during the moderate exercise hyperemia from which vasoconstriction was induced, was about equal on the two sides. Experiments were accepted only when this was the case.

For statistical evaluation paired differences in response between the test limbs and the normal limbs were calculated and tested by Student's t test and Wilcoxon's test (Documenta Geigy 1962 p. 191) at each frequency and dose level. Calculation of thresholds and slopes according to the technique used in Paper III (se the present text p. 31) was used in the infusion experiments.

Results and comments

In the experiments where the vasoconstrictor nerves were stimulated in a graded fashion the slope of the dose-response curve was smaller in the test limb than in the normal limb (Fig. 1 in Paper II and Fig. 6). The response was significantly decreased ($P<0.05$) in the test limb for stimulation frequencies of 4 impulses per sec or above. Here, as well as in the experiments described on page 21 where responses to constrictor fibre stimulation were studied, no distinct threshold could be noted.

The results of the experiments where noradrenaline was given intra arterially are shown in Fig. 7. There was no difference in threshold between the two legs. However once a constrictor response was elicited the slope of the dose-response curve was lower in the previously hypotensive limb (test limb) than in the normal limb. The difference in slope was significant ($P<0.05$).

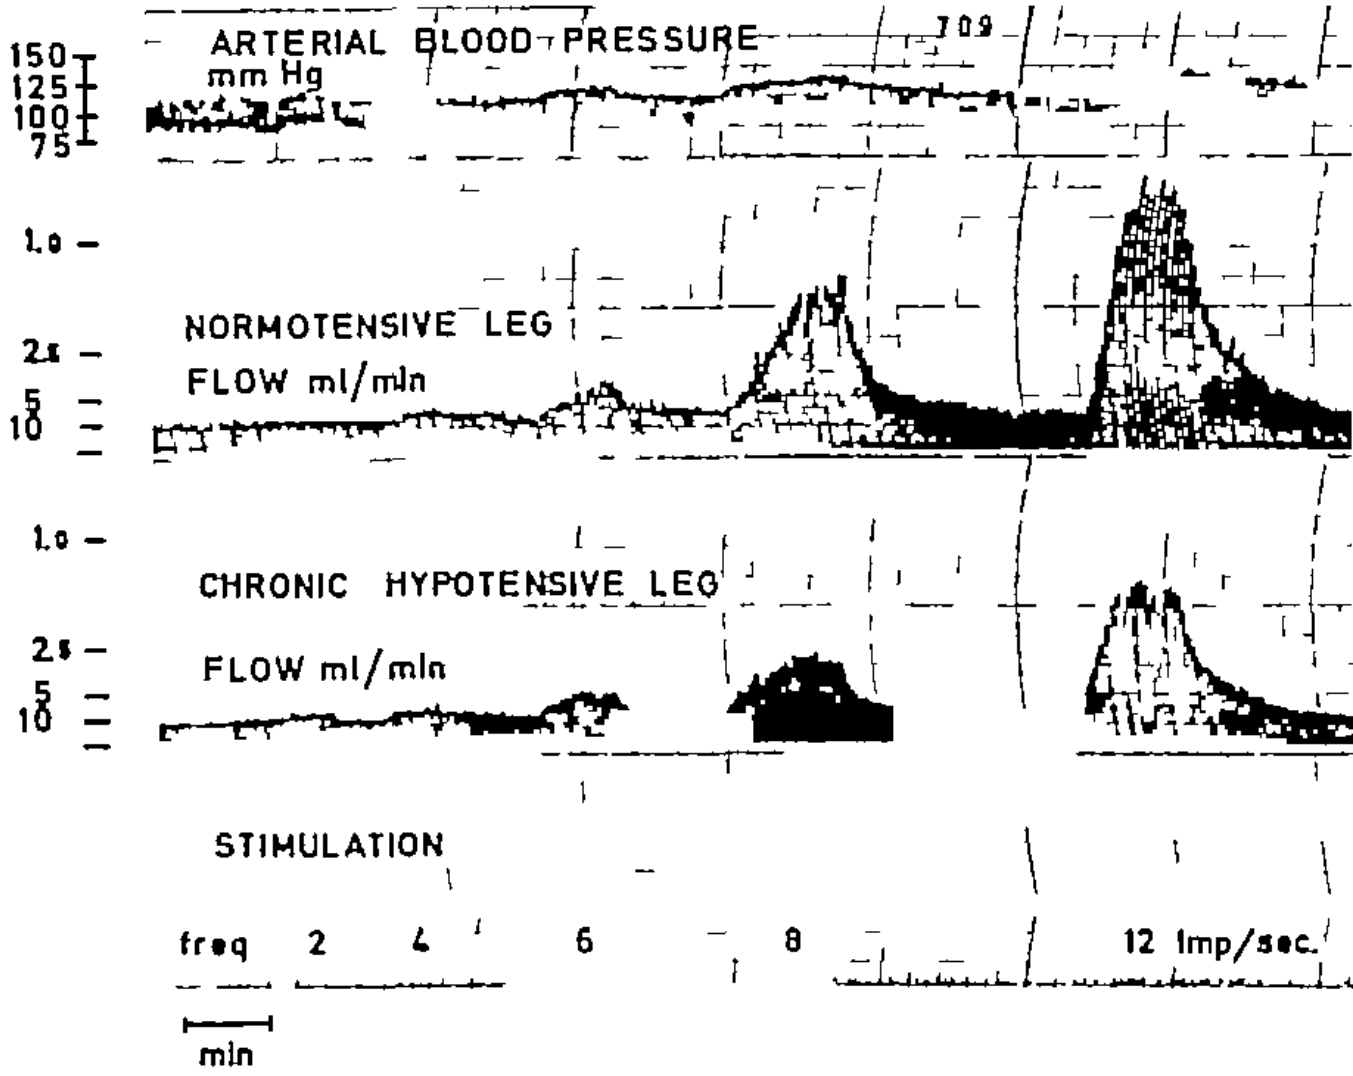

Fig 6. Registration of calf blood flow during graded vasomotor nerve stimulation to the legs. One leg (lower curve) had been exposed to moderate arterial hypotension, by means of arterial occlusions, for about 4 weeks. During the acute experiment the two legs had identical perfusion pressures, since the arterial communications had been established in the hypotensive leg.

The findings of a decreased slope of the dose-response curve of the test limb and of identical thresholds to noradrenaline in the two limbs are what would be expected if the wall/lumen ratio of the resistance vessels in the test limb had been reduced, in this case as a result of some weeks of arterial hypotension with consequent relaxation of the regional vessels.

From a theoretical point of view there are alternative explanations (p. 19) It seems unlikely however that the decreased slope of the dose-response curve in the test limb should be due to a reduced ability of morphologically unchanged vascular smooth muscles to develop contraction force. It was thus observed that the difference in slope between the test

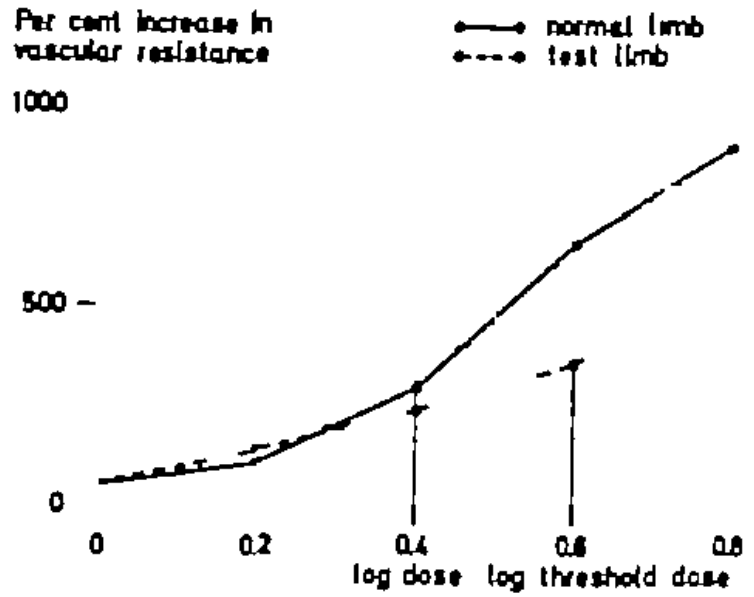

Fig. 7 Relationship (mean curves) between graded intraarterial noradrenaline infusion and percentage changes of blood flow resistance in calf muscle of cats, where the arterial blood pressure in the test limb had been kept reduced by about 40 per cent for 3—5 weeks. In order to illustrate differences in slope individual differences in sensitivity (threshold) are compensated by giving log dose minus log threshold dose on the abscissa. Note the steeper curve in the normal limb.

limb and the normal limb was about the same whether the perfusion pressure was kept high or low This indicates that there was no "overload of any weakened vascular smooth muscle cells that might lead to a difference in slope. Moreover had a reduced contractility of the smooth muscles occurred, causing them to shorten to different extents to identical noradrenaline doses or stimulation frequencies, then one might expect this difference to be largely proportional to the response to all doses or stimulation frequencies analogous with the observations reported by Cannon and Rosenblueth (1949) (see p 19) On the contrary there was a clear tendency for the difference to become more marked as the constriction became larger (Fig. 7) which suggests the influence of a difference in wall thickness. It does not seem reasonable to explain the difference in slope simply as an effect of a changed frequency distribution curve or as a changed vascular reactivity to vasodilating agents (p 19)

In five cats exposed to unilateral arterial hypotension for about five weeks corresponding sections of the femoral arteries from the two sides were compared histologically*) In order to distend the vessels to the same inner lumen the arteries from three of the cats were cannulated with

*) For these examinations dr Johan Silve-Söderberg, at the Department of Pathology in Göteborg, gave valuable advice as well as important technical assistance.

catheters of the same size and fixed in this position Special care was taken to cut the vessels at right angles to their longitudinal axis. The vessels were then photographed and the wall thickness measured (on equidistant points along the inner circumference) In two cats the surface area of the sections was calculated on photographs from undistended vessels. In all five experiments the measurements showed a decreased arterial wall mass in the vessel exposed to the reduced blood pressure compared with the normal vessel. The measurements were, however performed on comparatively large arteries and can therefore only be taken as a circumstantial evidence in favour of structural changes in the arterioles.

Human study

III. Aspects of the nature of the increased vascular resistance and reactivity to noradrenaline in hypertensive subjects

Since Paper III was published in 1968 further experimental results have accumulated and permitted additional calculations on the material These new results and calculations are therefore included in the presentation given below

It was the aim of this work to study the hemodynamic situation in a peripheral vascular bed of hypertensive patients from certain aspects, and to compare it with the corresponding situation in matched controls.

Material

Twenty seven patients, referred to the medical clinics of Sahlgren s hospital in Göteborg for examination and treatment of their hypertension have been studied. The clinical examinations included disease and family history physical examination X ray study of the heart, ophthalmoscopic examination of the eyes, ECG test for proteinuria, urine sediment, urine culture pitressin test of the renal ability of urine concentration, urography determination of vanillomandelic acid in the urine and determination of serum creatinine and serum electrolytes. Almost all patients were examined with renal angiopraphy Uric acid and renin were sometimes determined in blood as well as aldosterone in urine.

In sixteen patients twelve men and four women, no obvious cause of the high blood pressure could be found The results from these patients with essential benign hypertension will be presented together Three of them earlier received small doses of hypotensive drugs (betanidine, reserpine hydralazine or saluretics) but all these drugs were withdrawn at least 24 hours before the experiment was done

In four cases, three men and one woman, the high blood pressure was probably of renal origin and the results from them will be commented upon separately two of them had malignant hypertension and were on treatment with hypotensive drugs (reserpine+hydralazine and betanidine respectively) also during the test. Seven patients were excluded from the material for reasons given in Table I

The hypertensive patients were compared with healthy blood donors, matched for sex, age, height and weight. Mean values for these variables in the two groups are given in Table II. The examination of the controls included anamnesis, physical examination of heart and lungs, palpation of radial and brachial pulses, ECG ophthalmoscopic examination of the eyes (by ophthalmologist) determination of electrolytes in serum, protein and glucose in urine, and urine excretion of electrolytes in 24 hours. Four controls were excluded (Table III)

Methods

Hand blood flow was determined by venous occlusion plethysmography and blood pressure measured intraarterially through a catheter in the ipsilateral brachial artery (for details see Paper III) During the whole experiment the patients were exposed to intense indirect heating in order to abolish vasoconstrictor activity to the skin vessels (Pickering 1936 Prinzmetal and Wilson 1936) The heating procedure was used because vasomotor tone to the skin vessels is mainly determined by the thermobalance and therefore of little interest in this connection Furthermore flow resistance in the hand with the patient resting at room temperature is very unstable. The plethysmograph temperature was kept at 33 C. Flow resistance in the hand, measured during indirect heating and at 33 C plethysmographic temperature and expressed as PRU_{100} was called "*basal*" *resistance*

At the end of the experiment *flow resistance at "maximal" dilatation* of the hand vessels was determined by first increasing the plethysmograph temperature to 43° C, followed by 5 min of arterial occlusion with hand muscle exercise to exhaustion. Blood flow was then determined. The highest flow value was taken as maximal blood flow and from this flow value, and the corresponding mean arterial pressure, flow resistance was calculated in PRU_{100}. The quotient between basal resistance and resistance *at maximal vasodilatation is called "basal tone" as it is regarded as reflect*ing the extent of smooth muscle contraction in the hand vessels during basal conditions (*i e* when virtually all vasoconstrictor influence was abolished)

Table I Hypertensive patients excluded from the material

Initials	Reason for exclusion
A.E.	Incomplete clinical examination
V.B.	Suspected primary hyperaldosteronism
G.A.	Suspected primary hyperaldosteronism
L.E.	Too high temperature in the plethysmographs
M.L.	Diabetes and malignant hypertension
E.A.	Unstable basal flow
K.P.	High and oscillating blood pressure, probably due to insufficient baroreceptor function

Table II Anthropometric data

	Mean values		Maximal difference between a hypertensive patient and his control
	Hypertensives	Controls	
Age (years)	43	44	+ 6, −11
Height (cm)	170	172	+ 6, −9
Weight (kg)	75	75	+ 7 −8

Table III Control subjects excluded from the material

Initials	Reason for exclusion
L.O.	High blood pressure
U.A.	Brachial artery thrombosis
R.E.	Unstable basal flow
B.O.	Chronic nephritis

Noradrenaline (0.5 μg per ml in 0.9 per cent saline) was given in stepwise increasing doses through the arterial catheter mentioned above. From the results obtained in this way dose-response curves were constructed with μg noradrenaline per min and 100 ml tissue volume (hand + forearm, since the infusion was given in the brachial artery) given in a loga

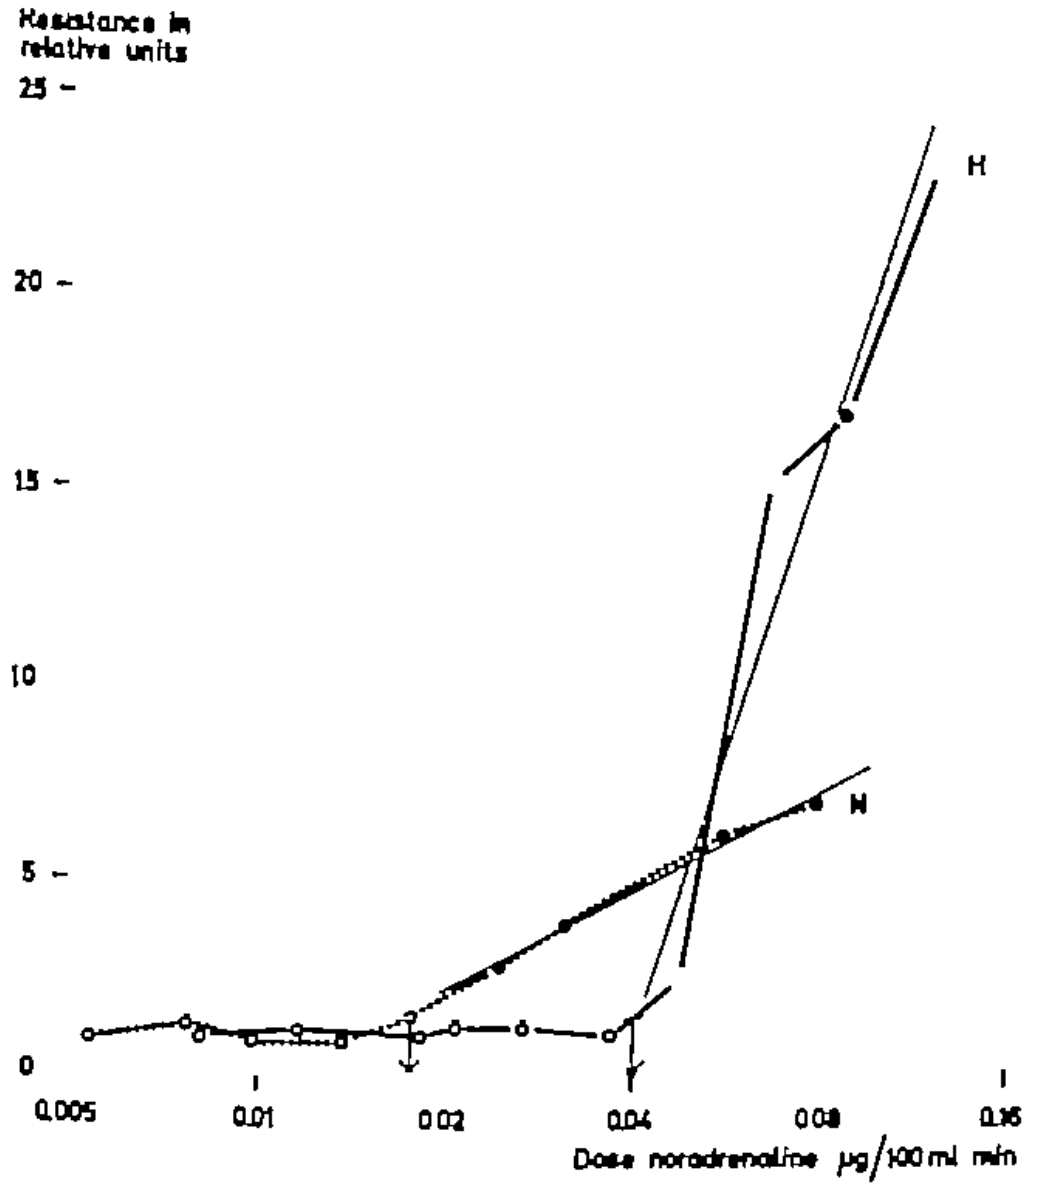

Fig. 8 Dose-response curves from one patient with essential hypertension (H) and his matched normotensive control (N). The regression lines, which characterise the slopes of the curves, are calculated according to the least squares method from the values superior to the threshold (solide circles). The threshold doses are indicated by arrows.

rithmic scale on the abscissa and the actual flow resistance in the hand divided by the basal resistance on the ordinate, since the basal resistance proved to be proportional to the resistance at maximal vasodilatation (p 15) From these curves the *threshold dose* and the *steepness* of the individual dose-response curve were determined in the following way (Fig. 8) The threshold was defined as the dose which produced a fifty per cent increase in resistance compared with the basal resistance. This dose was interpolated from the dose-response curve. The slope was calculated in two different ways. In Paper III the slope of the dose-response curve was given

as the increase in resistance from the threshold up to the resistance at a nor adrenaline dose twice as large as the threshold dose. In the calculations of the slope, presented in Table IV a straight line was adapted to the values above the threshold according to the least squares method (Fig 8) The highest resistance values, corresponding to rather small flow values, were as a rule excluded, as the methodological error in the flow determination here was comparatively large. Attempts were also made to describe the curve with other functions than the straight line, but none of these functions were substantially superior to the straight line.

In all experiments blood flow was simultaneously determined in the opposite hand in order to check that no transient activations of the vasoconstrictor fibres were disturbing the results, *e g* when noradrenaline was given Recordings, where these control measurements in the other hand revealed the presence of intermittently enhanced sympathetic activity were excluded from the subsequent calculations (Fig. 9 see below)

The hypertensive patients and their controls were compared in pairs. Student s t test and Wilcoxon s test (Documenta Geigy 1962 p 191) were used P values less than 0 05 were considered significant*)

Critical aspects of the material and methods

All the controls were blood donors There is, however no reason why they should differ in their blood pressure level and hemodynamic situation from the general population.

Eight essential hypertensives and five controls were smokers. They were not allowed to smoke before or during the test, but three hypertensives (no controls) had done so in the morning before the test. However as the test began at least two hours later there was probably no nicotine effect left at that time. It is unlikely that these differences between the two groups can affect the main conclusions of the study

The crucial question whether it is possible in a physiological study in man to reach a truly maximal vasodilatation of the hand vessels, is discussed later (p 38) as well as the concept of basal tone, as defined above

In the hypertensive subjects, as well as in the normotensive controls, basal hand blood flow was usually comparatively stable. It was, however intermittently reduced in both hands for brief periods (Fig 9) These periods of symmetric flow reduction were probably due to transient bursts of vasoconstrictor fibre activity reaching both vascular beds simultaneously and to an equal extent. The degree of stability of basal blood flow

*) The statistical evaluation of the results was supervised by fil. kand. Bo Eriksson at the Statistical Department of the University of Goteborg.

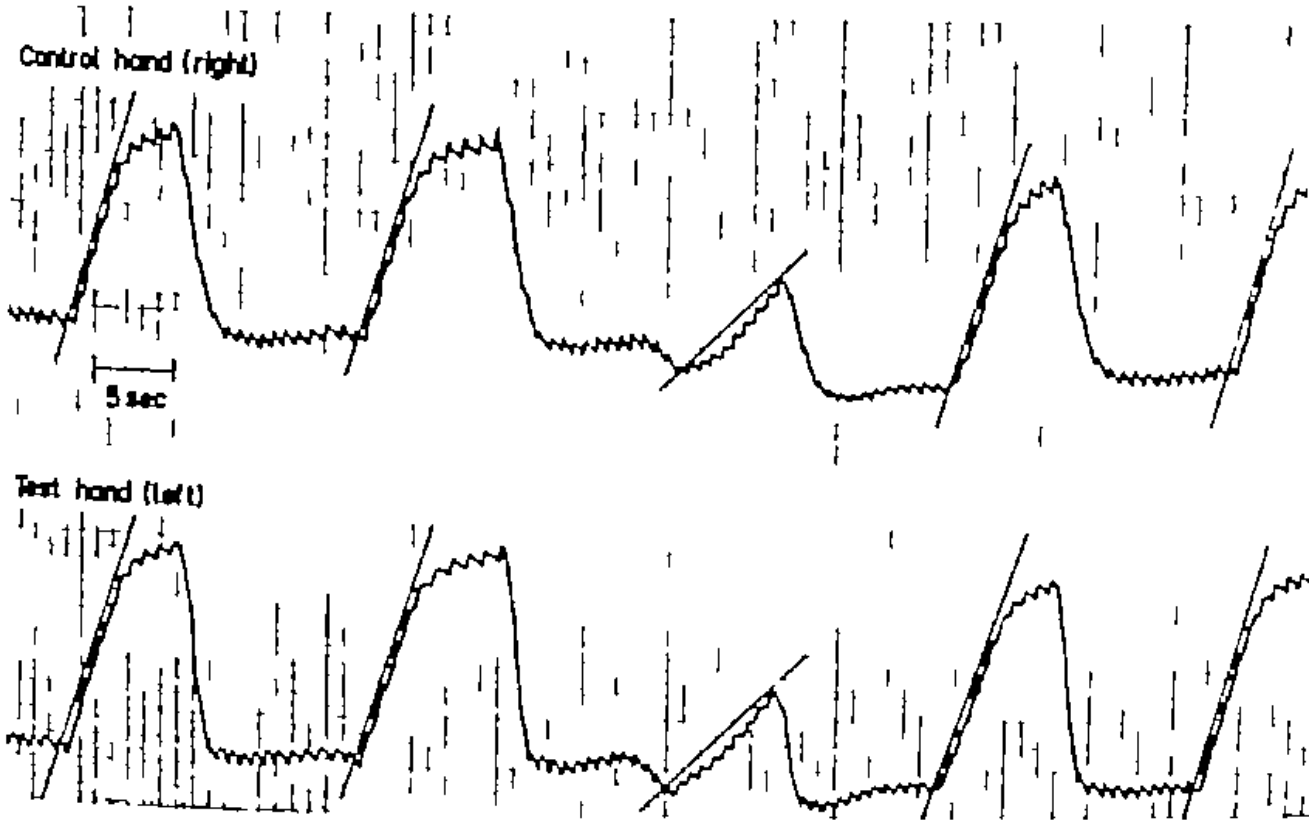

Fig. 9 Plethysmographic recordings of hand blood flow in an indirectly heated control person. Observe the episode of symmetric vasoconstriction in the two hands, probably due to bursts of vasoconstrictor activity to the hands.

varied from one patient to another However only one hypertensive patient and one control had to be excluded from the study because unstable basal blood flow (Table I and III) In order to further eliminate the effect of vasoconstrictor fibre activity such flow determinations were excluded from the calculations, where the control hand indicated the presence of sympathetic activity These exclusions were of the same frequency and changed the flow values to the same extent in the two groups.

If dose-response curves for vasoconstrictor or vasodilator drugs are to be compared in corresponding vascular beds from two subjects along the lines described in this study it is important that the vascular smooth muscles in the basal state display about the same degree of contraction (Duff *et al* 1953) For one and the same type of vessel an increase in resistance from five to ten units is probably neither equivalent to an increase from ten to fifteen nor to an increase from ten to twenty since these changes occur at different levels on the dose-response curves. As will be discussed later there was, however no significant difference in basal tone between hyper

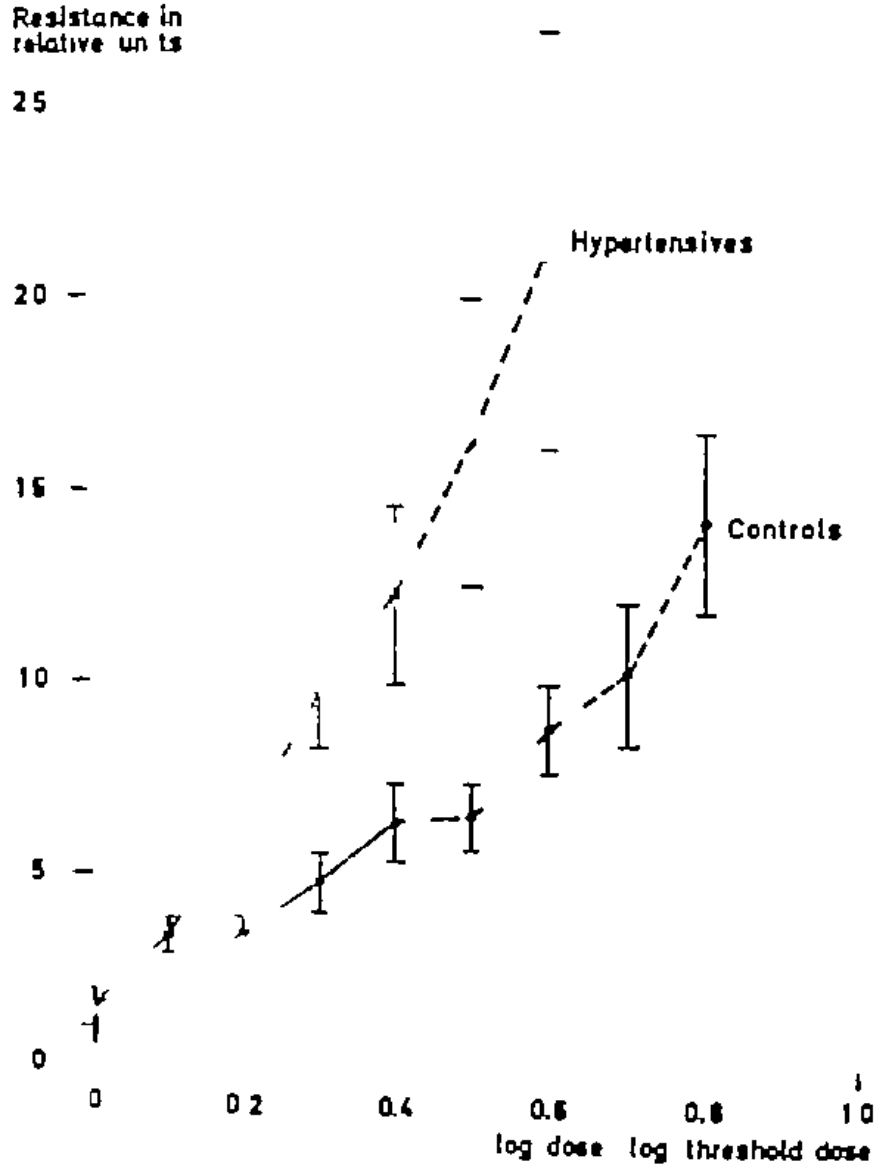
tensives and controls in the present study and therefore the degree of muscle contraction in the basal state can be assumed to be about equal.

Another factor of importance for the interpretation of the dose-response curve is the magnitude of the hand and forearm blood flow during basal conditions. The blood concentration of the drug depends of course not only on the amount of drug injected per time unit but also upon the blood flow into which it is admixed. This is probably the reason for some correlation ($r=0.6$) in the control group between the basal hand blood flow and the threshold of the dose-response curve. Average basal hand blood flow however was equal in the hypertensive and the control groups. Furthermore, when the threshold doses were related to the individual basal hand blood flow values, the slight difference in mean threshold doses between hypertensives and normotensives decreased. The noradrenaline was, however diluted in the total flow passing the brachial artery that is, hand and forearm blood flow together Forearm blood flow was not recorded in the present experiments. The values reported in the literature, for resting forearm blood flow in hypertensives and healthy controls, differ somewhat from one author to another but are as a rule slightly higher in the hypertensive than in the normotensive groups. Therefore, when total blood flow in hand and forearm was calculated from the present flow values for hand and from average figures for forearm blood flow found in the literature, this calculated total flow was somewhat higher in the hypertensives than in the controls, but the difference was only between 0 and 13 per cent. It is therefore probable that the blood flow in which the infused noradrenaline was diluted during basal conditions, was very nearly the same in the two groups.

Results

In Table IV it is evident that there is a large difference between the two groups in flow resistance at maximal vasodilatation a difference that was statistically highly significant. The difference between basal resistance in the two groups was also significant and of the same order of magnitude. This means that the basal tone, reflecting the degree of smooth muscle shortening from maximal dilatation to basal state, was equal in the two groups. The threshold dose showed a slight tendency to be smaller in the hypertensive group than in the control group but the difference was not significant.

In view of the finding, discussed above, that the threshold dose in the control group was correlated to the basal blood flow the individual threshold doses were divided by the corresponding basal hand blood flow



values. The figure obtained in this way can be regarded as a closer estimation of the lowest blood concentration of noradrenaline, which in the individual case produced a barely noticeable vasoconstriction in the hand. When the threshold doses were calculated in this way the difference between hypertensives and controls was reduced from thirteen to seven per cent.

The slopes of the dose-response curves of the hypertensive group and of the control group overlapped to some extent. Some hypertensives had comparatively flat curves, some controls rather steep ones. However when the mean values for the slopes of the lines adapted to the individual dose-response curves were calculated, the value for the hypertensives was much higher than that for the controls, the difference being significant both with Student's t test and with Wilcoxon s test. Figure 10 illustrates the mean dose-response curves for hypertensives and controls, compensated for the differences in individual threshold values. Among the other differences, shown in Table IV those which were significant with Student's t-test, were also significant with Wilcoxon s test, which, unlike the t test, does not call for a normal distribution of data.

In order to test the effect of the duration of the high blood pressure and the effect of different degrees of severity of the hypertensive disease on flow resistance at maximal vasodilatation the patients were regrouped for

Table IV Hand blood flow resistance and its changes during i. a. infusion of noradrenaline in patients with benign, essential and practically untreated hypertension as compared with matched normotensive controls. For definitions and details see text.

	Normotensives n = 16	Hypertensives n = 16	Significance	
			t-test	Wilcoxon test
Mean arterial blood pressure (mm Hg)	100 % (83)	146 % (121)	$P < 0.001$	$P < 0.01$

1 10 Dose sponse curves where the individual differences in threshold value have been eliminated in order to illustrate the difference in slope between hypertensives and controls. On the abscissa is given the logarithm for the dose minus the logarithm for the threshold dose, on the ordinate the resistance as a multiple of basal resistance. Means ± SEM are given for 16 patients with benign essential hypertension and 16 matched controls (the solid lines). The dashed lines represent reduced numbers of persons, between 9 and 15. For details see text.

comparison in two different ways. Firstly they were divided into three subgroups in group 1 the high blood pressure had been known for less than 2 months in group 2 for more than 2 months but less than 2 years, and in group 3 for more than 2 years. Secondly the patients were grouped in stages according to the recommendations of a WHO expert committee (1962) Table V gives the blood flow resistance in the hand at maximal dilatation for the hypertensive groups compared with their matched controls.

Table I Blood flow resistance in the hand at maximal vasodilatation in patients with benign essential hypertension as compared with matched controls. The patients were grouped in three groups according to the known duration of the high blood pressure. They were also grouped in WHO stages.

Known duration	n	Normotensives	Hypertensives
< 2 months	7	100 % (1.77)	125 % (2.20)
2 months – 2 years	2	100 % (1.30)	203 % (2.64)
> 2 years	7	100 (1.59)	195 % (3.11)
WHO stage			
I	7	100 % (1.54)	178 % (2.74)
II	7	100 % (1.80)	138 % (2.49)
III	2	100 % (1.36)	213 % (2.90)

Table II Hand blood flow resistance and its changes upon i.a. infusion of noradrenaline in patients with renal hypertension as compared with matched normotensive controls. Two patients had malignant hypertension and were treated with hypotensive drugs. For definitions and details see text.

	Normotensives n = 4	Hypertensives n = 4
Mean arterial blood pressure (mm Hg)	100 % (82)	138 % (113)
Resistance at maximal dilatation (PRU_{max})	100 % (1.8)	150 % (2.7)
Basal resistance (PRU_{ba})	100 % (3.8)	161 % (6.1)
Basal rate	100 % (2.1)	110 % (2.3)
Noradrenaline threshold dose (μg/100 ml min)	100 % (0.032)	128 % (0.041)
Steepness of noradrenaline dose-response curve	100 % (4.4)	150 % (6.6)

The subgroups are too small to permit valid statistical analyses, and the durations are, of course, not entirely safeguarded in this way but there is a tendency towards increasing flow resistance at maximal dilatation with increasing known duration of the high blood pressure. It is also interesting to note the comparatively high flow resistance in the group with the mildest disease and even in the group with a known duration of less than 2 months.

The results from four cases with renal hypertension and their matched controls are given in Table VI Two of these patients had malignant hypertension and were treated with hypotensive drugs.

This material is too divergent and too small to permit safe conclusions, but there is a tendency here too towards an increased basal resistance as well as resistance at maximal dilatation in the hypertensive group It should be observed that in Table VI the slope is calculated in a somewhat different way from that used in Table IV (*i. e* in the same way as was done in Paper III see the present text p 31) and therefore the absolute figures for steepness are not directly comparable in the two tables.

Discussion

Flow resistance at maximal dilatation

The findings in this study dealing with the hand vessels, strongly indicate the presence of structural changes in the resistance vessels as the cause of the higher resistance at maximal dilatation in patients with benign essential hypertension. Studies by Folkow Grimby and Thulesius (1958) and by Conway (1963) indicate that the same is true also for the forearm vessels. Data given by Pickering (1936) Prinzmetal and Wilson (1936) and Stead and Kunkel (1940) on forearm blood flow can also be taken to support this opinion though the interpretation given by these authors at that time was different. Results concerning the cerebral blood flow (Stead and Kunkel 1940 and Novack *et al* 1953) point in the same direction (see Table VII)

A possible objection to this opinion would be that in the present study the vascular muscles might after all not have been completely relaxed at maximal dilatation and, if so the remaining tone might be different in the two groups. Such a tone could then hardly be explained by an increased vasomotor nerve activity as all the experiments were performed during indirect heating which is known to produce an almost complete inhibition of the activity in these nerves in both normotensive and hypertensive subjects (Pickering 1936 and Prinzmetal and Wilson 1936)

As for the idea of a circulating vasoconstricting substance as the cause of a residual tone it must be stressed that such a substance would then have to be quite unique in its ability to withstand the measures in the experimental procedure for establishing maximal dilatation. Thus, model experiments in two control subjects (Fig 11) showed that this procedure completely eliminated the effects of noradrenaline, when given intraarterially even in amounts two to three times as large as those which during basal conditions increased resistance more than 200 per cent.

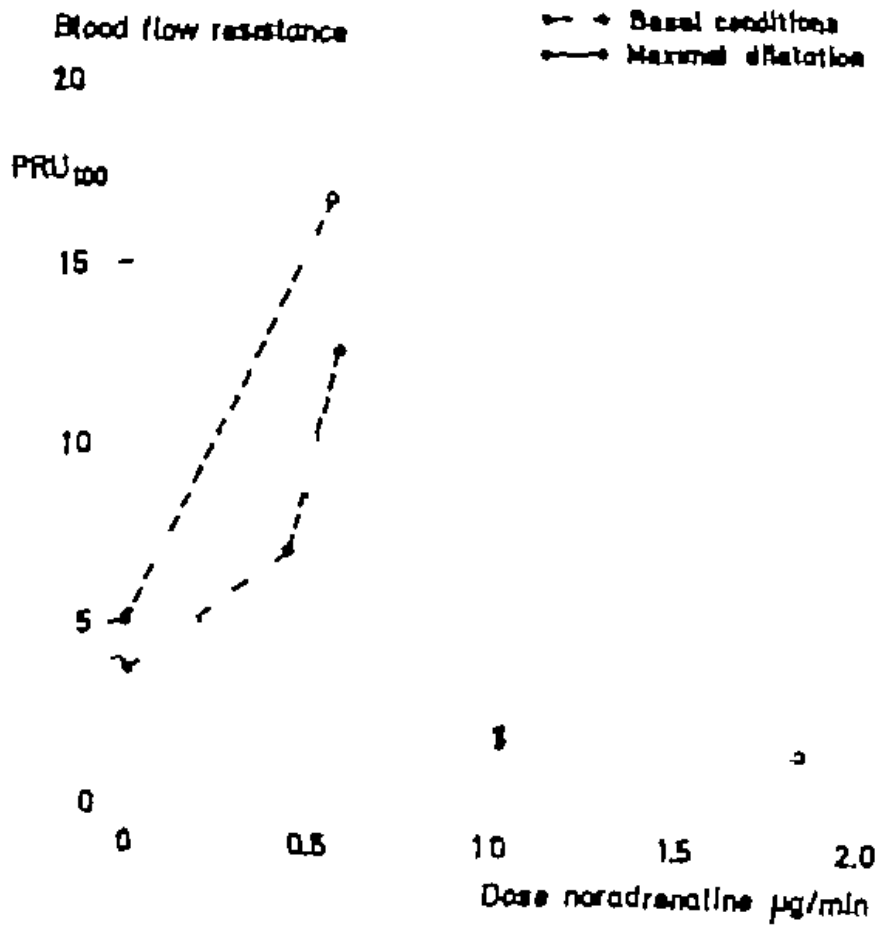

Fig 11 Effect of noradrenaline, given intraarterially on hand blood flow resistance during basal conditions and maximal dilatation in two healthy controls.

Likewise model experiments with angiotensin exclude this substance as a possible cause of the increased resistance at maximal dilatation since its effect is abolished by indirect heating alone. Fig. 12 shows one of two similar experiments, in which angiotensin was given intravenously to a healthy subject in amounts which increased systemic mean blood pressure about 30 per cent. When the subject was in "normal" thermoequilibrium at room temperature hand blood flow resistance increased about 100 per cent when angiotensin was given but when the same, and even the double, amount was given with the subject indirectely heated, hand blood flow resistance remained unchanged despite a 30 per cent increase in mean arterial pressure. The effect of angiotensin during ordinary thermal equilibrium is in agreement with results of Brod *et al* (1969) who observed that angiotensin given intravenously to resting patients at room temperature reduced skin blood flow despite a rise in blood pressure.

One explanation of the present findings on the indirectly heated patients may be that a great part of the angiotensin effect on skin vessels is medi-

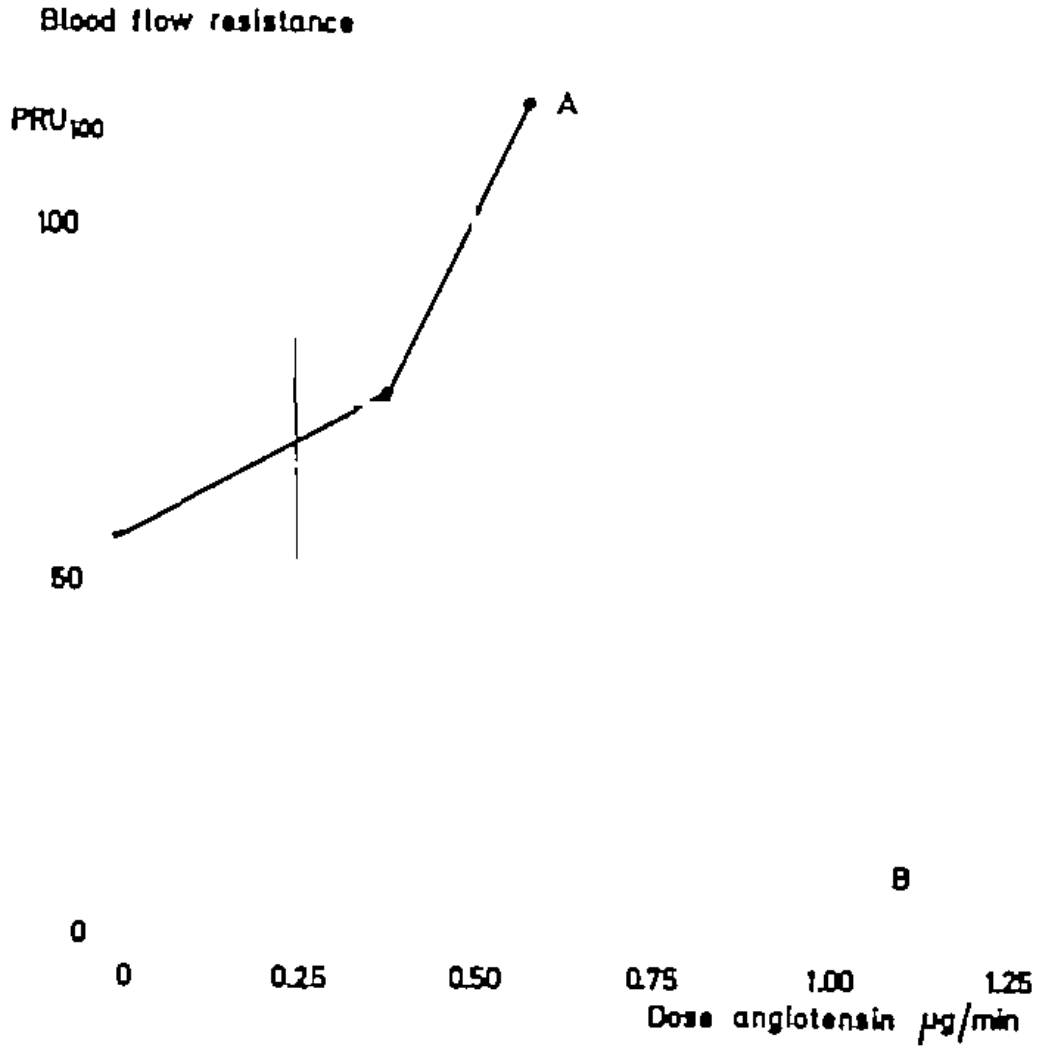

Fig. 12. Effect on hand blood flow resistance of angiotensin given intravenously to healthy person, resting at room temperature (A) and indirectly heated (B).

ated by the vasoconstrictor fibres, the activity of which is inhibited durir indirect heating. Johnsson, Henning and Åblad (1965) could block major part of the angiotensin effect on the hand blood vessels by pher benzamine and guanethidine. Therefore a neurogenic increase of tone, as caused by the possible presence of increased amounts of sin, could not be determined in the present experiments, since the genic influence was eliminated by the indirect heating. However follows that such a factor cannot be the cause of the increased f stance at maximal vasodilatation in the hand found in the pres ments.

Even if the extensive accumulation of vasodilator influen produce maximal dilatation were unable to fully block the circulating vasoconstrictor substance, this substance would be

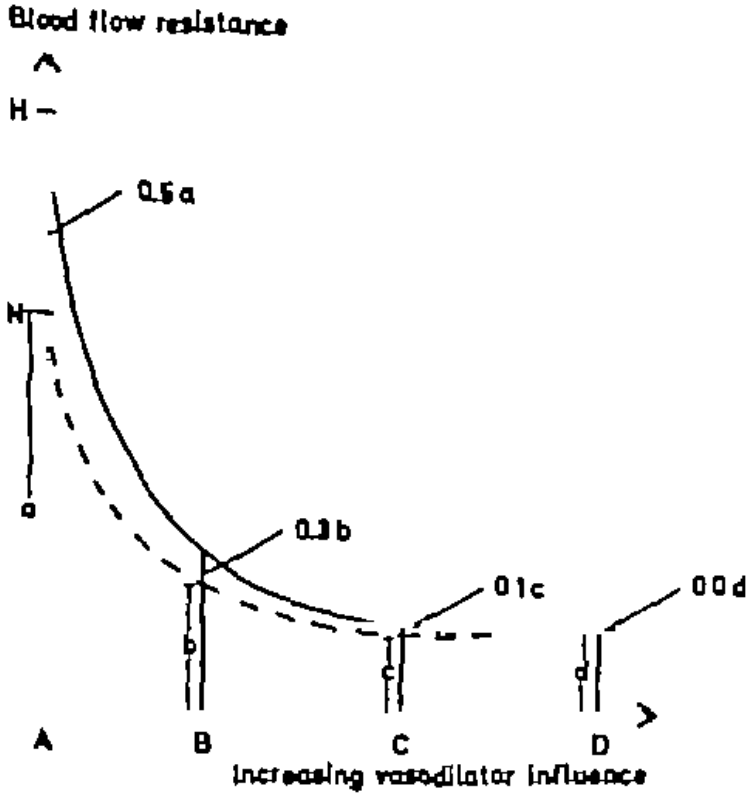

Fig. 13 Hypothetical curves illustrating the effect of increasing vasodilator influence on normal vessel (N) and on another vessel (H) which is exposed to constant vasoconstrictor activity e.g. a circulating pressor substance. At A (basal condition) resistance is supposed to be 50 per cent higher in H than in N, but at maximal dilatation D resistance is equal in the two beds. During submaximal dilatation the percentual increase in resistance produced by the vasoconstrictor acid Iry in H must be somewhere between 0 and 50 per cent. This means that even if the procedure for maximal dilatation produces only submaximal vasodilatation, basal tone, calculated as defined in the text, will still be higher in the vascular bed exposed to vasoconstrictor influence than in the other one, see the table below

	Basal tone	
	N	H
D (maximal dilatation)	a/d	1.5a/d
C (submaximal dilatation)	a/c	1.5a/1.1
B (" ")	a/b	1.5a/1.3b

exert greater vasoconstrictor effects during basal conditions than during dilatation (Fig 13) thus producing a high "basal tone" Basal tone was, however found to be equal in the two groups.

Reports in the literature support the opinion that the procedure used in the present study to relax the vascular smooth muscles is very effective Krog *et al.* (1960) used a similar method to dilate the hand vessels maximally They had the same high plethysmograph temperature and increased the length of the ischemic period in a stepwise fashion until blood flow fell

not increase any further This means that the maximal dilator response had been reached by way of the naturally occuring vasodilator metabolites which are known to be very effective. The authors found maximal blood flows of the same magnitude in healthy persons as was found in the present study *i e* about 60 ml per minute and 100 ml tissue. It is not possible to reach the same high flow levels by pharmacological means. The highest flow values reported by Duff *et al* (1953) with intraarterial administration of high doses of acetylcholine and histamine was 15—30 and 20—40 ml per min and 100 ml tissue, respectively High doses of adenosine triphosphate increased hand blood flow maximally to between 25 and 55 ml per min and 100 ml tissue (Duff Patterson and Shepherd 1954)

An increased blood viscosity in hypertensive patients is a theoretically possible explanation of the increased flow resistance during basal conditions as well as during maximal vasodilatation in this group of patients. However most authorities seem to agree that blood viscosity is largely normal in well-established hypertension (Pickering 1968 pp 179—180) Tibblin *et al* (1966) observed in a small number of hypertensive subjects a 20—25 per cent increase of blood viscosity *in vitro* which seems somewhat surprising, since the difference in both plasma viscosity and hematocrit were only minor Recent comparisons of blood viscosity *in vivo* and *in vitro* indicate, however that *in vitro* values are much higher and also exhibit much larger spread than *in vivo* values (Djojosugito *et al* 1970) For such reasons it is difficult at present to evaluate the true relevance for the *in vivo* situation of a small or moderate difference in blood viscosity as measured *in vitro* Whatever the case, an increase of blood viscosity would have to be in the order of 60 per cent to explain the whole increase in resistance at maximal dilatation and would not explain the increased vascular reactivity observed (see below)

As pointed out on page 18 many different types of structural change in the vascular bed may explain an increased resistance at maximal vasodilatation. However an increased wall/lumen ratio is the only single change which can also explain the increased slope of the dose-response curve

The fact that the blood vessels could be dilated also in hypertensive patients (Prinzmetal and Wilson 1936, Goldring *et al* 1941) may be an argument against a quantitatively important sclerosis of the resistance vessels, leading to a rigidity of their walls, but it is no argument against other types of morphological changes of the vessels. In fact, an increased wall/lumen ratio due to vascular smooth muscle hypertrophy and/or an increase of other normal wall tissue elements inside the vascular smooth muscle sheath, will increase vascular reactivity rather than decrease it (Folkow

1956 Folkow Grimby and Thulesius 1958 Paper I and Paper II) The claim that histological changes cannot be seen in all vascular regions and not in all patients with hypertension (Pickering 1936 Moritz and Oldt 1937 Duff 1957) is likewise no valid argument, because most methods for demonstration of a true wall/lumen change are rough and inadequate to estimate minor changes. It should be stressed that even small shifts of the inner radius of the vessel have large effect on flow resistance, as this is inversely proportional to the fourth power of the radius. Furthermore most morphological studies of the vessels in hypertensive vascular disease have dealt with qualitative changes in the vascular wall instead of quantitative changes in the normal constituents of the vascular wall, which are much more difficult to evaluate. The absence of an increased vascular reactivity in Raynaud's disease is, of course, no argument against structural changes of major hemodynamic importance in hypertensive patients, as Mendlowitz *et al* have claimed (1962) since the nature of the vascular changes present Raynaud's disease may differ fundamentally from that in hypertension.

Basal vascular tone

The finding of a largely normal basal tone in patients with benign essential hypertension indicates that significantly increased amounts of direct acting circulating constrictor agents, or other factors causing vascular smooth muscle excitation, cannot be present during the prevailing experimental conditions. They would then have elicited an increased basal tone, even if the dilatation were not truly maximal (p. 40 Fig. 13) This does, of course, not exclude the possibility that in other situations such factors may be involved, being then superimposed on the structurally based increase of flow resistance. Thus, in hypertensive patients during daily life, there might occur at least intermittently an increased vasomotor fibre activity which in this study was largely inhibited by the indirect heating (p. 29)

As Gaskell and Diosy (1959) pointed out, the increase in critical closing and critical opening pressures in the fingers of hypertensive patients after sympathetic nerve blockade (Yamada and Burton 1954 Gaskell and Kruman 1958 Gaskell and Diosy 1959) does not necessarily imply an increased activity level of the individual smooth muscle cells. It may as well be due to some kind of wall thickening, *e g* edema, or smooth muscle hypertrophy in the arteriolar wall.

The concept of an increased smooth muscle tone, as caused *e g* by circulating pressor substances, has been widely accepted as the main hemodynamic factor behind the increased blood pressure in essential hyperten-

sion although no one has definitely proved the existence of such an increased tone. Such a proof would call for a determination of flow resistance both at maximal dilatation and at rest relating these to each other as proposed by Folkow in 1956 Quite contrary to the widely accepted but unproved concept of an increased smooth muscle tone in hypertension many data given in the literature, when recalculated from this point of view indicate that vascular tone at rest is normal in hypertension and that in the forearm it may even be lower in hypertensive patients than in normal subjects (Table VII) One would expect the quotient between the flow resistance at rest and during maximal dilatation to be higher in the hypertensives than in the controls in case smooth muscle tone had really been increased, even if the vasodilatation were submaximal (Fig 13)

Threshold to noradrenaline

The threshold dose of noradrenaline was not significantly different in the two groups, even though it tended to be slightly smaller in the hypertensive group However because the threshold dose was defined as the dose which gave a significant vasoconstriction (50 % increase of resistance) the tendency to a lower threshold in the hypertensive group might simply be due to the steeper dose-response curve in this group Further after compensation for the individual differences in basal flow the slight difference in mean threshold values for the two groups was almost abolished. Thus, there was no evidence of any increased sensitivity of the vascular smooth muscles to noradrenaline in patients with essential hypertension.

The normal noradrenaline threshold in the hypertensive group is hardly compatible with the hypothesis that the fundamental fault in essential hypertension should be a more or less blocked noradrenaline pump reuptake in the nerve endings. Such a block would probably decrease the noradrenaline threshold (e g Svedmyr 1968)

Slope of dose response curve for noradrenaline

The increased slope of the dose-response curve in the hypertensive group is in good agreement with what one would expect to find if the wall/lumen ratio in the resistance vessels were increased, whether this were due to smooth muscle hypertrophy or to hypertrophy of other wall elements situated inside the smooth muscle sheath A possible "water logging" of the arteriolar walls would have the same effect (Tobian and Binion 1952) but there is little evidence of this type of change in essential hypertension. However there may be other explanations also as discussed on page 19 but as mentioned earlier these explanations are for various reasons unlikely As

Table VII Data taken from the literature and recalculated according the principles adopted in the present study Resistance during — often *submaximal) — vasodilatation (C) and at rest (B) is regularly higher in the hypertensive than in the normotensive groups. Vascular tone t rest* (B/C), which is calculated in an analogous manner to basal tone in the present study is usually of the same order in the two groups. (E = essential hypertension; R = enal hypertension; A = primary hyperaldosteronism; Mal. = malignant hypertension, Mixed = mixed group).

to a decreased reactivity to vasodilator metabolites in hypertensive patients, there are experimental results speaking against this possibility (Abramson and Fierst 1942) The vessels of hypertensive patients dilate as readily to e g brief periods of ischemia or exercise as do the vessels of normotensive subjects.

Most previous investigators have used only a single or a few doses of constrictor drugs in testing vascular sensitivity and reactivity Usually they have not differentiated between a true increase of sensitivity i e a decreased threshold as combined with a parallel shift of the dose-response curve to the left, and an increased slope of the curve. It is then impossible to say whether the vascular smooth muscles display any increased sensitivity it can only be stated that the vessels are more reactive, but this can as mentioned, be due to very different mechanisms.

In studies by Duff (1957) Doyle, Fraser and Marshall (1959) Scroop and Whelan (1968) more complete dose-response curves were given. In Duff's experiments the hypertensives generally showed steeper dose-response curves than the normotensives, but this was apparently not the case in the experiments performed by Doyle. In both studies there was a tendency towards a decreased threshold in the hypertensive group Scroop and Whelan found no difference at all between hypertensives and controls.

Part of the explanation of the discrepancy between these and the present results may be technical. It seems, for instance, preferable to analyse separately the thresholds and slopes of the individual dose-response curves and then use these values in the calculations, instead of calculating mean curves for the hypertensive and control groups as did the authors mentioned above According to the experience gained in the present study, [illegible] differences in threshold within the groups are rather large. [illegible] where som subjects showed quite marked responses, others had [illegible] to react. In such conditions it would not be appropriate [illegible] "mean" curves according to the principles applied [illegible] Furthermore, Duff's study has been criticized because [illegible] did not correspond in age and sex to the hypertensives [illegible] performed their study on patients on current [illegible] pressure and this may of course seriously [illegible] material was furthermore small, and it also [illegible] sex to the hypertensives.

Another question, which has not been co[illegible] the effect of an increased basal smooth [illegible] curve. It is difficult to predict how such an [illegible] curve and if no attempt has been made to [illegible]

two groups is equal, as was done in the present experiments, it is difficult to evaluate the significance of differences in response. The similarity in basal tone found in the present study in the two groups of subjects indicates that the dose-response curves were performed from about equal initial states of vascular smooth muscle activity. This fact greatly facilitates the interpretation of the results.

Conclusions.

The present finding of an increased resistance at maximal dilatation combined with a normal basal tone, in agreement with previous observations by Folkow, Grimby and Thulesius (1958) and by Conway (1963) strongly suggests the presence of hemodynamically important morphological changes in the resistance vessels of patients with essential hypertension. The observation of an increased slope of the dose-response curve combined with an essentially unchanged threshold to noradrenaline also lends support to this idea. When taken together these findings indicate *the presence of a wall thickening in the resistance vessels of such a nature that it encroaches upon the lumen even at maximal dilatation and causes an increased wall/lumen ratio*.

Such a structural change, which may be a simple expression of the normal tendency of tissues to respond with adaptive hypertrophy to increase load (see Paper II), will freely allow for a completely normal, perhaps even enhanced, range of vasodilatation — vasoconstriction but from a "raised baseline". If generalized the change may in fact account for the major part of the rise of resistance in the resting equilibrium of well-established essential hypertension. None of the alternative factors discussed above can alone explain *all* the experimental findings. Moreover several of them are highly hypothetical or even unlikely, while the presence of "hypertrophic" changes in arterial-arteriolar walls can hardly be doubted. It is striking however that the important hemodynamic consequences of such changes have been largely overlooked, until attention was drawn to the fact that both the resistance at maximal dilatation and the entire range of vascular adjustments will be "reset to a higher level" by such changes and that hypertensive subjects indeed display a raised flow resistance also at maximal dilatation (Folkow 1956, Folkow, Grimby and Thulesius 1958, Conway 1963).

SOME ASPECTS OF THE PATHOGENESIS OF VASCULAR CHANGES IN HYPERTENSION

In essential hypertension many causative factors have been discussed, but up to now no single cause of the elevated blood pressure has been definitely demonstrated It is generally agreed upon that this, by far the most common type of high blood pressure, has a distinct genetic element (see Pickering 1968 p 236) Even if the genetic element is one factor it is likely that several factors are involved to establish this disease, and the pressure level *no doubt is the resultant of a great number of influences* (Page and McCubbin 1965) Two factors, which may be of particular importance for the pathogenesis of essential hypertension, will be discussed below

The cardiovascular system in healthy persons as well as in hypertensive patients, is normally exposed to a sympathetic nervous tone, which varies from one moment to another For many reasons, particularly because of the impact of psycho-emotional factors, initiated at cortico-hypothalamic levels, large variations in blood pressure also occur in subjects with normal blood pressure as a normal effect of the "stress of daily life" (Hinman Engel and Bickford 1962, Pickering 1968 p 53 Bevan, Honour and Stott 1969)

It is possible that the vascular changes in essential hypertension are caused by an intermittently increased nervous drive on the cardiovascular system, as a result of a more or less stressful environment It is also possible that there exists a hereditary tendency of the highest autonomic centres to respond in an especially marked manner in terms of efferent discharge, to *per se* ordinary stress situations of daily life (Hines and Brown 1933) If the response to stressful situations are mimicked in rats by weak but often repeated electric hypothalamic stimulations in the defence area, this will gradually lead to hypertension which remains during periods when no stimulations are performed (Folkow and Rubinstein 1966) Furthermore, if the living conditions for mice are so arranged as to lead to repeated stressful situations, this produces high blood pressure, which persists for at least a month after the stimulus is eliminated (Henry Meehan and Stephens 1967) There is no contradiction between such a view concerning the role of the autonomic nervous system and the observations by *e g* Prinzmetal and

Wilson (1936) and Pickering (1936) and others, who found that the el v tion in peripheral resistance in resting subjects persisted after sympath nervous blockade and therefore concluded that the high flow resistance this situation could not be explained by an increased vasomotor activit Naturally such a measurement does not take into account the possibility o an intermittently increased vasomotor activity during daily life. Such factor may well constitute the trigger mechanism for the gradual development of other changes, particularly structural adaptations of the resistance vessels in the direction of an increased wall/lumen ratio

Another possibility has been stressed by Folkow (Folkow 1956 1961 Folkow Grimby and Thulesius 1958) Suppose there is a genetically bound disposition in patients with essential high blood pressure to develop vascular smooth muscle hypertrophy and other adaptive structural changes in the resistance vessels more readily than "normal" persons. Such a disposition might be one of the expressions of an increased "mesenchymal endowment" (Backer 1956) which in other respects seems to reveal itself in subjects with essential hypertension as a 'mesomorphic' body build (Robinson and Brucer 1940) If so adaptive vascular changes might develop as a response to vasomotor and other stimuli on the cardiovascular system, which are *per se* fully normal in both magnitude and duration. Furthermore, in hemodynamic studies in rats with genetically based high blood pressure (Folkow *et al.* 1970 a, b) the same type of changes were found to be generalized to the entire systemic vascular bed as those that have been observed in the present study on the hand of patients with essential hypertension. Thus, these rats with "primary" hypertension display an increased resistance at maximal vasodilatation, a normal threshold to noradrenaline, an increased slope of the dose-response curve and an increased maximal contractile strength of the resistance vessels. All these findings are in complete accord with the hemodynamic consequences of an increased wall/lumen ratio in the resistance vessels and such a change seems to be the only single factor which can explain them If this hypothesis were correct, *i. e.* if the increased tendency to exhibit morphological vascular changes would constitute the genetic element, then such changes should be looked upon not just as a consequence of the rise in blood pressure but as the *primary* factor in the pathogenesis of essential hypertension.

GENERAL SUMMARY AND CONCLUSIONS

The study has been concerned with the hemodynamic importance of structural vascular changes in essential hypertension particularly the hemodynamic effects of an increased wall/lumen ratio in the resistance vessels.

In Paper I two kinds of vessels in the cat's hind paw were compared cutaneous A—V shunts which have thick walls and a high wall/lumen ratio and "nutritional" resistance vessels, with relatively thinner walls. Blood flow resistance was measured during stepwise increases in dosage of noradrenaline, infused intraarterially or intravenously and stepwise increasing frequencies of vasomotor nerve stimulation. When dose-response curves were calculated there was found to be no difference in threshold indicating an equal noradrenaline sensitivity of the smooth muscles in the two types of vessels, but once the threshold was surpassed the vascular bed rich in thermoregulatory A—V shunts exhibited a much steeper curve than the bed mainly consisting of "nutritional" resistance vessels. An increased slope of the dose-response curve must be expected from a theoretical point of view in vessels like A—V shunts as a consequence of the high wall/lumen ratio

In Paper II the rebuilding of a vascular bed due to a changed intravascular pressure was studied. The arterial inflow to one hind limb the test limb of the cat was reduced some 30—40 per cent by arterial ligatures. After 3—5 weeks the test limb was compared with the "normal limb at the same perfusion pressure and otherwise identical conditions. As in Paper I blood flow resistance was measured during graded vasomotor nerve stimulation and graded intraarterial noradrenaline infusion and the thresholds were found to be the same in the two legs, indicating an identical smooth muscle sensitivity to noradrenaline However for doses exceeding the treshold, the response was significantly smaller in the test limb implying a decreased slope of the dose-response curve in the leg which had been exposed to hypotension These findings suggest that a hemodynamically important structural change with a decreased wall/lumen ratio in the resistance vessels takes place already within 3—5 weeks in a vascular bed exposed to a moderate hypotension These structural vascular changes, which go in the opposite direction to those seen in hypertension, may be considered as an inactivity atrophy consequent to the compensatory de-

crease in smooth muscle tone in the resistance vessels [illegible] d perfusion pressure.

In Paper III sixteen patients with benign essential [illegible] re compared with sixteen matched controls (sex, age, hei[illegible] d flow resistance in the hand was determined in vari[illegible] plethysmography and intraarterial blood pressure mea[illegible] *mal vasodilatation resistance* was increased in the hyp[illegible] om pared with the controls in the same proportion as the [illegible] that is about 50 per cent. This finding, which strongly [illegible] tural changes in the vascular bed, implies that, for identical [illegible] nooth muscle shortening, flow resistance will always be about [illegible] gher in the hypertensive group. Resistance during indirect hea[illegible] d *basal resistance* was also about 50 per cent higher in the hype[illegible] than in the controls. This means that *basal tone* which was defin[illegible] mal resistance divided by the resistance at maximal dilatation [illegible] which was thought to reflect the degree of smooth muscle shortening [illegible] maximal vasodilatation to the basal state, was the same in the two group[illegible]

This finding is contrary to the common opinion that blood flow resistance in essential hypertension is increased because of an increased smooth muscle activity. However as basal resistance was recorded during indirect heating, which implies almost complete vasomotor blockade, basal tone has no bearing on the question of an increased vasomotor tone to the vessels, produced e. g. by angiotensin.

Blood flow resistance was also measured during graded infusions of noradrenaline intraarterially and dose response curves were plotted. The *smooth muscle sensitivity* in the resistance vessels, as expressed by the *threshold* was equal in the two groups, but the *slope of the dose response curve* was considerably increased in the hypertensive patients, and this fact may explain the increased vascular reactivity observed in patients with high blood pressure.

The increased slope of the dose response curve and the increased resistance at maximal dilatation, in combination with the normal basal tone and normal noradrenaline threshold, strongly indicate hemodynamically important structural changes of a nature which increases vascular wall thickness and partly encroaches on the lumen at maximal dilatation. If other vascular beds are structurally changed in the same degree as the hand vessels, these morphological changes may almost completely explain the increase in peripheral resistance observed in cases of established essential hypertension.

Such changes can not be considered as late complications to the high

blood pressure, as they are also seen in patients with high blood pressure known for less than two months and in patients with mild degrees of high blood pressure, belonging to WHO stage I The animal studies discussed in Paper II also indicate that adaptive structural changes in the vessels take place very quickly

It is probable that any situation where vascular smooth muscle activity is increased, with or without blood pressure elevation, can cause adaptive structural changes in the vessels. In such a case a primary blood pressure elevation may become permanent and potentiated due to structural changes. An alternative hypothesis concerning the pathogenesis of the structural vascular changes in essential hypertension is that the basic fault in this disease would be a hereditary increased tendency to smooth muscle hyper trophy as one expression of a mesomorphic" body build (Folkow 1956)

APPENDIX 45

INTRODUCTION

In study of the left atrial receptors of the heart, note has been taken of the correlation between the atrial pressure and the vagal afferent nerve impulses. It has been demonstrated that a linear correlation exists between the atrial volume and the average frequency of discharge of B-type left atrial impulses (PAINTAL 1953 a)

The relationship between the mean femoral artery pressure and the average frequency of impulses in the splanchnic nerve has been analysed quantitatively (MILLAR and BISCOE 1965) A positive inverse correlation was found between these two variables.

The dependence of the sympathetic efferentation upon direct or indirect baroreceptor stimulation has been shown by several workers (ADRIAN 1933 BRONK et al. 1936, GREEN 1959 DOWING and SIEGEL 1963) A positive inverse correlation has been found between the average frequency of impulses of the sympathetic nerves and the carotid sinus pressure (SPICKLER, KEZDI and GELLER 1965)

In the present work an attempt has been made to examine the v-wave of the left atrial pressure curve as a function of time and the corresponding number of B-type impulses (preliminary results HAKUMÄKI et al. 1968) Although the ventricular filling is only partially and to a varying extent regulated by atrial filling and contractility the sum of B- and A type impulses was determined and correlated with the relative stroke volume of the left ventricle

The neural regulation of the heart from cycle to cycle was studied by simultaneous recordings of left atrial vagal afferent and third sympathetic postganglionic efferent nerve impulses under conditions of raised (preliminary results HAKUMÄKI 1968, 1969) and lowered left atrial pressure.

SURVEY OF LITERATURE

In a study of the vagal afferent impulses from the neck of a cat, ADRIAN (1933) found that a slender nerve could easily be separated from the trunk of the vagus and that this had impulses associated with the rhythm of the heart. The impulses were increased by raising, and diminished by lowering the blood pressure The cardiac vagal afferent nerves have been studied by WHITTENRIDGE (1948) and JARISCH and ZOTTERMAN (1948), who demonstrated that these impulses had their origin in the atria and large veins. According to JARISCH and ZOTTERMAN two types of impulses existed one appeared during atrial filling, and the other during atrial contraction PAINTAL (1953 a) named these impulses B- and A types, and showed that the average frequency of discharge of the B-type impulses bears a linear correlation to the volume of haemodynamically isolated atrium. PAINTAL (1953 b) also found that the number of right atrial B-type impulses in a cardiac cycle is linearly correlated with the venous pressure when the pressure is raised with pituitrine. In his monograph, PAINTAL (1963 a, p 114) states that a positive correlation exists between the number of left atrial B-type impulses per cardiac cycle and the difference in peak pressure and threshold pressure of the atrial pressure curve

Atrial A-type impulses have been studied by DICKINSON (1950) who found a linear correlation between the "frequency of discharge per second" and the atrial pressure. KOLATAT KRAMER and MÜHL (1957) found a positive correlation between the number of A type impulses and the peak pressure during atrial contraction

The cardiac minute output and the number of B-type impulses per minute have been investigated by LANGREHR and KRAMER (1960) who did not find any distinct correlation. However they demonstrated a distinct positive correlation between the number of B-type impulses per minute and the thoracic blood volume According to LANGREHR (1960) a positive correlation exists between the stroke volume per duration of systole and the relative frequency of B-type impulses.

The sympathetic efferentation has been studied by ADRIAN, BRONK and

PHILIPS (1932) They found in cats and rabbits that the activity of cervical and abdominal sympathetic nerves underwent a change with the frequency of the heart beats or of the respiration. This finding was supported by the work of BRONK et al. (1936) who found both "tonic" and "grouped" activity in cardiac sympathetic efferent nerves. Asphyxia increased the tonic activity while hyperventilation and a rise in blood pressure reduced it. The grouped activity was similar in the right and left cardiac sympathetic nerves, and was diminished by stimulation of the aortic nerve. GREEN (1959) has also demonstrated that stimulation of the baroreceptors depressed the efferent sympathetic activity and induced bradycardia. The activity of the left inferior sympathetic cardiac nerve has been investigated in cats by DOWNING and SIEGEL (1963), who reported that the spontaneous activity in the nerve varies with the rhythm of the heart and of the respiration. Bilateral vagotomy and carotid sinus denervation were found to increase the influence of the respiration upon the sympathetic discharge. They also suggested that systemic hypoxia has little effect upon the cardiac sympathetic centre. Sympathetic cervical and splanchnic efferent activity has been studied by MILLAR and BISCOE (1965) with anaesthetized rabbits. They indicated four types of activity (1) Spontaneous activity with respiratory rhythm, inhibited partially or completely with a rise in the arterial pressure induced by intravenous adrenaline, (2) an irregular spontaneous activity without relation to respiratory or arterial blood pressure with the possibility of increasing the activity of the nerve by adrenaline injection (3) fairly regular spontaneous activity increased on a rise in arterial pressure, (4) brief high-frequency bursts of action potentials not affected by the arterial pressure. The authors also demonstrated a positive inverse correlation between the average frequency of the impulses in the splanchnic nerve and the mean femoral arterial pressure when hypotension was induced with haemorrhage.

EXPERIMENTAL PROCEDURES

Material and experimental conditions

The experimental animals were 21 adult cats, eight females and 13 males weighing between 1 9—4 8 kg. Action potentials were recorded after preparation of the nerves from the left vagus an third cardiac sympathetic nerves. Simultaneous recording of the blood pressure from the left atrium was made in all the experimental animals and the flow and pressure of the ascending aorta in four of them The combinations of different recordings are listed in Table 1 contained in the Appendix.

The cats were anaesthetized with chloralose urethane mixture (chloralose 0 09 g and urethane 0 125 g in 7 ml Ringer solution per kg body weight intramuscularly) The level of the anaesthesia was evaluated by examination of the reflexes to touch and sound When necessary and additional 3—5 ml of the mixture was administered intravenously The bladder was cannulated to prevent shivering (JEWETT 1964). The reduction in blood volume was roughly estimated, according to the excreted amounts of fluids in urine, respiration bleeding and evaporation during the surgical and preparation phase It was compensated with Ringer solution infusion into the femoral vein Wet compresses were used on and around the wounds to minimize evaporation With the animal supine the trachea was cannulated towards the lung and closed towards the larynx. Artificial respiration was given with an E & M Instrument Co Inc Physiograph at a frequency of 13—20 per minute with a positive pressure of 8—12 cm H_2O The respired gas was room air

The thorax was opened on the left side between the fourth and fifth intercostal space In those cases in which the nervous action potentials were recorded inside the thoracic cage the first four ribs were removed and the upper lobe of the left lung was resected.

The pressure measurement and injection cannulas were inserted in the left atrium through the apex of the auricular appendage so that the injection cannula was above the opening of the pressure measurement cannula In

this way an attempt was made to preclude any direct influence of the injections upon the pressure measurement. In the flow determination experiments, the ribs were intact, and the thorax was closed partially after implantation of the flow transducer (see p. 10) around the ascending aorta and the cannulas to the left atrium. In these cases, the action potentials were recorded from the left cervical vagus nerve. The thorax was half filled with body warm saline to obtain fluid between the outer wall of the ascending aorta and the flow transducer.

The acid base balance was determined in four animals by the customary Astrup technique. The results indicated a tendency towards respiratory alkalosis and metabolic acidosis. The pH values ranged from 7.20 to 7.27 and the readings for P_{CO_2} from 17.0 to 31.0 mm Hg.

The durations of the different phases of the experiments were as follows: induction of anaesthesia ½—1 hour, surgical procedures ½—1 hour, mineral oil pool formation and nerve preparation ½—1 hour. The actual recording phase lasted 1—2 hours, in accordance with the condition of the experimental animal.

The atrial B- and A type receptors (PAINTAL 1953 a) were stimulated by an injection of Ringer solution (8—15 ml with 6—15 sec) into the femoral vein or blood (3—8 ml within ½—8 sec) into the left atrium. The blood for successive injections into the left atrium was taken direct from the left atrium of the experimental animals. The reaction of the receptors was also tested by a reduction in the atrial pressure, with blood suction (5—8 ml, within 3—8 sec) from the left atrium or (15—30 ml within 10—30 sec) from the femoral vein.

The temperature of the experimental animal was tested, the rectal and mineral oil pool temperatures being taken with an electric (Ellab Copenhagen) thermometer. The temperature was regulated with a heating lamp, and held between 37—38° C.

Left atrial and aortic pressure, and ascending aorta flow measurements

The left atrial pressure was recorded through a cannula inserted into the left atrium through the apex of the auricular appendage. The aortic pressure was recorded by a needle inserted through the right carotid artery into the aorta. The cannula and needle were connected by polyethylene tubings led to two Sanborn 267 BC transducers, and on to the Sanborn 350—1100 cm carrier preamplifiers. (Fig. 1)

The aortic pressure was recorded in flow measurements only. In some experiments, the results were also stored in a Pi-6200 tape recorder and subsequently filmed. The flow was recorded with a Nortec ultrasonic Doppler

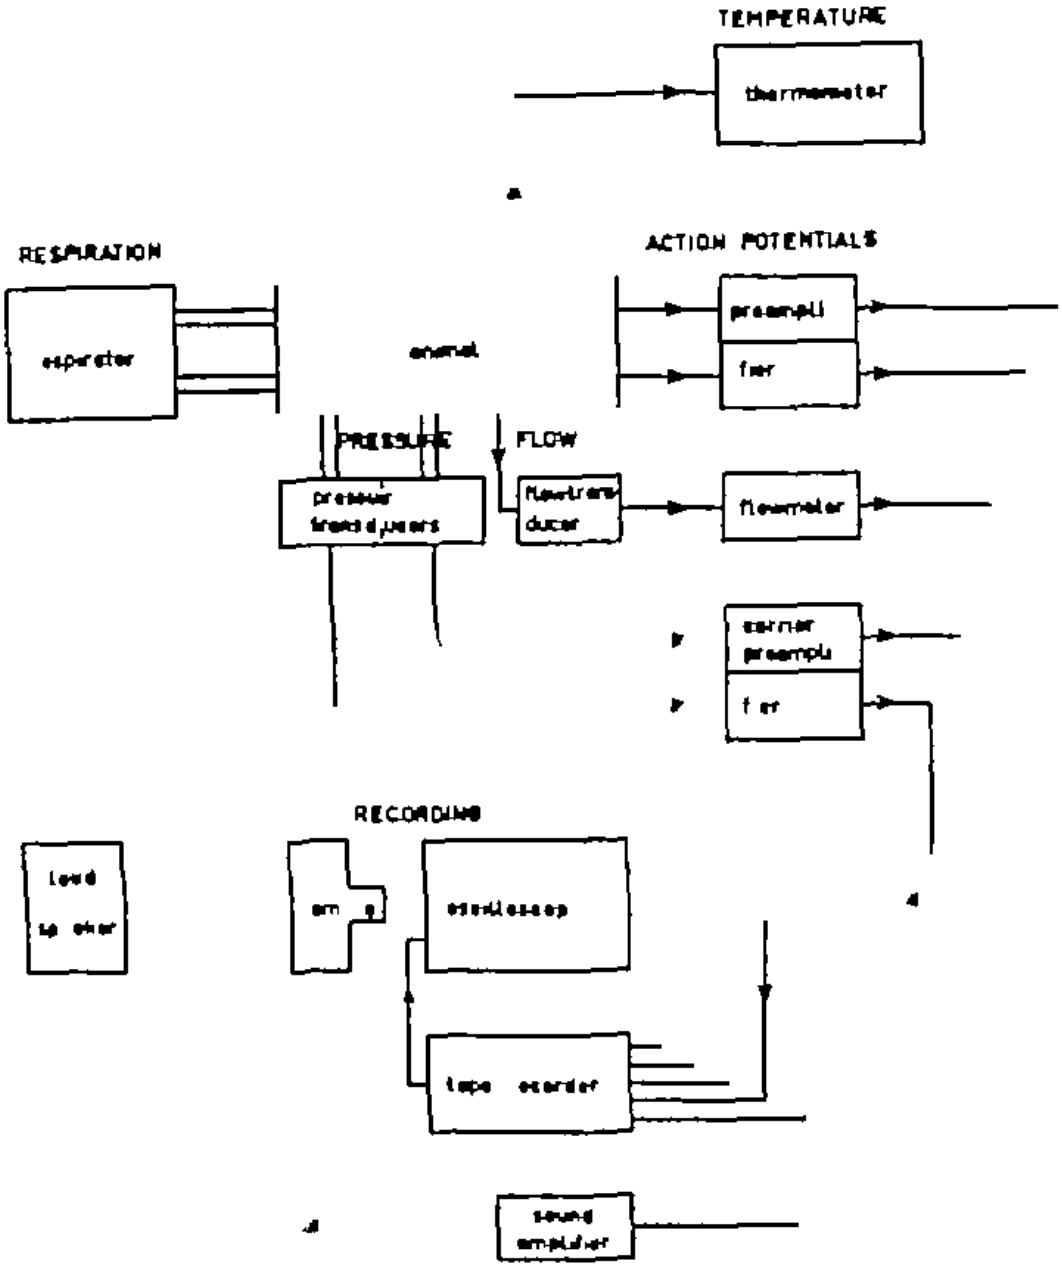

Fig 1 Recording system

shift transducer from the ascending part of the aorta The signal generator and the amplifiers for the flow transducers were made by the Technical Univeruty Applied Electronics Laboratory Bio-electronics Research Group. Otaniemi, Finland.

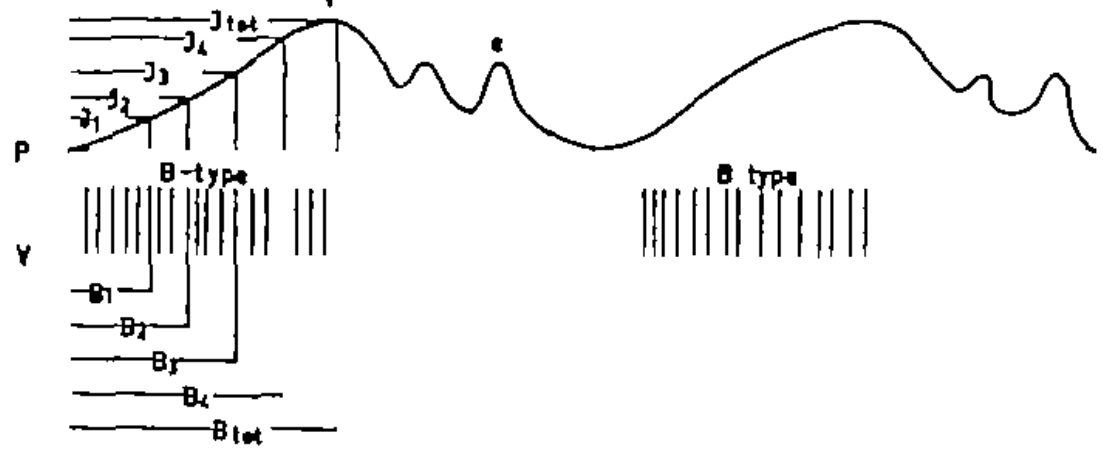

Fig. 2. P — left atrial pressure curve (with threshold pressure level — horizontal line), v a and c are the waves of the pressure curve. V — vagal afferent left atrial (B-type) impulses. I_1, I_2 I_{tot} are the pressure impulses (— the area between the threshold pressure and v-wave) and B_1 B_2 B_{tot} are the correspondi g numbers of B-type impulses.

Calculation of the pressure impulses of the v-wave of the left atrial pressure curve and the left ventricular relative stroke volume

The pressure impulse (I) of the v-wave of the left atrial pressure curve can be expressed by an equation

$$I = \int P_{v\text{-}diff} \times dt,$$

in which $P_{v\text{-}diff}$ is the pressure difference between the threshold pressure (Fig. 2 horizontal line from P) and some occasional point of the v wave, and t is the time interval between these two points.

On calculation of the pressure impulse during one atrial cycle the v-wave was divided into arbitary parts, and the corresponding areas between the horizontal line and v-wave measured (I_1 I_2 I_{tot}) In calculating the pressure impulses in different cycles, the I_{tot} was measured from different v-waves. I_{tot} was determined from the point at which the B-type impulses normally ceased at the top of the v wave.

The relative stroke volume of the left ventricle was calculated from the following equation

$$V = \int v \times dt,$$

in which V = relative stroke volume (shadowed area of Fig. 3) v = velocity of the blood stream, and t is the time interval from the 0-level (horizontal

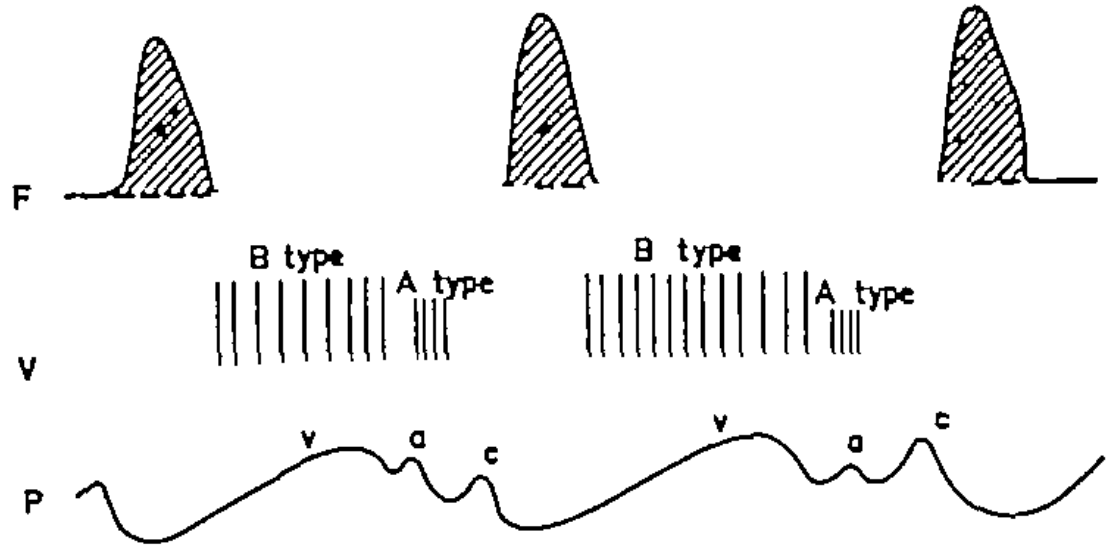

Fig. 3 F = blood velocity curve and 0-level. V = vagal afferent B- and A type impulses, P = left atrial pressure curve shadowed area = relative stroke volume.

line of F in Fig. 3) of the blood stream velocity curve, just before the ventricular contraction to the point at which the velocity curve is again at the 0-level after the contraction

The pressure impulse and the relative stroke volume were determined by a planimeter

Nerve preparation and recording of the action potentials

With the animal in a Faraday cage, preparation of the nerves was effected with a Zeiss binocular operation microscope. In the thorax, the mineral oil pool was formed of pleura parietale, and on the neck of muscles and fascias. The movement resulting from respiration and pulsation was minimized by means of bent metal plates inserted into the thoracic cage. The compression of vessels and nerves was avoided. Generally the aim was that of getting a calculable multifibre nerve preparation of the vagus, but some experiments also resulted in single fibre recordings. The action potentials were recorded monopolarly by platinum electrodes from thin vagal cardiac branches after the central connection of the fibre had been cut. Multifibre postganglionic efferent sympathetic activity was recorded from the third sympathetic cardiac nerve without cutting. The nerve impulses were led to Tektronix 122 preamplifiers, and on to a Tektronix 565 oscilloscope with six traces (Fig. 1) The action potentials were filmed from the screen with a Physiologie Milano (Arduine) camera the speed of the film was 15.2 cm per sec. Some of the results were stored on a magnetic tape and subsequently filmed

Determination of left atrial vagal afferent B- and A type impulses and sympathetic efferent postganglionic impulses

Preparation of the vagal nerves was selective, so that the recording was made only from the left atrial fibres The localization of the receptors in this phase of the experiment was determined by means of PAINTAL s (1955) identification system and with intra-atrial injections Finally localization was checked at the end of each experiment by the point of maximal impulsation to the touch of a needle All the receptors recorded were in the left atrium

The sympathetic postganglionic impulses were counted from separate sympathetic bursts, and in all the experiments under conditions of normal and raised left atrial pressure. The bursts were easily distinguishable from each other (Fig. 9 a, d, e) Some few impulses between the two bursts were counted to the nearest burst (Fig. 9 a the few impulses marked with a black wedge between the third and fourth sympathetic burst were counted to the third one) Under hypovolaemic experimental conditions in which the sympathetic activity was quite continuous the line between two bursts was determined as the point at which the activity was least (Fig. 9 b and c the vertical lines between the bursts)

All the vagal and sympathetic impulses were counted with the aid of a magnifying glass The maximal difference between the results counted independently by two persons from the films of multifibre preparation was 4 ± 1 %. No difference was observable between the results in single fibre counting.

CALCULATION OF THE RESULTS OF NEURAL ACTIVITY

Calculation of the difference in the sums of B- and A type impulses during sympathetic silence

The difference in the sums of B- and A type impulses was calculated as follows all the B-type impulses of each cycle were summed up from the artificial rise in the left atrial pressure to the cycle before the sympathetic activity recommenced (Fig. 9 d and e from point A to point B) From this sum was substracted the sum of A type impulses, counted in the same way *The control values were counted by substraction of the A type impulses* per heart cycle from the B-type impulses in the same cycle (Fig. 9 d, from A_0 to A = a heart cycle)

The time of sympathetic silence was measured from the point at which the sympathetic activity ceased to the point at which it recommenced (Fig. 9 d and e from point C to point D)

Calculation of the ratio of B- and A type impulses

The ratio of the numbers of B- and A type impulses was calculated by the following equation

$$\frac{B}{A} = \frac{B_0 + B_{R1} + B_{R2} + B_{R3}}{A_0 + A_{R1} + A_{R2} + A_{R3}}$$

in which B_0 and A_0 are the numbers of impulses counted from the film (Fig. 4) 200—400 msec before the comparable sympathetic burst (n_s).
B_{R1} B_{R2}, B_{R3}, and A_{R1} A_{R2}, A_{R3} are the values calculated from the numbers of impulses (B_1 B_2, B_3 and A_1 A_2, A_3) by the following equation

$N_R = N \cdot e^{-\frac{}{k}}$ in which N_R = B_{R1} B_{R2}, B_{R3} or A_{R1} A_{R2}, A_{R3} N = B_1 B_2, B_3 or A_1 A_2, A_3 and e is the Neper's number (e = 2.71) k is a coefficient (= regression coefficient from sympathetic silence time, differ

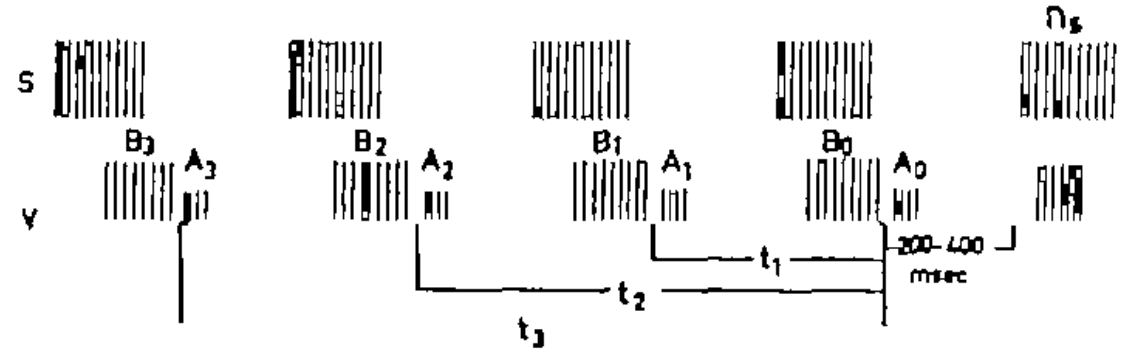

Fig 4 S = sympathetic impulses, n_s = number of sympathetic impulses of a sympathetic burst, V = vagal B- and A-type impulses, B_0 B_3 and A_0 A_3 number of B- and A-type impulses per heart cycle. t t_3 = time differences.

ence in the sums of B- and A type impulse correlation, Table 5 of the Appendix, b), t = the time difference from the corresponding cycle (B_1A_1, B_2A_2, B_3A_3) to the B_0A_0. t was determined from the P wave of the EKG which occurred as a mild artefact in each recording of action potentials (see Discussion p 34)

STATISTICAL METHODS

The mean $\bar{x}$ of observations x_1 x_2 x_n was calculated by the following formula

$$\bar{x} = \frac{\sum_{i=1} x_i}{n}$$

and variance s^2 from

$$s^2 = \frac{\sum_{i=1} (x_i - \bar{x})^2}{n - 1}$$

and the standard deviation is then s_x.

The covariance of observations x_1 x_2, x_n and y_1 y_2, y was arrived at from

$$s_{xy} = \frac{\sum_{i=1} (x_i - \bar{x})(y - \bar{y})}{n - 1}$$

The coefficient of linear correlation was calculated by the following formula

(1) $$r = \frac{s_{xy}}{\sqrt{s^2_x \; s^2_y}}$$

and the regression coefficient from

$$b = \frac{s_{xy}}{s^2_x}$$

and the point at which the regression line meets the y axis $a = \bar{y} - b\bar{x}$

The z transformation of the correlation coefficient was determined from

(2) $$z = \tfrac{1}{2}\ln \frac{1 + r}{1 - r}$$

and the mean of the transformed correlation coefficients $z_1 \; z_2, \quad z_k$ from

$$\bar{z} = \frac{\sum_{i=1}^{k} (n_i - 3) z_i}{\sum_{i=1}^{k} (n_i - 3)}$$

in which z_i were calculated by means of formulae (1) and (2) from observations $x_1 \; x_2, \quad x_{n_i}$ and $y_1 \; y_2, \quad y \quad i = 1 \; 2, \quad k.$

The variance of $\bar{z}$ is now

$$V(\bar{z}) = \frac{1}{\sum_{i=1}^{k} (n - 3)}$$

$$\text{The variable } u = \frac{\bar{z}_1 - \bar{z}_2}{\sqrt{V(\bar{z}_1) + V(\bar{z}_2)}}$$

is now approximately normally distributed It can employed for comparison of the similarity of the means of transformed correlation coefficients of two groups.

To test the significance of the difference between two means, the t test was calculated from the following formula

$$t = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{n_1 s^2_{x_1} + n_2 s^2_{x_2}}{n_1 + n_2 - 2} \left(\frac{1}{n_1} + \frac{1}{n_2}\right)}}$$

(cf HALD 1960)

RESULTS

Left atrial B- and A type impulses, under conditions of normal and changed left atrial pressure.

The pressure impulse and the number of left atrial B-type impulses in single and multifibre nerve preparations

The number of left atrial B-type impulses, and the corresponding pressure impulses, were studied in six single and 13 multifibre nerve preparations in 13 experimental animals.

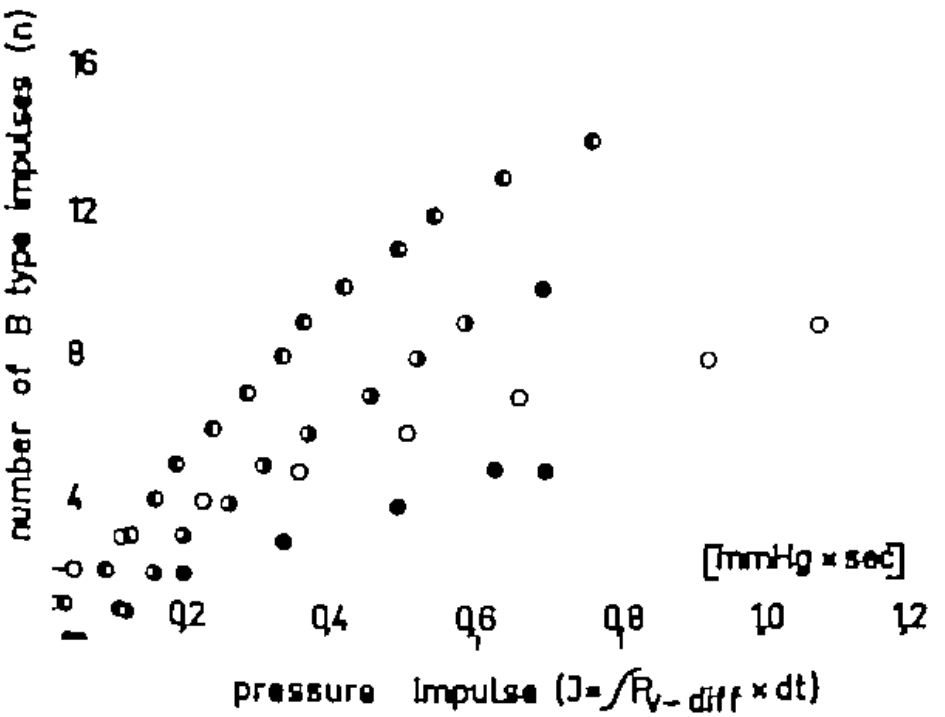

Fig 5 Number of the vagal afferent left trial B-type impulses (n) as a function of the pressure impulse (I) of the v-wave of the left atrial pressure curve, during one and the same heart cycle in single fibre nerve preparations. The figure relates to four normal cycles of four experimental animals.

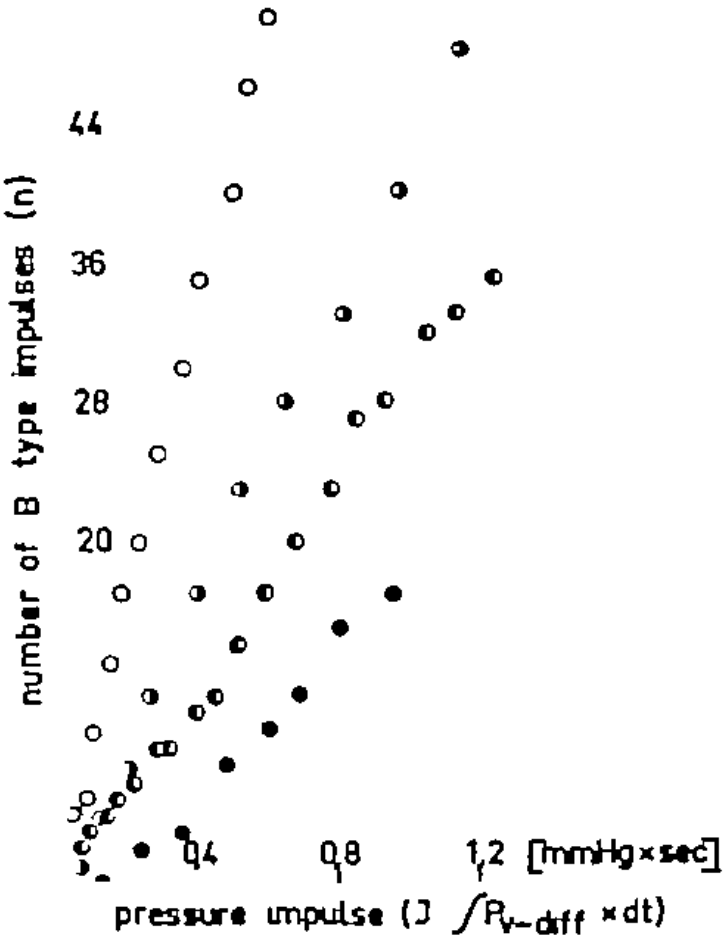

Fig. 6 Number of the vagal afferent left atrial B-type impulses (n) as a function of the pressure impulse (I) of the v-wave of the left atrial pressure curve during one and the same heart cycle in multifibre nerve preparations. The figure relates to four normal cycles of four experimental animals.

In single fibre preparations, the number of B-type impulses, as a function of the pressure impulse of the v wave during one and the same heart cycle, has a positive correlation in normal cycles (Fig. 5)

The arithmetical mean of the correlation coefficients, calculated from randomly chosen 12 heart cycles of six experimental animals, was 0.986 The other statistical values are listed in Table 2 of the Appendix.

In multifibre nerve preparations, it seems that the number of B-type impulses as a function of the pressure impulse of the v wave during one and the same normal heart cycle has a linear correlation (Fig. 6)

The mean of the correlation coefficients, calculated from 12 randomly chosen heart cycles in six different experimental animals, was 0 995 The other statistical values are listed in Table 3 of the Appendix. It is observable that a linear relationship exists between these two variables in multifibre nerve preparations

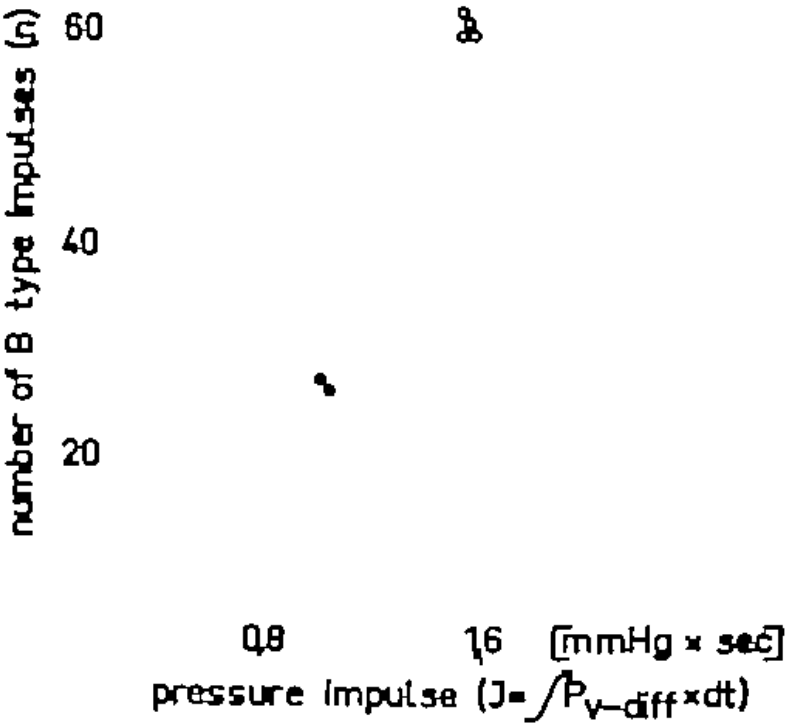

Fig 7 Number of vagal afferent left atrial B-type impulses per heart cycle (n) as a function of the pressure impulse (I) of the v-wave of the left atrial pressure curve, in different cycles, when the atrial pressure was raised by an injection (open circles). The closed circles illustrate the variation during artificial respiration in normal cycles. (Table 4 exp. animal No 16).

The difference between the correlation coefficients of multifibre pressure impulse and single fibre, pressure impulse was tested by z transformation. The u-value was + 3 432 and $P < 0.001$ (P = risk) This result implies that the correlation coefficients of multifibre, pressure impulse differ significantly from single fibre, pressure impulse correlation coefficients.

In different successive cycles, when the left atrial pressure was elevated by an injection (3—10 ml during 2—10 sec), the number of B-type impulses displayed a positive correlation with the pressure impulse in single and multi fibre nerve preparations (Fig. 7 and 8)

The correlation coefficient of 19 different cases of a rise in the left atrial pressure in 13 experimental animals varied from 0 701 to 0.970 and the number of tested cycles from 6 to 50 The mean of the correlation coefficients was 0.889 The other statistical values are listed in Table 4 of the Appendix. The correlation between these two variables may be linear No obvious difference was apparent in the relationship between the single and multi-fibre nerve preparations.

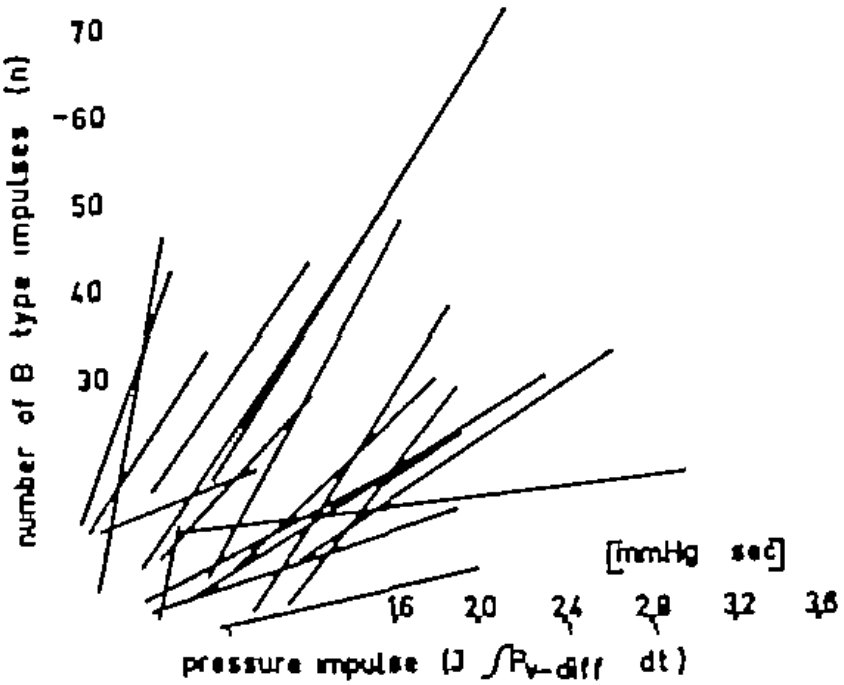

Fig 8 Number of vagal afferent left atrial B-type impulses per heart cycle (n) as a function of the pressure impulse (I) of the v-wave of the left atrial pressure curve, in different cycles, when the atrial pressure was raised by an injection The figure relates to 19 rises in 13 experimental animals. The lines are illustrative and drawn in accordance with statistical alues. (Table 4 of the Appendix).

l type impulses under conditions of raised and lowered left atrial pressure

The increase in left atrial A type impulses was induced by intra atrial and femoral injections The effect of the injections upon the number of A type impulses was calculated in 37 rises of 10 different experimental animals. The mean of the control values was 9 3 impulses per cycle, and the mean of the raised values 12.5 impulses per cycle The difference between the two values is significant ($t = 4\,57$ $f = 223$ $P < 0\,001$ t = t value of Student t test, f = degrees of freedom and P = risk)

The suction of blood from the left atrium increased the number of A type impulses The control and the raised values of A type impulses were tested in six different experimental animals, and in six different suction cases The mean of the control values was 8 5 imp per cycle and that of the raised values 12.2 imp per cycle The difference between these two numbers is significant ($t = 5\,07$ $f = 111$ $P < 0\,001$)

These results imply that the raising and lowering of the left atrial pressure increases the number of A type impulses.

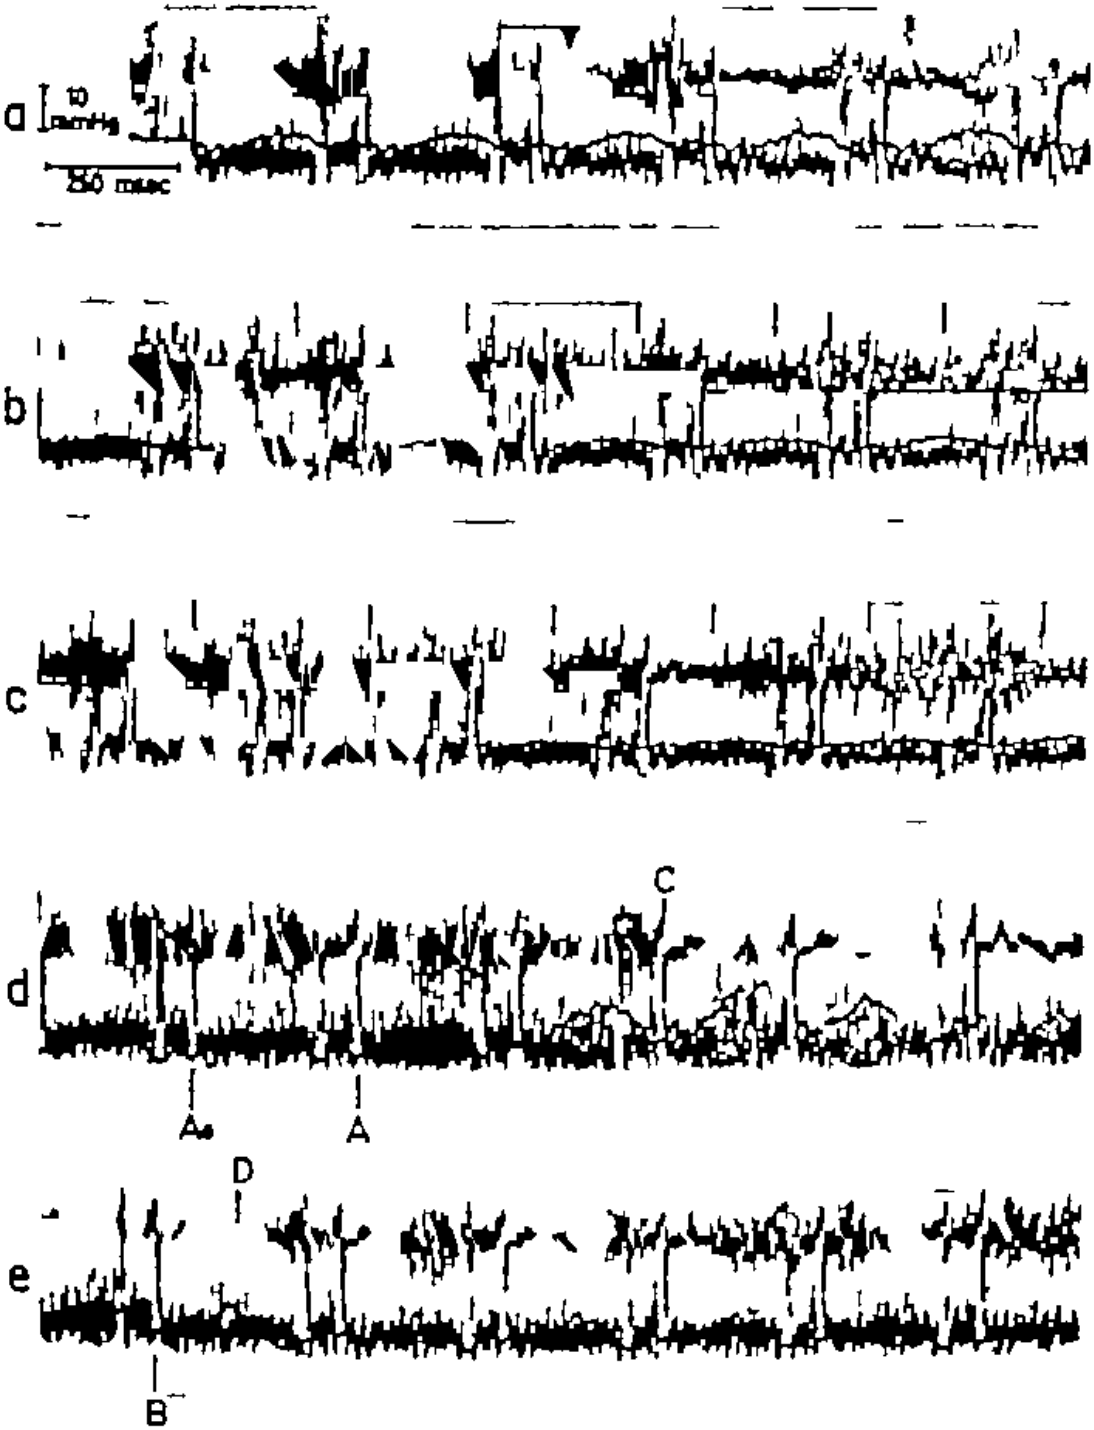

Fig 9 Influence of lowering or raising the left atrial pressure upon the left atrial vagal afferent impulses (B-type and A-type) and upon the sympathetic postganglionic efferent cardiac impulses. The upper impulses are sympathetic, and the lower impulses vagal. The lower oscillating curve, below the upper straight, is the left atrial pressure curve. (The alphapeths A_e, A, B, C, D include to the text of p. 16). a) control b) reduction in blood volume by 15 ml, c) after reduction by 30 ml, d-e) influence of the left atrial pressure rise upon the vagal (B- and A-type) impulses and sympathetic impulses (with 5 ml of blood/1 sec, weight of animal 3.8 kg) estimated total blood volume 212 ml.

Effect of B- and A-type left atrial impulses upon the sympathetic postganglionic activity of the heart under conditions of normal and changed left atrial pressure.

B-type impulses and the activity of sympathetic cardiac fibres

The rise in the left atrial pressure increases the number of B-type impulses, and diminishes the sympathetic activity of the heart (Fig. 9 d-e)

The inhibition of the sympathetic activity was partial or total, depending on the injected volumes per time unit. In particular the blood injections (3—8 ml within ½—5 sec) into the left atrium in most cases induced total sympathetic silence (Fig. 9 d-e) The diminution in sympathetic impulses followed 200—400 msec (mean 308 msec) after the increase in B-type impulses (calculated from the P wave of the EKG which occurred as a mild artefact in the recording of action potentials to the beginning of the next sympathetic burst)

A positive inverse correlation was apparent between the number of

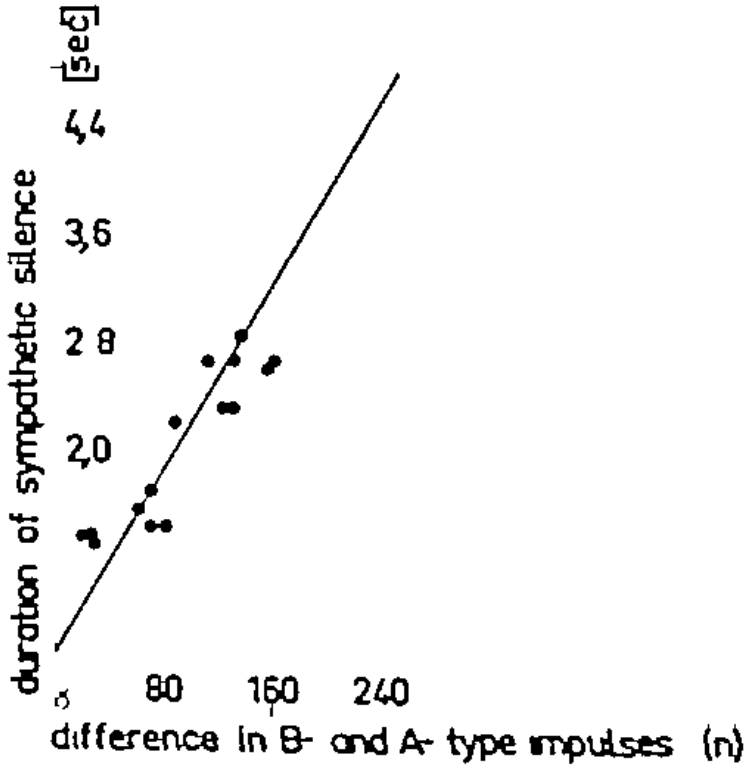

Fig 10. Duration of the silence of the sympathetic postganglionic efferent cardiac activity as a function of the difference in the sums of the left atrial afferent vagal B- and A-type impulses (n) under conditions of normal (open circles) and raised (closed circles) left atrial pressure. The impulses were recorded from multifibre nerve preparations, and the volume injected varied from 3 ml to 8 ml within ½—5 sec. The weight of the animal was 3.8 kg. (Table No 5 p animal No 11)

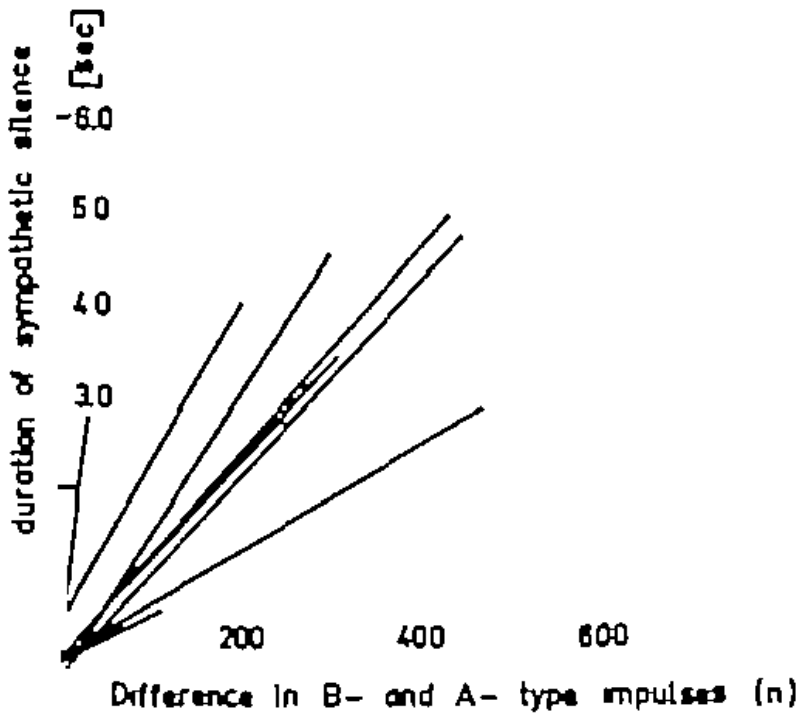

Fig. 11 Duration of the silence of the sympathetic postganglionic efferentation to the heart as a function of the difference in the sums of the left atrial afferent vagal B- and A type impulses (n) under conditions of normal and raised left atrial pressure, of eight multifibre nerve preparations from seven experimental animals. The lines are drawn in accordance with statistical values. (Table 5 of the Appendix).

B-type impulses and the number of sympathetic impulses in all cases of pressure rise.

The mean of the correlation coefficients calculated for 15 rises in seven experimental animals was —0 659

An attempt was made to test the nature of the inhibition in the central nervous system (= CNS) with eight nerve preparations from seven experimental animals forming the difference in the sums of the B- and A-type impulses of each injection These differences were correlated with the corresponding silence time of the sympathetic activity within the same nerve preparation (see p 16)

It seems that a linear correlation exists between these two variables (Fig. 10 and 11).

The correlation coefficient varied from 0.925 to 0.992, and the number of points from 8 to 25. The mean of the correlation coefficients was 0.965 The other statistical values are listed in Table 5 of the Appendix.

In suction experiments, the left atrial pressure was lowered and the number of B-type impulses diminished, with a simultaneous increase in sympathetic outflow to the heart (Fig. 9 a-c). A positive inverse correlation

was observable in all the tests with blood suction, between the number of B-type impulses and the number of sympathetic impulses (Fig. 12) In six suction tests in six cats the mean of the correlation coefficients between the number of B-type impulses and the number of sympathetic impulses was —0 682.

A type impulses and the activity of sympathetic cardiac fibres

In most instances, the rises in the left atrial pressure induced an increase in A type impulses, particularly under normo- and hypovolaemic conditions. The increase was not always demonstrable under hypervolaemic conditions by an injection It was found that the diminution in sympathetic activity was delayed in those cases in which an increase in A type impulses occurred during atrial injection as compared with the experiments in which the increase in A type impulses was unobservable or cases in which the sympathetic silence was induced by a very fast injection within one cardiac cycle.

In three experimental animals, the atrial contractions, which occurred during ventricular premature beats in response to intra-atrial injections, caused an increase in A type impulses. This was followed by one two bursts of sympathetic impulses after a delay of 300—400 msec in the middle of the sympathetic silence

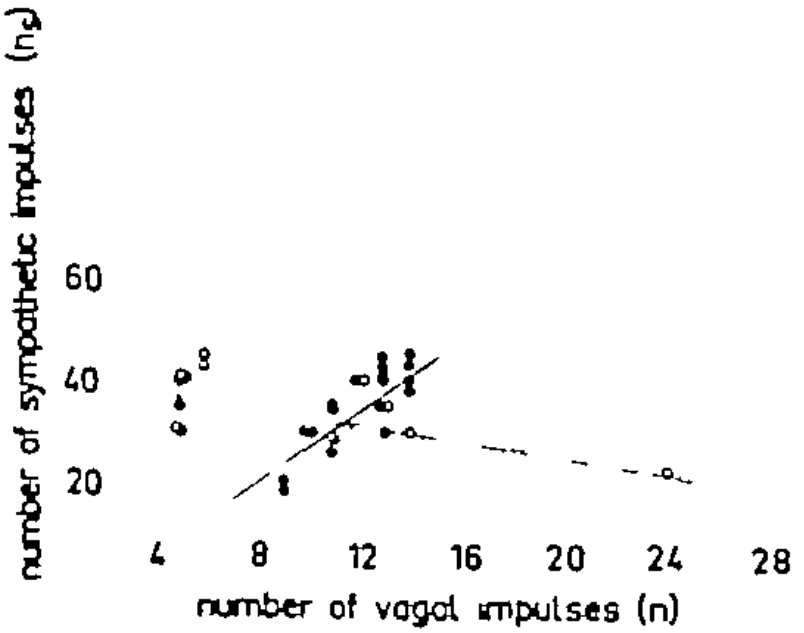

Fig 1 Number of sympathetic efferent postganglionic cardiac impulses (n_s) as a function of the v gal afferent left atrial impulses (n) when the left atrial pressure was lowered by blood suction. The points in respect of one experimental animal are calculated from cycle to cycle during the course of the suction. The lines are drawn in accordance with statistical values. B-type mpulses pen circles A type impulses = closed circles, (Table No 6, exp. animal No 11).

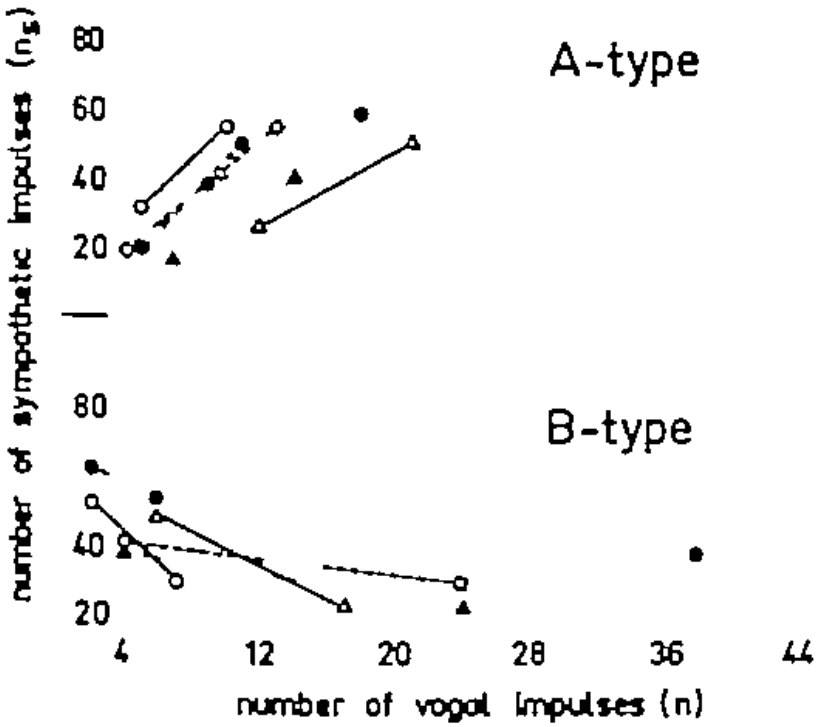

Fig 13 Number of sympathetic efferent postganglionic cardiac impulses (n_s) as a function of the vagal afferent left atrial impulses (n) (B-type, A-type) when the left atrial pressure was lowered by blood suction. The lines are illustrative, and drawn in accordance with the statistical values from six suctions in six experimental animals. (A-type in Table 6 of the Appendix).

In suction tests, a linear positive correlation was apparent between the number of A-type impulses and the number of sympathetic impulses following after a delay of 200—300 msec (Fig. 12 and 13)

The correlation coefficient varied from 0 761 to 0 917 and the number of points, from 12 to 24 was calculated from six suction cases in respect of six different experimental animals. The mean of the correlation coefficients was 0 864 The other statistical values are listed in Table 6 of the Appendix.

Ratio of B- and A type impulses and the number of sympathetic impulses.

The ratio (see p 16) of B- and A-type impulses was calculated and correlated with the number of sympathetic impulses in cases of pressure rise A positive inverse correlation seems to exist between these two variables (Fig. 14 and 15).

The correlation coefficient, calculated from 15 cases of pressure rise in seven experimental animals varied from —0 455 to —0 926 (mean —0.659)

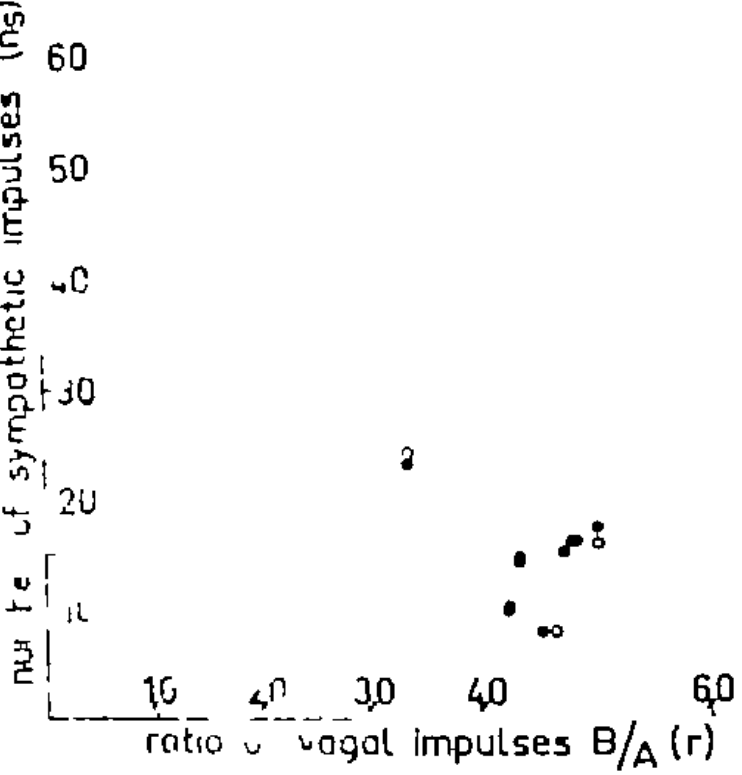

Fig 14 Number of sympathetic postganglionic efferent cardiac impulses (n_s) as a function of the ratio (r) of the numbers of B- and A type afferent cardiac impulses in one experimental animal during two different cases of pressure rise (injection of blood into the left atrium closed circles, 3 ml within 1 sec open circles, 5 ml within 1 sec). (Table No 7 exp. animal No 17)

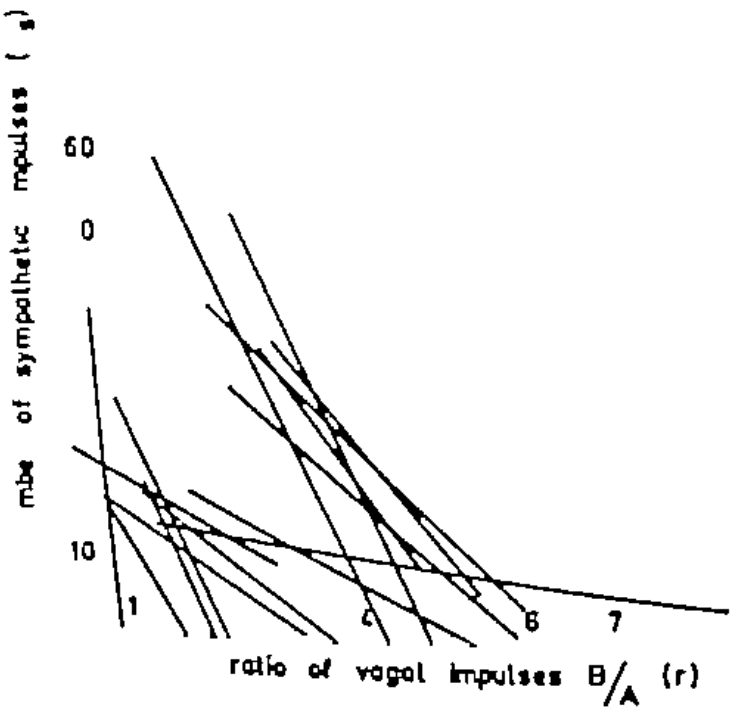

Fig 15 Number of sympathetic postganglionic efferent cardiac impulses (n_s) as a function of the ratio (r) of the numbers of B- and A type vagal afferent cardiac impulses in 15 cases of pressure rise in seven experimental animals. (3—8 ml within ½—5 sec). The lines are drawn in accordance with statistical values and are illustrative. (Table 7 of the Appendix).

and the number of points from 12 to 23 The other statistical values are listed in Table 7 of the Appendix.

In suction tests a positive inverse correlation also existed between the two variables. The correlation coefficient varied from —0 614 to —0 863 (mean —0 733) and the number of points from 12 to 24 calculated from six *suctions in six different experimental animals The statistical values* are listed in Table 8 of the Appendix.

Left atrial B- and A-type impulses, and the left ventricular relative stroke volume.

The sum of the numbers of B- and A type impulses during one heart cycle, and the following relative stroke volume, were correlated from eight tests of pressure rise and four experimental animals (Fig. 16 and 17) The blood volume *of the cats was first reduced with suction of blood (20 ml)* from the femoral vein or from the left atrium. A part of the blood volume, 8—15 ml, was injected into the femoral vein or 4—8 ml into the left atrium. The response in the stroke volume and nerve impulses was followed during the course of the injection

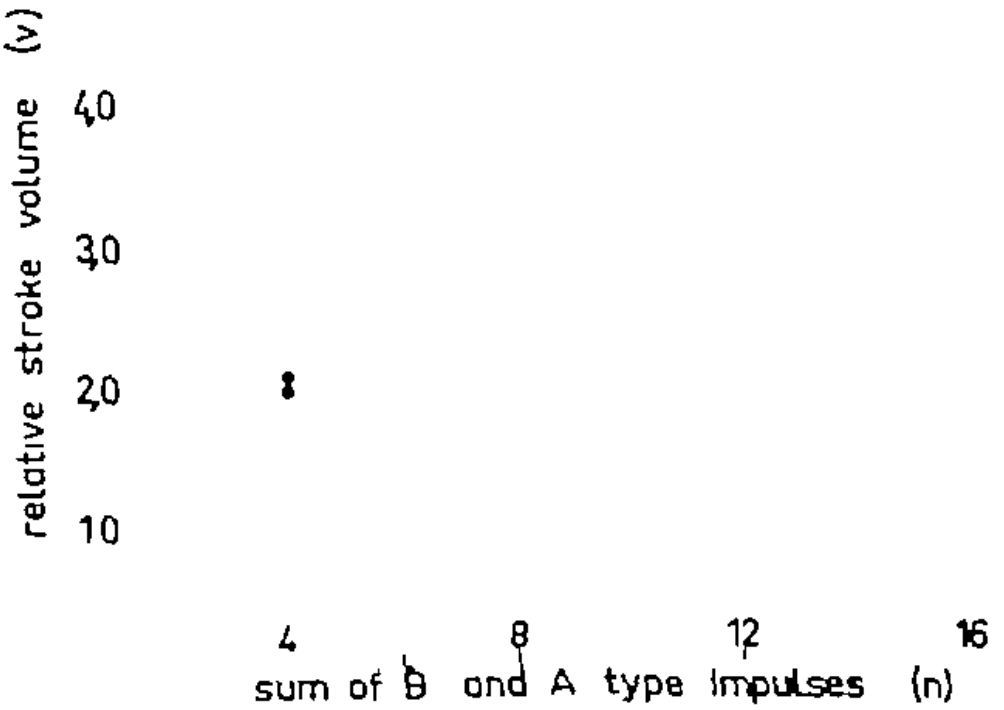

Fig 16 Relative stroke volume (V) as a function of the sum of left atrial vagal B- and A-type impulses ( ) in different successive cycles when relative stroke volume was increased with an intra-atrial injection of blood (4 ml/during 4 seconds). (Table N 9 exp. animal No 12 2).

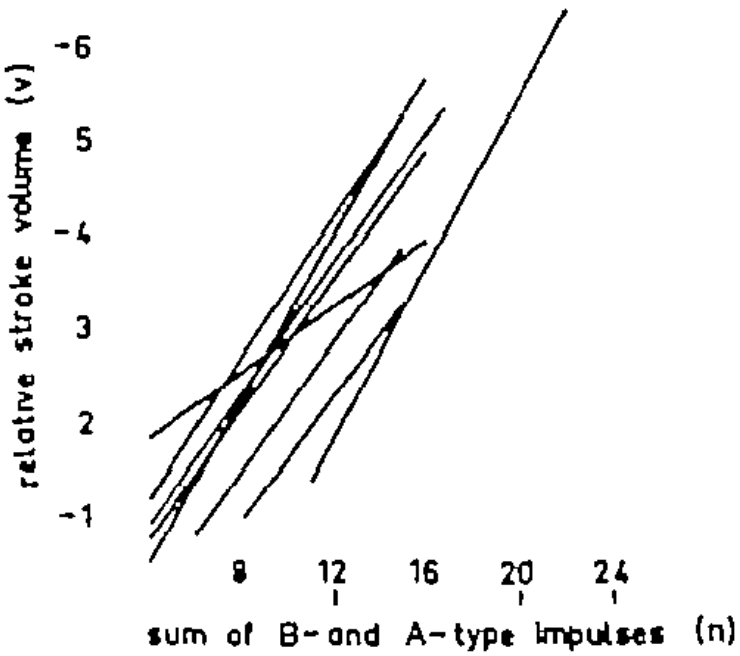

Fig. 17 Relat left ventricular stroke volume (V) as a function of the sum of vagal afferent left atrial B- and A type impulses (n) in different cycles when the relative stroke olume wa nereased with femoral or intra-atrial injections of blood. The lines are drawn accordance w ith statistical values and are illustrative. (Table No 9 of the Appendix).

The correlation coefficient varied from 0 748 to 0 893 and the number of points from 13 to 83 The other statistical values are listed in Table 9 of the Appendix.

DISCUSSION

Experimental conditions

Reference was made to the earlier work of JARISCH and ZOTTERMAN (1948) for use of the chloralose urethane mixture, but the amount of urethane in 7 ml of Ringer solution was reduced from 0.250 to 0 125 g as it was observed that the higher dose caused some cardiac depression which appeared as cardiac arrest (cf GILES, QUIROZ and BURCH 1969)

Since lowering of blood pH both in respiratory and non respiratory acidosis is known to increase the plasma catecholamine concentration (MORRIS and MILLAR 1962 a, b) and a rise of CO_2 in inspired oxygen the sympathetic efferent activity (MILLAR and BISCOE 1965) the acid base balance was followed during four experiments. In general, a tendency toward metabolic acidosis was encountered. An attempt was made to compensate this by hyperventilation. It is suggested here that the acid base balance was not changed when the tests were performed during short periods.

The nerve preparation was made by modification of the techniques of JARISCH and ZOTTERMAN (1948) and PAINTAL (1953 c). In every recording, the nervous connection of the vagus from the heart to the CNS was partially cut. The effect upon the sympathetic activity of this dissection was tested in four experimental animals no difference was noted in the response to the atrial pressure elevation before and after cutting. This indicates that the dissected fibres are responsible for no more than a small part of the total activity coming to the CNS from the left atrium. Moreover in the nerve preparation phases of this work, nerve impulses of right atrial origin were found in the fibres of the left vagus.

The sympathetic postganglionic activity was recorded, as the system of recording was easier than that in preganglionic acitivity Also, samples of the sympathetic activity to the heart were obtainable.

The recorded samples of the nervous activity of the sympathetic nerves are likely to represent the total sympathetic activity to the heart. This is suggested by the findings in the preliminary experiments (not included in

the material) that no distinct difference was apparent in the sympathetic activity of the second and third left sympathetic cardiac nerves, recorded simultaneously In harmony with these findings, BRONK et al (1936) failed to detect any appreciable differences in the activity of the right and the left cardiac sympathetic nerves.

The samples from vagal fibres do not represent the total activity of B- and A-type impulses to the CNS since the share of each type of impulse in the whole recording is occasional However the ratio of B- and A type impulses is comparable during the course of one and the same experiment with the same nerve preparation if the recording and experimental conditions are constant. This is suggested by the mere fact that in pressure rise cases a parallel increase was seen in the numbers of B- and A type impulses.

Left atrial pressure and pressure impulse

PAINTAL (1953 a) observed a linear correlation between the left atrial volume and the average frequency of discharge of B-type impulses in a haemodynamically isolated atrium preparation In a later work PAINTAL *(1963 b) found that the best correlation prevails between the number of* B-type impulses per heart cycle and the amplitude of the v wave. LANGREHR (1960) in turn demonstrated the existence of a positive correlation between the mean left atrial pressure and the number of B-type impulses.

In the present work, the pressure impulse (I) was calculated for study of the pressure as a function of time. A linear correlation seems apparent between the number of B-type impulses per heart cycle and the pressure impulse of the v wave in multifibre nerve preparations. The correlation between the pressure impulse and the number of B-type impulses in a single fibre nerve preparation is probably not linear although the statistical values are significant This result in respect of multifibre nerve preparations is similar to the findings of BERGSTRÖM (1966) and VILJANEN (1967) BERGSTRÖM showed that in cats the time integral of the applied pressure bears, within given limits a linear correlation to the total number of the impulses during the time in question in the sensory nerve fibres of skin. VILJANEN found a linear correlation between the mechanical pressure impulse and the number of EMG impulses of human intercostal muscles in respiration

The finding in the present work is explicable by the hypothesis that multifibre nerve preparations contain many fibres of receptors with different activation thresholds and nerve impulses from the receptors are summed to the same pressure impulse This type of summation has been suggested by BERGSTRÖM (1961) in his study of the touch and stretch receptors of frog s skin

When the pressure impulse reaches a higher level, the relationship deviates, so that a smaller number of impulses corresponds to a given pressure impulse (HAKUMÄKI et al. 1968).

B-type impulses and the sympathetic activity of the heart

In the present study a rise in the left atrial pressure resulted in an increase in B-type impulses and a diminution in sympathetic activity This indicates that the B-type impulses inhibit the sympathetic system. This is in keeping with the results obtained by JARISCH and ZOTTERMAN (1948) and ÖBERG and WHITE (1968), who by means of stimulation of the central end of the cardiac vagal nerves, in most cases induced a bradycardiac response. OKADA, OKAMOTO and NISIDA (1961) showed also that injection into the external jugular vein or compression of the right atrial wall caused inhibition in the interior cardiac sympathetic nerve. The responses were interpreted as reflecting sympathetic inhibition

It is obvious, furthermore, that the B-type impulses regulate the sympathetic silence time. This is supported by the present finding that the increase in B-type impulses during a few cycles induced a sympathetic silence for many cycles after the injection, although the corresponding number of impulses, during silence was not increased (Fig. 9 d-e).

A-type impulses and the sympathetic activity of the heart.

AMANN and SCHAEFER (1943) first recorded A-type impulses from vagal afferent nerves. The correlation between the "frequency of discharge per second" of A type impulses and the pressure of the right atrium was shown to be linear in cats by DICKINSON (1950). KOLATAT KRAMER and MÜHL (1957) have found a positive correlation between the pressure of the a wave and the number of A-type impulses in frogs.

SCHAEFER (1950 1960) has suggested that the atrial receptors both activate and inhibit the sympathetic system, so that a small amount of atrial distension causes cardiac acceleration, and maximal excitation of the cardiac sensory nerves a bradycardiac effect. PEARCE, HENRY and CHAPMAN (1956) have proposed that A type impulses may signify a state of high "tone" and low filling, in the central control of the cardiovascular system

The following findings made here support the hypothesis that A type impulses activate the sympathetic system

1 During intra-atrial injections the dimmution in sympathetic activity was delayed as the A type impulses were increased

2. The atrial contractions, which occurred during ventricular premature

beats in response to intra atrial injections, caused an increase in A type impulses. This was followed by one or two bursts of sympathetic impulses in the middle of the sympathetic silence.

3 In suction tests, a linear positive correlation was found between the number of A type impulses and the number of sympathetic impulses

4 The ratio of B- and A type impulses had a positive inverse correlation with the number of sympathetic impulses.

Some findings in earlier works may be explained by the function of A type impulses JARISCH and ZOTTERMAN (1948) and ÖBERG and WHITE (1968) found that in some experiments stimulation of the central end of the vagal cardiac branches also induced a rise in blood pressure with an associated bradycardia. The finding of HINDERLEIDER et al (1968) that denervation of the dog s heart diminished the constriction capacity of the spleen in hypovolaemic states is very interesting. It is obvious that the *denervation of the heart inhibited the activating influence of A type impulses* upon the sympathetic system.

Theoretical background of calculation of the ratio of B- and A type impulses and the difference in the sums of B- and A type impulses

Calculation of the ratio of B- and A type impulses was based upon the hypothesis that the *influence of the afferent neural activity in the CNS is* "in activated" in accordance with the formula $N_R = N \quad e^{\frac{-t}{k}}$ presented This formula was derived by simplification of the formula for exponential decay applied by GRODINS (1963 p 49) It is patent to all that the afferent activity is "inactivated" according to the formula stated above. This is supported by the response of pupil diameter to light stimulus and the Respiratory Heart Rate reflex, in which the similar exponential decay of the responses is seen after the stimulus (cf CLYNES 1961 1962) Coefficient k decides the slope of the inactivation curve in relation to the time, and might provide information on the capacity of the CNS to inactivate the afferent left atrial activity With the equation above the "residual activity (N_R) was calculated that is, the activity which still affects the CNS after time t It is suggested here that the effect upon the CNS of B- and A type impulses is "inactivated in the same way All the residual activities" were summed up from three successive cycles, and the ratio was derived as indicated earlier $\left(\frac{B}{A} = \frac{B_0 + B_{R1} + B_{R2} + B_{R3}}{A_0 + A_{R1} + A_{R2} + A_{R3}}\right.$ see p 16$\left.\right)$

The regression coefficient of the time of duration of sympathetic silence in relation to the difference in the sums of B- and A type impulses (see p 25 Table 5 of the Appendix) has been used as the value of the k coefficient in the formula $\left(N_R = N \quad e^{\overline{k}}\right)$

The difference in the sums of B- and A type impulses was derived by application of the theory of the opposite functions of B- and A type impulses to the sympathetic activity Thus the difference in the inhibitory and activating units is comparable with the duration of the inactivation of the sympathetic efferentation The regression coefficient was found by mechanical stimulation of receptors feeding to the CNS and thus provides some information of the tonus in the CNS of the animal. The coefficient also indicates the duration of inhibition in the sympathetic outflow per unit of neural inhibition, under those experimental conditions. The regression coefficients are not mutually comparable, as the number of active fibres (B A and sympathetic) in the recording system is occasional.

Ratio of B- and A type impulses

The ratio of B- and A type impulses was also calculated on the assumption that they have an opposite function upon sympathetic cardiac efferentation. The ratio can be correlated with the number of sympathetic impulses. It was further concluded that the sympathetic activity is influenced not only by this proceeding, but also by a few earlier vagal bursts of impulses (B and A, see Fig. 4, p 17) This conclusion was arrived at from the finding made in the present work that intra-atrial injection within a few atrial cycles induced an increase in B-type impulses and in the duration of sympathetic silence during the following cycles, although the numbers of B-type Impulses during silence were near the control values (Fig. 9 d-e) In addition during premature ventricular contractions elicited by the fast intra-atrial injections, there was a massive increase in A-type impulses (associated with simultaneous atrial contraction) followed by one — two successive sympathetic bursts, although the number of B-type impulses was high. In the system of calculation, there was observed the effect exerted by previous cycles upon the sympathetic burst.

It is obvious that changes in vagal afferent cardiac activity influence the next sympathetic burst after 200—400 msec. This delay is supported by Iggo and Vogt (1960), who came to the conclusion that there was a latent period of 200 msec between the stimulus of baroreceptors and the inhibition of sympathetic outflow In the present work, a massive increase in B-type

impulses, induced by an injection resulted in a sympathetic silence after 200 msec.

The ratio of B- and A-type impulses represents the amount of inactivation per unit of activation It appeared that this ratio has a positive inverse correlation with the number of sympathetic impulses. This implies that an increase in the left atrial pressure conditions induced a change in vagal afferentation of the heart which influenced the sympathetic efferentation This efferentation is dependent upon the ratio of B- and A type impulses. The preliminary results have been published by HAKUMÄKI (1968).

For testing of the influence mechanism of the B- and A type impulses upon the sympathetic system, the following combinations were also calculated and correlated with the number of sympathetic impulses (n_s) (see Fig. 4 p 17)

- Number of B-type impulses from the previous cycle (B_0)
- Number of B-type impulses from the previous cycles calculated by the formulae presented (B)
- Number of A type impulses from previous cycle (A_0)
- Number of A type from the previous cycles calculated by the formulae presented (A)
- The ratio of B- and A type impulses from the previous cycle $\left(\frac{B_0}{A_0}\right)$

The coefficients of linear correlation obtained for the above interrelations were not so significant as the correlation coefficient of the ratio of B- and A-type impulses and the number of sympathetic impulses (n_s) The differences between the correlation coefficients were significant This indicates the correctness of the suggestion made in the present work in respect to the influence mechanism of B- and A type impulses upon the sympathetic activity

Difference in the sums of B- and A type impulses

The difference in the sums of B- and A type impulses was calculated for estimation of the amount of inhibition which induces a given sympathetic silence The result near linearity indicates that under these experimental conditions, and within given limits, the CNS inhibits the neural activity mainly in the same way Moreover it indicates that the difference in the inactivating and activating impulses bears a linear correlation to the duration of sympathetic silence The preliminary results have been published by HAKUMÄKI (1969)

Left atrial B- and A type impulses and the left ventricular relative stroke volume.

LANGREHR and KRAMER (1960) did not find a distinct correlation between the cardiac output and the sums of activity of B-type impulses. The correlation between the thoracic blood volume and the atrial B-type impulses was distinct. LANGREHR's finding (1960) of a positive correlation between the stroke volume per duration of systole and the relative frequency of B-type impulses is similar to the results obtained in the present work.

Although the left ventricular filling is regulated only partially and to a varying extent by left atrial filling pressure and left atrial contractility the sum of B- and A type impulses was calculated and correlated with the left ventricular relative stroke volume. The correlation between these two variables seems linear although the result can be considered indirect, as the stroke volume is a result of ventricular contraction and the B- and A type impulses have their origin in the atrial functions.

Role of baroreceptor activity

BRONK et al. (1936), DOWING and SIEGEL (1963) and SPICKLER, KEZDI and GELLER (1965) have shown that both mechanical and electrical stimulation of the baroreceptors or their afferent nerves diminish the sympathetic efferent activity. In preliminary experiments (not included in the present material) the influence of the intra-atrial injection upon baroreceptor activity and the sympathetic system was tested with simultaneous recording of the aortic baroreceptor afferent and cardiac sympathetic postganglionic efferent impulses. No marked increase in baroreceptor activity was apparent during and after the left atrial injections (3—8 ml within ½—5 sec) although sympathetic silence was found to emerge. This finding can be explained by the results of ALLISON and SAGAWA (1967) that the aortic arch reflex receptors operate usually between 100—300 mmHg. DOWING and SIEGEL (1963) found that raising the carotid sinus pressure from 35 to 130 mm Hg reduced the sympathetic activity but little. It might be possible that the intra atrial injections (3—8 ml within ½—5 sec) in the present work do not exert any marked influence upon the baroreceptor activity and, through this, upon the sympathetic outflow. Nevertheless, changes in the sympathetic activity were inducible by stimulation of the left atrial receptors. In this context, it may be mentioned that GUPTA et al. (1966) demonstrated that a progressive increase in blood volume increases the activity of atrial receptors much more than the activity of aortic baroreceptors. Further OKADA, OKAMOTO and NUMDA (1961) have shown that bilateral aortic nerve cutting did not induce any changes in the response of the cardiac sympathetic efferentation to intravenous infusion

However in those tests in which the vagal afferent and sympathetic efferent cardiac activity was followed in different blood volume conditions (Table 7 of the Appendix, marked with x), the influence of baroreceptor activity upon the sympathetic activity is obvious. Premature ventricular beats, induced by intra atrial injections also diminish the baroreceptor activity and affect the sympathetic outflow

It would appear that cardiac sympathetic efferentation is also controlled by the atrial receptors.

Bainbridge reflex

The neural pathways of the BAINBRIDGE reflex (1915) have been studied by LEDSOME and LINDEN (1967) who in their experimental system were able to show that the reflex has an atrial origin

COLERIDGE and LINDEN (1955) found that the cardiac acceleration oc curred more frequently when the control level of heart rate was low before injection When the rate was high, the acceleration was seldom induced and was not very significant. The findings of COLERIDGE and LINDEN are explicable as follows. In the experiments in which the control level of heart rate before the injection, was low the increase in blood volume induced an increase in B- and particularly in A type impulses, so that the ratio of B- and A type impulses diminished and induced an increase in sympa thetic activity and cardiac acceleration. In the experments in which the initial frequency was high, the increase in blood volume mainly induced an in crease in B-type impulses (as the A type impulses were near their maximum number) and the ratio of B- and A type impulses was not changed or was increased This did not introduce any changes in the sympathetic activity or diminish it in cases of bradycardia. The neural regulation of the heart would be expressed by the formula

$$\frac{I}{E} = \frac{\text{number of vagal efferent impulses}}{\text{number of sympathetic efferent impulses}}$$

where I is the number of inhibitory impulses (including the B-type impulses) and E the number of excitatory impulses (including the A type impulses). The regulation system based upon the above formula is supported by JEWETT s (1964) finding of a linear correlation between the vagal afferent impulses and the length of the heart cycle MARGUTH RAULE and SCHAEFER (1951) WEIDINGER, HETZEL and SCHAEFER (1962) and JEWETT (1964) made an interesting observation of the opposite functions of the vagal efferent and sympathetic afferent impulses. The above equation is an attempt to formulate a quantitative presentation of the mechanism of heart regulation on the basis of earlier works and the present findings

SUMMARY

1 A study has been made of the impulsation of the vagal left atrial afferent fibres and of the left third sympathetic cardiac nerve under conditions of normal and changed left atrial pressure in 21 open-chest anaesthetized cats. Simultaneously the left atrial pressure and in some experiments, the flow and pressure of the ascending part of the aorta were determined

2. A comparison was made between

— the pressure impulse of the v wave of the left atrial pressure curve, and the number of left atrial B-type impulses in single and multifibre nerve preparations.

— the difference in the sums of B- and A type impulses and the duration of the sympathetic inhibition.

— the ratio of B- and A type impulses and the number of sympathetic impulses.

— the sum of B- and A type impulses, and the left ventricular relative stroke volume

3 The number of B-type impulses was found to bear a linear correlation with the pressure impulse of the v-wave in a multifibre nerve preparation during normal atrial filling.

4 When the left atrial pressure was raised artificially

— the number of B-type impulses and the corresponding pressure impulse in different cycles were positively correlated

— the difference in the sums of B- and A type impulses had a linear positive correlation with the duration of sympathetic inhibition.

— the ratio of B- and A type impulses presented a positive inverse correlation to the number of sympathetic postganglionic impulses.

5 The number of A-type impulses showed a linear positive inverse correlation with the number of sympathetic impulses upon lowering of the left atrial pressure by blood suction.

6. The sum of B- and A type impulses had a positive correlation with the left ventricular relative stroke volume when the left atrial pressure was elevated from "subnormal" post suction levels.

7 On the basis of the present results and of some findings by others it is suggested that the A type impulses stimulate the sympathetic activity of the heart, while the B-type impulses exert an inhibitory action. The Bainbridge reflex is re-evaluated on the basis of this concept.

8. A hypothesis is presented of the influence and inactivation mechanism of the vagal cardiac afferent impulses in the CNS

ACKNOWLEDGEMENT

I wish to express my deep gratitude to Professor U.S von Euler under whose guidance it has been my priviledge to work. I am much indebted to Dr L. Stjärne for all his help advices and stimulating discussions during the performance of this work. To all members of the department I wish to express my sincere thank.

This study was supported by grants from the Swedish Medical Research Council, projects No B 68-14 X 97-04 B 69-14X 97-05A B 70-14X 97 06 B K 70-14X 3027-01A Reservationsanslaget, Karolinska Institutet Stiftelsen Lars Hiertas Minne Svenska Sällskapet for Medicinsk Forskning

Apart from certain hitherto unpublished results, the present thesis is based on the following papers

1 Inhibition by prostaglandin E of noradrenaline release and of effector response to nerve stimulation in the cat spleen. Life Sci. 1969 8 389—395 (Together with J Brundin)

2 Control by prostaglandin E_2 of sympathetic neurotransmission in the spleen Life Sci. 1970 *9* 269—278

3 Inhibitory action of prostaglandins E_1 and E_2 on the neuromuscular transmission in the guinea pig vas deferens. Acta physiol. scand. 1969 *77* 510—512. (Together with U S v Euler)

4 Inhibition by prostaglandin E_2 of sympathetic neurotransmission in the rabbit heart. Acta physiol. scand. 1970. (Preprint) (Together with L. Stjärne and Å. Wennmalm)

5 Antagonism between prostaglandin E_2 and phenoxybenzamine on noradrenaline release from the cat spleen. Acta physiol. scand. 1969 *76* 383—384

6 Antagonism by calcium of the inhibitory action of prostaglandin E_2 on sympathetic neurotransmission in the cat spleen. Acta physiol. scand. 1970. (Preprint)

These papers will be referred to below by their arabic numerals.

Abbreviations used

NA = noradrenaline PG = prostaglandin TA = tyramine PBA = phenoxybenzamine DMI = desmethylimipramine.

IV SUMMARY AND CONCLUSIONS 28

V REFERENCES 31

I INTRODUCTION

In 1930 Kurzrok and Lieb reported that addition of human seminal fluid to isolated uterine strips alters their contractile state in a complex way causing either contraction or relaxation. This appears to be the first observation of a biological effect that can be accounted for by prostaglandins, although it was for some time believed that acetylcholine was the active principle (Kurzrok and Lieb 1930 Cockrill, Miller and Kurzrok 1935)

Shortly after this Euler and Goldblatt independently described the vasodepressor and smooth muscle stimulating properties of human semen (Euler 1934 Goldblatt 1933 1935) Similar effects were obtained with seminal fluid from other species and with extracts of the vesicular glands of rams (Euler 1934) By preparing different extracts of seminal fluid and prostate and vesicular glands Euler found the active principle to be present in a fraction containing lipid soluble acids. With reference to the tissue source this novel kind of biologically active substance was named prostaglandin (Euler 1935 1936) From further studies it was concluded that the active principle is a lipid soluble fatty acid probably containing a double bond and a hydroxy group (Euler 1939)

More recent chemical work, mainly by Bergström and coworkers, made it apparent that prostaglandin is not a single substance but rather a family of biologically active lipids. In 1957 the first prostaglandin (PGF) was obtained in pure crystalline form (Bergström and Sjövall 1957) Shortly afterwards a more lipid soluble factor was isolated and termed PGE_1 (Bergström and Sjövall 1960) The two PG s proved to be unsaturated hydroxy acids with the empirical formulas C_{20} H_{34} O and C_{20} H_{32} O respectively (Bergström *et al* 1962 a) Further studies led to the isolation of several *related PG s and to determination of their chemical structures* (Bergström *et al.* 1962, b, *c*, 1963 a, b, Samuelsson 1963 1964 a, Hamberg and Samuelsson 1965 1966 Nugteren *et al* 1966) which are shown in Fig 1

The fundamental work of Euler and Goldblatt in the prostaglandin field made it natural that the initial work to isolate PG s was performed with extracts of seminal fluid and of accessory genital glands. However studies with sensitive methods have revealed that PG s are not confined to the

Fig. 1 Structural formula of prostaglandins

genital sphere but have a broad distribution in mammalian tissues. Thus PG s have been shown to be present in or released from a variety of tissues, such as lung (Bergström *et al* 1962 d) brain Samuelsson 1964 b, kidney (Lee *et al.* 1965) adrenals (Ramwell *et al* 1966) and spleen (Davies, Horton and Withrington 1967) The high activity and the wide spectrum of biological actions of PG s has subsequently led to the proposal of several hypotheses concerning their physiological function. These aspects have recently beeen reviewed (Bergström 1967 Bergström, Carlson and Weeks 1968 Horton 1969) and the discussion will therefore be limited to observations considered to be of interest in connection with the present study

The observed vasodepressor and smooth muscle stimulant properties of crude prostaglandin have in many respects been confirmed using pure PGE_1 and PGE_2. Thus the two compounds lower the arterial blood pressure in many animal species and in man (Bergström *et al* 1959 a, b, Holmes, Horton and Main 1963 Bergström and Euler 1963 Berti *et al* 1964) The blood pressure increasing effect of NA is also counteracted by PGE_1 and PGE_2 (Holmes, Horton and Main 1963 Bergström Carlson and Orö 1964) The reduction of the blood pressure is probably mostly due to vasodilation, since the two compounds have been shown to decrease flow resistence and to increase blood flow in tissues (Horton and Main 1963 Nakano and McCurdy 1967 Weiner and Kaley 1969) Peripheral resistance vessel strips in the dog show a biphasic dose—response curve with relaxation after small and contraction after high doses of the two compounds (Strong and Bohr 1967) On the other hand coronary aortic and carotid strips, and nasal vessels *in vivo* respond only by contraction on addition of PGE_1 or PGE_2 (Strong and Bohr 1967 Khairallah, Page and Türker 1967 Jackson and Stovall 1968)

The effect of PGE and PGE_2 on non—vascular smooth muscle is more complex in that they produce either contraction or relaxation, and potentiation or inhibition of responses to sympathetic nerve stimulation and to NA. Intestinal smooth muscle generally seems to be contracted by PGE_1 and PGE_2 (Bergström *et al* 1959 a, Bergström and Euler 1963 Horton and Main 1963) although relaxation has also been reported (Khairallah, Page and Türker 1967) Similarly the two compounds induce contraction of uterine muscle of some animal species, but relaxation in man (Bergström *et al.* 1959 a, Horton and Main 1963 Bygdeman 1964) The smooth muscle of the bladder is also contracted by PGE_1 (Naumada 1967) and in the eye the two compounds induce miosis (Wautzman and King 1967)

On the other hand several smooth muscle tissues respond with relaxation to PGE_1 or PGE_2. This has been demonstrated in the fallopian tube, in the

ureter and in tracheal muscle (Horton and Main 1963 Main 1964 Boyarsky and Labay 1968)

PGE_1 and PGE_2 have been shown to potentiate the mechanical responses to NA and to sympathetic nerve stimulation in several smooth muscle tissues. Thus PGE_1 enhances the contractile effect of NA on isolated rat and guinea pig seminal vesicles (Eliasson and Risley 1966) In the guinea pig *preparation PGE and PGE_2 magnify smooth muscle contraction* induced by hypogastric nerve stimulation (Naimzada 1969) The smooth muscle contractile responses to hypogastric nerve stimulation in the rat and guinea pig bladder and in guinea pig vas deferens are all increased by PGE_1 (Mantegazza and Naimzada 1965 Naimzada 1967)

On the other hand an antagonistic action of PGE_1 has been observed in many tissues. Thus in vas deferens, colon fundic strips and uterus of rats, and in uterus and tracheal chain of guinea pigs the responses to NA *in vitro* independently if relaxation or contraction, are antagonized by PGE_1 administered in subtreshold doses (Clegg 1966) Similarly the smooth muscle contractile response to sympathetic nerve stimulation is also counteracted by PCE in a number of tissues, such as rabbit vas deferens and oviduct and cat spleen (Mantegazza and Naimzada 1965 Brundin 1968 Hedqvist 1968)

The observations in a variety of smooth muscle tissues of antagonistic as well as agonistic actions of PGE_1 and PGE_2 were found rather intriguing and worth further consideration. To study this aspect three different sympathetically innervated muscle tissues were used, the cat spleen, the guinea pig vas deferens and the rabbit heart The methods used involved registration in the presence of PGE and PGE_2 of the mechanical responses to nerve stimulation and to NA, as well as analysis of the amount of NA overflowing in response to nerve stimulation with the aim to determine pre and postjunctional actions of the two compounds.

Experiments were carried out using cat spleens, guinea pig vasa deferentia, rabbit hearts and bovine splenic nerves.

Cat spleen The operation procedure was performed under general anaesthesia according to the method worked out at this laboratory (Hedqvist, Olivero and Stjärne 1968 Hedqvist and Stjärne 1969) The isolated spleen with intact vascular and nerve supply was transferred to a perfusion chamber maintained at 37° C, and perfused with a slightly modified Krebs-Henseleit's solution (NaCl 6 04 g, KCl 0 354 g, $MgSO_4$ 7 H_2O 0.294 g, $CaCl_2$ 0.282 g, Na pyruvate 0.524 g, Na l-glutamate 0.416 g, KH_2PO_4 0 163 g, $NaHCO_3$ 2.1 g, dextrose 2.08 g per 1000 ml H_2O) containing 2 % dextran and aerated with 5 % CO_2 in O_2. The flow rate was kept at 8—10 ml/min by means of a constant rate perfusion pump (Sigma motor) Ascorbic acid (20 μg/ml) was added to the perfusion fluid to protect noradrenaline (NA) in the medium, and hydrochloric acid was infused into the venous collecting system to maintain a suitably low pH in the perfusate. The effluent from the spleen was divided into 10 ml portions by means of an automatic fraction collector The splenic nerves were electrically stimulated by platinum electrodes. Trains of 200 pulses were applied by a Grass S4 stimulator operated at a frequency of 10/sec, a duration of 2—3 msec, and at supramaximal voltage, usually 10—15 V

Splenic capsular and trabecular contraction (splenic contraction) was measured as shortening of the organ, using a Harvard heart/smooth muscle transducer Changes in the perfusion pressure were measured with a Statham P23 transducer Both parameters were recorded on a Grass Model 5 Polygraph

In most experiments the NA stores of the spleen were labelled by intraarterial infusion of 30 μC of ^{3}H-dl-NA to facilitate monitoring of the outflow of total NA from the organ. The labelled NA was infused for 15 min at the beginning of the perfusion period. At least 30 min were then allowed to elapse before the main experiment was started.

Guinea pig vas deferens The animals were killed by a blow on the head and the vasa deferentia dissected out, freed from adjacent tissue and split longitudinally The preparation was mounted in a 20 ml bath at 37 C

with Tyrode solution of the following composition (NaCl 8 g KCl 0 2 g, CaCl 0.2 g, MgCl 0.1 g $NaHCO_3$ 1 g dextrose 1 g per liter of H O) and areated with 5 % CO_2 in O Electrical stimulation of the preparation was carried out with a Grass S4 stimulator coupled to a timer delivering 5 sec trains of rectangular pulses of 0 2—2 msec duration at frequencies of 20—40/sec and at supramaximal voltage, usually about 40 V each half or whole min The preparation was stimulated transmurally by two perspex—shielded electrodes placed on each side along the organ at a few mm distance (Birmingham and Wilson 1963) Contractions of the organ were recorded isometrically Hexamethonium (100 µg/ml) did not affect the contractile effect of stimulation, while guanethidine (1 µg/ml) abolished the stimulation response indicating postganglionic nerve stimulation.

Rabbit heart Rabbits were killed by a blow on the head and the hearts with intact sympathetic nerve supply were dissected out according to Hukovic and Muscholl (1962) and Löffelholz and Muscholl (1969) The preparation was perfused by Langendorff technique with Tyrode solution (NaCl 8 g, KCl 0 2 g CaCl 0.2 g $MgCl_2$ 0 2 g, $NaHCO_3$ 1 g, $NaH PO_4$ 0 05 g dextrose 1 g per liter of H O) aerated with 5 % CO in O_2 To the perfusion fluid were added ascorbic acid (40 µg/ml) to protect NA in the medium, and in most cases atropine (10^{-6} g/ml) The sympathetic nerves leaving the stellate ganglion were pulled through a plastic tubing with platinum ring electrodes in the wall Electrical stimulation of the nerves was carried out with Grass S5 stimulators, delivering 30 sec trains of rectangular pulses of 1 msec duration, at frequencies of 1 5 and 10/sec, and at supramaximal voltage usually about 30—40 V A strain gauge transducer was attached to the apex of the heart and myocardial contractile force and heart rate were recorded on a Grass Model 5 D Polygraph The effluent from the heart was collected in 2 min periods, immediately acidified and chilled. The NA content of representative samples was assayed fluorometrically as described below In a series of 6 control experiments the amounts of NA appearing in the effluent in response to 3 consecutive periods of nerve stimulation (300 pulses at 10/sec) at 15 min intervals were 112±19 ng 101±20 ng and 100±24 ng, (means ± S E.M)

Splenic nerves Bovine splenic nerves were obtained at the slaughter house within 30 min *post mortem* and immediately chilled with ice. The nerves were carefully dissected free from contaminating tissue and were in most cases delicated They were then placed in a nerve chamber with the midportion of the nerves kept in the same medium as was used in the cat spleen experiments (dextran excluded) The temperature of the chamber was kept constant at 37 C Stimulation of the nerves was carried out with

platinum electrodes and a Grass S4 stimulator operated at a pulse duration of 2—3 msec, using ascendant current, and at supramaximal voltage. Single pulses or short trains of rectangular pulses were delivered at 1 min intervals. The recording electrodes (platinum) were connected via a cathode follower to a DC preamplifier (Grass P 6 12 A, frequency response 0—10000 Hz) and a cathode ray oscilloscope (Tektronix 502)

Analysis The outflow of NA from the spleen was monitored by determining the radioactivity in the different crude perfusate fractions. 0.5 ml aliquots were counted in a 7 3 toluene absolute ethanol solution, containing 4 g of 2—5 diphenyloxazole and 100 mg of 1 4 bis-2(4-methyl—5-phenyloxazolyle) benzene per liter of toluene, in a Packard Liquid Scintillation Spectrometer Quenching was monitored by internal standards of H-dl-NA.

In the cat spleen and rabbit heart experiments representative perfusate samples were purified on alumina and their NA content assayed fluorimetrically according to Euler and Lishajko (1961) The NA values obtained in the different studies are expressed as free NA base and are not corrected for losses of about 25 % during the purification procedure. In control experiments the recovery of NA added to perfusate samples and carried through the entire procedure of purification and fluorimetrical determination was 70.4±2.2 % mean ±SEM, n = 12. Addition to the perfusate of PGE_1 or PGE_2 ($3\times10^{-}$ M) did not materially change the recovery of NA, being 73 9±2.0 % mean ±SEM, n = 6 with PGE_1 and 73 3±2.2 % mean ±SEM n = 6 with PGE_2

Agents used (doses used in the different studies refer to the salts unless otherwise stated) Atropine sulphate dextrane (Macrodex® M. 70000 Pharmacia) guanethidine sulphate (Ismeline® Ciba) hexamethonium chloride dl noradrenaline 7 H hydrochloride (New England Nucl. Corp) l noradrenaline bitartrate (used as free base) phenoxybenzamine hydrochloride (Dibenyline® Smith, Kline and French) prostaglandin E_1 [1] prostaglandin E_2 [1] tyramine hydrochloride.

[1] Kindly put at disposal by Professor S. Bergström, Karolinska Institutet, Stockholm, Sweden, and Dr J Pike, Upjohn Co., Kalamazoo, U.S.A.

III RESULTS AND DISCUSSION

A. Evidence for PGE_1 and PGE_2 acting as inhibitors of sympathetic neuromuscular transmission.

1 Effect of PGE_1 in the cat spleen (Paper 1) In the cat spleen experiments the vascular response to stimulation of the splenic nerves was counteracted in a dose—dependent manner by infusion of PGE (Fig 2) The pressor response to intraarterially administered NA was also reduced by PGE (Fig 1) On the other hand, the action of the compound on the outflow of NA in response to nerve stimulation was rather variable and showed no correlation between the administered dose and the effect obtained. In some cases PGE_1 caused a marked and reversible reduction of the efflux of NA in response to nerve stimulation. However in most experiments PGE_1 did not appreciably alter the outflow of NA, in spite of a clearcut depression of the vascular response This observation does not necessarily exclude a prejunctional action of the compound in these experiments. Certain adrenolytic drugs increase markedly the outflow of NA in response to sympathetic nerve stimulation (Brown and Gillespie 1957) So does an increased rate of flow through the organ (Hertting and Schiefthaler 1963 Follow Haggendal and Lisander 1968) By analogy PGE_1 which induces vasodilation and increased blood flow and counteracts the vascular response to NA (Horton and Main 1963 Steinberg *et al* 1963) would be expected to increase the outflow of NA in response to nerve stimulation by facilitating washout of NA released from the nerve terminals. Thus the absence of increased NA overflow seen in most experiments, is compatible with, and may be taken as further indication of an inhibitory prejunctional action of PGE leading to decreased transmitter release.

Blakeley *et al* (1968) using the cat spleen perfused with whole blood have reported that PGE increases the outflow of NA in response to nerve stimulation. They also found an increased rate of flow through the organ, which may thus contribute to the raised output figures for NA. However this cannot be the only explanation since PGE was also shown to increase the NA overflow after α-receptor blockade by phenoxybenzamine. Another and more reasonable explanation for increased transmitter overflow seems

to be improved microcirculation in the presence of PGE_1 since the compound was also found to inhibit the formation of platelet trombi in the penicillar arteries of the organ. In line with this assumption is the fact that the NA output figures in the cat spleen are several times higher when the organ is perfused with saline medium than with whole blood (Brown and Gillespie 1957 Blakeley Brown and Ferry 1963 Thoenen, Hürlimann and Haefely 1963 Hedqvist and Stjärne 1969) It is interesting to note that Davies and Withrington (1968, 1969) did not see any action of PGE on the effector responses either to nerve stimulation or to NA in the dog spleen perfused with whole blood

It may be concluded that PGE_1 counteracts the vascular response to nerve stimulation in the cat spleen. While this effect is mainly based on inhibition of the effector response to the NA released, it also appears to involve an inhibitory prejunctional action on NA release.

2 *Effect of PGE_2 in the cat spleen (Paper 2)* Low doses of PGE_2 were found to reduce the pressor as well as the splenic contraction responses to nerve stimulation. Higher doses of PGE_2 further depressed the splenic contraction response while the vascular response tended to increase again although it usually remained below that obtained during the preceding control stimulation. The effect of PGE_2 on the splenic contraction response to NA was weak and inconsistent. On the other hand the effect of PGE_2 on the vascular response to NA was found to be highly dose-dependent. Thus low doses of the compound reduced the pressor response while high doses produced a distinct potentation. This biphasic dose response curve may explain the above mentioned increase of the vascular response to nerve stimulation in the presence of high doses of PGE_2 as the result of a potentiating effect on released NA rather than facilitated release of NA from the nerves.

The effect of PGE_2 on the outflow of NA in response to nerve stimulation was much more consistent than that of PGE_1 In all doses used (6×10^{-8}—6×10^{-6} M) PGE_2 caused a clearcut decrease of the NA overflow response (Fig 1) The inhibition progressively increased with the dose of the compound, leading to NA output figures in the presence of PGE_2 6×10^{-6} M of the order of 20 per cent of those obtained during the preceding control stimulations. After the end of the infusion of PGE_2 the overflow response increased again For the lower doses of PGE_2 the time for complete restoration of the response was usually about 10 min and progressively increased with the dose used, often to exceed 30 min at 6×10^{-6} M.

In the dog spleen perfused with blood, PGE_2 does not alter the "splenic" responses to nerve stimulation or to NA (Davies and Withrington 1968,

1969) Species differences and/or differences in concentrations of PGE_2 used, may possibly account for the dissimilarity in effects produced in the cat and dog spleen.

The experimental data obtained in the cat spleen show that PGE_2 depresses the function of the sympathetic neuromuscular system of the organ, and that the compound exerts this action mainly prejunctionally.

3 *Interaction between PGE_2 and phenoxybenzamine in the cat spleen (Paper 5)* The interrelationship between the action of PGE_2 and phenoxybenzamine (PBA) on the outflow of NA in response to nerve stimulation will be discussed in detail in a later section and will therefore be only briefly mentioned here. While PGE_2 depresses the NA outflow in response to nerve stimulation PBA strongly potentiates this response, in the cat spleen (Brown and Gillespie 1957). In the present study exogenous PGE_2 was found to counteract this effect of PBA, leading to NA output figures close to those obtained during control stimulations in the absence of PBA and PGE_2 (Fig. 1). Since PBA blocks the mechanical motor response to nerve stimulation, the inhibitory effect of PGE_2 on NA outflow in this case can only be explained in terms of a prejunctional action. The fact that PBA has also been shown to abolish the outflow of endogenous PGE_2 in response to nerve stimulation in the spleen (Davies, Horton and Withrington 1967) raises the intriguing question whether the mechanisms of the potentiating effect of PBA on NA outflow in response to nerve stimulation could at least in part be due to "removal" of endogenous PGE_2 acting as brake on the transmitter release from sympathetic neurons.

4 *Effect of PGE and PGE in the guinea pig vas deferens (Paper 3)* At low concentrations PGE and PGE_2 were found to inhibit the contractions of the isolated guinea pig vas deferens elicited by transmural (postganglionic) nerve stimulation (Fig. 1). On the other hand higher concentrations, of the order of 100 ng/ml, potentiated the response to this type of stimulation. The contractile effect of NA was generally slightly enhanced even by doses found to inhibit the response to nerve stimulation.

The action of PGE on the hypogastric nerve—vas deferens preparation shows considerable species variation. In the guinea pig Mantegazza and Naimzada (1965) found that the contractile responses to adrenaline and to nerve stimulation were enhanced by PGE while it had no effect on the responses in rat and cat and in the rabbit preparation actually depressed the responses to both types of stimulation. In line with this last mentioned effect is the report that PGE both *in vivo* and *in vitro* reduces contractions

of the rabbit vas deferens induced by adrenaline (Holmes, Horton and Main 1963) In the guinea pig vas deferens Graham and Al Katib (1967) found that PGE_1 markedly enhanced the contractile effect of NA. In the same preparation PGE has also been reported to cause minor changes in the response to nerve stimulation varying from slight inhibition to moderate potentiation (Sjöstrand and Swedin 1968)

These data show that PGE_1 and PGE_2 alter the contractile effect of nerve stimulation or of exogenous catecholamines in the vas deferens, although there seems to be considerable species variation in the mode of response. In view of the present results it seems likely that in anyone species the dose of PGE_1 or PGE_2 used determines whether the action will be stimulatory or inhibitory

The NA overflow from the guinea pig vas deferens in response to nerve stimulation was not measured. However inhibition by PCE_1 and PGE_2 of the contractile response to nerve stimulation and potentiation by the same dose of the response to exogenous NA cannot be wholly explained by post junctional effects. By analogy with the results from the cat spleen it must be concluded that the two compounds in addition to having postjunctional effects also act prejunctionally decreasing the amount of NA released from the nerve terminals. A dual action of PGE_1 and PGE_2 might explain the inhibition of the response to nerve stimulation at low doses of PGE_1 and PGE_2, and potentiation by high doses. At a low dose the two agents act predominantly at the prejunctional level, reducing the release of transmit ter and thus the contractile response. At a higher dose the release of NA from the nerve terminals is probably still reduced, judging from the obser vations in the spleen but the progressively increasing potentiation of the smooth muscle stimulating effect of the NA released, in the high PGE and PGE_2 dose range, may thus lead to a net increase of the contractile response.

The observations on the guinea pig vas deferens discussed here have recently been confirmed by other authors, using the same preparation and PGE_2 (Ambache and Zar 1970) Additional support for a prejunctional action of PGE_1 and PGE_2 is the finding that after complete denervation of the guinea pig vas deferens the contractile response to direct electrical stim ulation is potentiated by PGE in doses, which in organs with intact nerve supply causes inhibition of the response to transmural nerve stimulation (Sjöstrand and Swedin 1970)

5 *Effect of PGE in the rabbit heart (Paper 4)* Stimulation of the sym pathetic nerves to the perfused rabbit heart for 30 sec periods at 1 5 and

10/sec produced a frequency—dependent increase in heart rate and in myocardial contractile force. Infusion of PGE_1 in doses ranging form 8×10^{-8} to 5×10^{-7} M markedly and reversibly reduced the chronotropic response. The inotropic response to nerve stimulation was also depressed by PGE_1 but to a lower extent than the chronotropic response

In contrast to the action on responses induced by nerve stimulation PGE_2 caused only weak and inconsistent effects on the chronotropic and inotropic responses to exogenous NA.

PGE_2 in the same doses as mentioned above markedly and reversibly depressed the outflow of NA to sympathetic nerve stimulation (Fig 1)

In connection with infusion of PGE_2 most fluorimetric analyses of NA in the effluent from perfused hearts were performed after stimulation at a frequency of 10/sec. However PGE_2 was found to inhibit the outflow of NA virtually to the same extent when the nerves were stimulated at 5/sec. At 1/sec stimulation the amount of NA in the effluent was too low to permit satisfactory evaluation. However judging from the inhibition of the effector response to nerve stimulation at 1/sec there is reason to believe that PGE at this frequency produced the same type of prejunctional interference as seen with higher frequencies of stimulation.

Recent observations made in the rabbit heart have shown that PGE in a similar manner as PGE_2 reduces the outflow of NA in response to nerve stimulation (Hedqvist and Wennmalm 1970) The chronotropic and inotropic responses to nerve stimulation are also reduced, while those to NA are only weakly and inconsistently affected by PGE_1 The only difference between PGE and PGE in the action on the rabbit heart seems to be that PGE more markedly reduces the inotropic response to nerve stimulation, while PGE appears to be more operative on the chronotropic response.

(*Concluding remarks* The data presented clearly demonstrate a prejunctional action of PGE and PGE_2 on the sympathetic neuromuscular system in the three tissues studied. This prejunctional effect apparently consists in direct inhibition of the process of NA release from the sympahtetic nerve terminals, as will be documented in the following section.

As to the relative activity in this respect there seems to be a certain species and or tissue difference Thus PGE_2 is at least more consistently effective than PGE in the cat spleen, while in the guinea pig vas deferens and in the rabbit heart PGE seems to be equally or more active This is in agreement with observations in other systems, according to which either PGE_1 or PGE_2 may be *quantitatively more efficient* although they produce qualitatively similar responses Horton and Main 1963 1966)

The results on the heart indicate that the two compounds exert their inhibitory action throughout the physiological range of impulse activity in sympathetic nerves (*cf* Folkow 1952 Celander 1954)

The demonstration that PGE and PGE_2 by a prejunctional action inhibit the sympathetic neuromuscular system in cat spleen guinea pig vas deferens, and rabbit heart makes it likely that this action of the two compounds is not confined to the animal species and tissues studied, but constitutes a principle generally present in sympathetically innervated tissues. Compatible with this view are several observations in other tissues, such as rat epididymal fat pad and rabbit vas deferens and oviduct (Berti and Usardi 1964 Mantegazza and Naimzada 1965 Brundin 1968)

The adrenal medulla, although homologue to sympathetic postganglionic nerves, does not seem to fit into this scheme. PGE_2 does not inhibit the catecholamine releasing effect of carbachol or acetylcholin in the isolated perfused adrenal gland or of splanchnic nerve stimulation *in vivo* (Hedqvist and Stjärne 1970)

B. Analysis of the prejunctional action of PGE_1 and PGE_2 in the sympathetic neuromuscular system.

Previous information concerning the mechanisms whereby PGE_1 and PGE_2 interact with the function of smooth and cardiac muscle seems to be exclusively related to postjunctional events. Thus hypopolarization or depolarization of the cell membrane has been supposed to explain enhancing or stimulating action (Khairallah Page and Türker 1967 Paton and Daniel 1967) The enhancing effect of PGE and PGE_2 has also been concluded to be mediated intracellularly by facilitation of excitation contraction coupling (Clegg, Hall and Pickles 1966) Antagonism of the smooth muscle response to NA has been explained by binding of NA to the adrenergic receptor (Clegg 1966) or by an intracellular action rendering the ionic calcium inactive (Strong and Bohr 1967)

The demonstration in the present experiments of a prejunctional action of the two compounds in the sympathetic neuromuscular system, prompted an attempt to study the target for this effect. However for technical reasons this is difficult since the chain of events from the propagated impulse in the postganglionic nerve fibre to extrusion of transmitter into the synaptic cleft may involve many steps and is only fragmentarily known It therefore must be kept in mind that the conclusive answer cannot be given at present and that data to be presented here provide only circumstantial evidence for or against some of the possible levels of action.

1 *Nerve conduction (Paper 6)* PGE injected retrogradely in the lingual artery does not inhibit contractions of the nictitating membrane induced by preganglionic nerve stimulation (Holmes, Horton and Main 1963) Nor is the ganglionic transmission in the superior cervical ganglion affected by PGE or PGE_2 (Kayaalp and McIsaac 1968) In the present study it was found that in bovine splenic nerves PGE_2 even in high concentration (3×10^{-4} M) did not alter the amplitude of action potentials elicited by electrical stimulation of the nerves (Fig 4) While these observations indicate that PGE and PGE_2 do not act as blockers of ganglionic transmission or of impulse conduction in sympathetic nerve trunks, they do not exclude the possibility that the two compounds may inhibit the propagation of nerve impulses in the fine fibres of the sympathetic ground plexus. Such intraterminal blocks have been suggested for drugs like guanethidine and bretylium (*cf* Iversen 1967) although they do not prevent the transmission of impulses in the postganglionic nerve trunk (Exley 1957 1960) However this action seems to be coupled to a selective accumulation in sympathetic nerves (Boura *et al* 1960 Bisson and Muscholl 1962) Since tritium labelled PGE_1 does not appear to accumulate in sympathetic nerves (Hansson and Samuelsson 1965) it does not seem likely that PGE and PGE_2 act by causing intraterminal block of nerve conduction.

PGE and PGE_2 do not affect the secretion of catecholamines from the adrenal medulla Miele 1969 Hedqvist and Stjärne 1970) In this tissue the resting membrane potential of the medullary cells is rather low and stimulation does not lead to reversal and overshoot but only to a minimal local depolarization Douglas, Kanno and Sampson 1967 Kanno and Douglas 1967) There does not seem to be any reason to believe that the resting membrane potential or the reversal and overshoot in response to stimulation in the sympathetic nerve terminals should differ qualitatively from that of other neurons. The differencies in electrophysiological properties between the two tissues might thus possibly explain why the release of NA from sympathetic nerves is inhibited by PGE and PGE_2 and the hormone secretion from the adrenal medulla is not.

2. *Stimulus secretion coupling (Paper 6)* Very little is known about the mechanism by which nerve impulses promote the release of NA from sympathetic nerves. However it seems established that the release process is critically calcium dependent (*cf* Ferry 1966 Simpson 1968) Thus the release of NA from the isolated rabbit heart as a result of stimulation is considerably reduced when the calcium content of the perfusion medium is lowered (Hukovic and Muscholl 1962) Similarly the release of NA from the

cat colon in response to nerve stimulation is prevented in calcium—free medium (Boullin 1966) In the cat spleen the amount of NA overflowing in response to nerve stimulation varies whit the calcium content in the per fusion medium (Kirpekar and Misu 1967) In several other preparations the effector response to sympathetic nerve stimulation is reduced or abol ished when calcium is omitted from the medium (Kuriyama 1964 Burn and Gibbons 1964 1965) Since the release of NA from sympathetic nerves in response to nerve stimulation is a calcium—dependent process, it seems possible that PGE_1 and PGE_2 may inhibit the release process by interfering with the availability of calcium. In view of this it is interesting that there seems to be, at the postjunctional level, a definite but so far unexplained interrelationship between PGE_1 and calcium. Thus in the frog and guinea pig heart PGE_1 increases the exchange of calcium (Arienti, Piccinini and Pomarelli 1967 Klaus and Piccinini 1967) On the other hand in rat stomach fundic strips the uptake of calcium is not increased by PGE while in this tissue the spontaneous loss of radiocalcium is affected by PGE_1 in a biphasic manner an initial acceleration later followed by retardation of the loss (Coceani *et al* 1969) In several tissues the action of PGE seems to vary with the calcium content in the medium. Thus, in the guinea pig heart the chronotropic and inotropic responses to PGE_1 are increased when the calcium concentration in the perfusion medium is lowered (Mantegazza 1965) Similarly the potentiating effect of PGE on the contractile effect of nerve stimulation in the guinea pig vas deferens, and the antilipolytic effect of the compound in rat epididymal fat, is mag nified by reducing the calcium content in the incubation medium (Mante gazza and Namyada 1965 Fassina and Contessa 1967) On the other hand, addition of calcium counteracts the inhibitory effect of PGE_1 on pla telet electrophoretic mobility (Emmons *et al* 1967) Similarly the short circuit current response to PGE_1 in the frog skin is reduced by excess cal cium (Fassina, Carpenedo and Santi 1969)

In the present study an increase of the calcium content in the medium perfusing the spleen was found to counteract the inhibitory action of PGE_2 and to restore to near normal values the amount of NA overflowing in response to nerve stimulation (Fig 1) This observation may indicate that PGE_2 interferes with transmitter release by inhibition of calcium influx induced by depolarization or by preventing calcium from reaching specific reactive sites in the interior of the neuron. Additional support for this view is given by the absence of action of PGE_2 on the NA releasing effect of TA, which is calcium—independent (Burn and Gibbons 1965 Lindmar Löffel holz and Muscholl 1967 Thoenen, Hürlimann and Haefely 1969) How-

ever the observation that the secretion of catecholamines from the adrenal medulla, which is calcium-dependent (Douglas and Rubin 1961 1963) is not affected by PGE_1 and PGE_2 (Miele 1969 Hedqvist and Stjärne 1970) might appear to make the calcium hypothesis less likely

3 *VI storage particles (Paper 6)* In recent years it has been increasingly clear that the NA store in postganglionic nerve endings cannot be regarded as a single homogenous pool (Trendelenburg 1961) Nerve stimulation has been assumed to release NA directly from the granules (Carlsson 1965) However the view has also been proposed that NA stored extragranularly possibly in the axonal membrane itself or closely associated with it might represent the small pool from which transmitter release occurs on arrival of nerve impulses (Euler 1966 1970 Stjarne 1966 Folkow Häggendal and Lisander 1968 Stjarne Hedqvist and Bygdeman 1969) Since PGE_1 and PGE inhibit the release of NA from the neurons induced by nerve stimulation it appeared desirable to study the effect of the two compounds on pharmacologically induced release of NA. For this purpose TA was chosen. The exact source from which NA is released by TA is not definitely known (*cf* Iversen 1967) *but it appears to be different from that from which NA is* released by nerve stimulation (Axelrod *et al* 1962) According to *in vitro* evidence TA accelerates the spontaneous loss of NA from nerve granules partly by a direct action, partly by inhibition of reuptake, (Euler and Lishajko 1968) The same mechanism may be relevant also for the *in vivo* effects of TA, since the temperature dependence of TA induced release of NA from the spleen is similar to that of spontaneous release of NA from isolated nerve granules (Wennmalm, Hedqvist and Stjärne 1970)

In the present study PGE_2 in a dose which caused a marked reduction of NA outflow to nerve stimulation, did not alter the efflux of NA induced by intraarterial infusion of TA into the isolated cat spleen (Fig 2) Moreover PGF and PGE (3×10^{-4} —3×10^{-3} M) did not affect the spontaneous loss of NA from incubated bovine splenic nerve granules (Hedqvist unpubl)

Thus processes directly associated with release of NA from nerve granules do not seem to be affected by PGE and PGE_2 However it is questionable whether NA release induced by nerve stimulation, even if it involves mobilization of granule bound NA, is immediately and directly dependent on the release from granules (for references, see above) The conclusion is so far negative Inhibition of spontaneous or TA induced release of NA from nerve granules does not seem to be the mechanism by which PGE and PGE depress the release of NA in response to nerve stimulation This indicates that the two compounds do not directly attack the nerve

granules themselves but rather some other link involved in the re[illegible] transmitter from sympathetic nerve terminals.

4 *NA synthesis (Paper I 2 6).* In the cat spleen experim labelled NA was infused in order to monitor the outflow of to[illegible] radioactive material released in response to nerve stimulation represent mostly unchanged NA (Hedqvist, Olivero and Str If newly synthesized NA is preferentially released by nerve stim Kopin *et al* 1968) an inhibitory action of PGE_1 and PGE_2 on t sis would be expected to cause a relative rise in the specific acti /gNA) of the NA in the effluent from the organ. However thi the case. PGE_1 and PGE_2 caused a closely parallel reduction of the of radioactive material and of fluorimetrically determined NA. Th present study gives no support for the possibility that inhibition o synthesis is of any major importance for the inhibitory action of the two compounds on sympathetic neurotransmission.

5 *Release of transmitter into the extracellular space.* Very little is known about the mechanisms by which NA, upon arrival of nerve impulses, is transported to the exterior of the axon. Nor do the present experiments provide any evidence for or against this process as possible candidate for action of PGE_1 and PGE_2. The striking differences in action of the two compounds on transmitter release from sympathetic nerves versus catecholamine secretion from the adrenal medulla, as well as the definite differences in secretory properties between the two tissues, may however justify a comment.

The feasibility for hormone secretion from the adrenal medulla by exocytosis seems to be well established (*cf* Douglas 1968). The evidence is that catecholamines secreted in response to splanchnic nerve stimulation or to acetylcholine appear in the effluent, accompanied by all soluble components of the medullary granules, in the same proportions in which they occur in the granules (Banks and Helle 1965, Douglas 1966, Blaschko *et al* 1967, Kirshner, Sage and Smith 1967). The exocytosis process has also been claimed to be all or none in character, leading to the extrusion of the total content of soluble components of individual granules (Viveros, Arqueros and Kirshner 1969).

Transmitter release from sympathetic nerves has also been postulated to occur by exocytosis (Douglas 1968). However the adrenal medulla and sympathetic nerves differ *in vivo* in catecholamine turnover as well as in sensitivity to drugs. Also the amine storage granules demonstrate certain

dissimilarities, such as in spontaneous amine—ATP release, response to drugs, and resistance to physical changes in the incubation medium (Stjärne 1964). Although stimulation of the sympathetic nerves of the spleen has been reported to involve the release of both NA and of presumably granular protein, there appears to be a large excess of NA in relation to protein in the effluent (De Potter *et al.* 1969). PBA induced potentiation of the outflow of NA in response to nerve stimulation does not cause increased efflux of granular protein (Moerman, personal communication). Similarly, after labelling the adenine nucleotides of catecholamine storage granules, catecholamine secretion from the perfused cat adrenal medulla, in response to carbachol, is accompanied by efflux of labelled nucleotides, while NA release from the isolated spleen, in response to nerve stimulation, is not. (Stjärne, Hedqvist and Lagercrantz 1970). Moreover, it has been enunciated that the amount of NA released by each nerve impulse corresponds to only a fraction of the NA content of individual nerve granules (Folkow, Häggendal and Lisander 1968, Stjarne, Hedqvist and Bygdeman 1969). On the basis of evaluation of the differences, as well as the similarities in secretory properties of sympathetic nerves and adrenal medulla, it has been postulated that exocytosis may be the mechanism whereby the process of transmitter release from sympathetic nerves is initiated, leading to breakthrough of the axonal membrane, and that other mechanisms take over for the continued transmitter efflux (Stjärne 1970).

Besides the differences in electrophysiological properties of sympathetic nerves and adrenal medulla, these dissimilarities in secretory properties might be sufficient reason why PGE_1 and PGE_2 affect transmitter release from the sympathetic nerves but not hormone secretion from the adrenal medulla.

In this context it is interesting that large amounts of PGE_2 are released from the spleen in response to nerve stimulation (Davies, Horton and Withrington 1967) accompanied by fading of the mechanical contractile response. The rate of fading progressively increases with the stimulation frequency and occurs in spite of an essentially unchanged NA content of the organ (Stjarne and Hedqvist to be published). This might be due to depletion of a small "transmitter pool". However, it might also represent active control of the release of transmitter exerted by endogenous PGE_2 secreted either from the smooth muscle cells or from other sources, possibly the nerve terminals themselves.

6. *Effect of PGE and PGE on the mechanisms of inactivation of transmitter released.* At least theoretically it is conceivable that PGE_1 and

PGE_2 could depress the motor response to nerve stimulation as well as the outflow of NA released by promoting its enzymatic inactivation or physical binding, in the nerves or extraneuronally

a) *Enzymatic degradation (Paper 1 2 6)* Considerable uncertainty remains about the relative importance of O-methylation or oxidative deamination in the inactivation of NA released from sympathetic nerves. Studies of the fate of intravenously administered labelled NA have shown that O-methylation is the main metabolic pathway for enzymatic inactivation of circulating NA (Axelrod *et al.* 1958) while deamination by monoamine oxidase represents the means for intraneuronal metabolism of NA not protected by binding (Kopin 1964) However neither metabolic route appears to be essential for the termination of the physiological action of NA released from the neurons in response to nerve stimulation (Brown and Gillespie 1957 Hedqvist and Stjärne 1969)

Theoretically PGE_1 and PGE_2 might reduce the effective outflow of NA by increasing the metabolic degradation of NA released. In the present study no direct analyses was performed of NA metabolites in the effluent from the cat spleen, in the presence of the two compounds. However the experiments seem to provide some evidence that the two compounds do not alter the rate of metabolic degradation of NA released from the nerve terminals. After labelling the NA stores with tritiated NA in order to monitor the efflux of NA from the spleen, PGE_1 and PGE_2 were found to cause simultaneous, closely parallel and reversible reduction of the efflux of total radioactive material and of fluorimetrically determined NA in response to nerve stimulation. Thus the conclusion may be drawn that PGE_1 and PGE_2 do not depress the outflow of NA released from sympathetic nerves by means of increased metabolic degradation.

b) *Physical binding (Paper 2)* Binding in the tissues represents a quantitatively important route for rapid removal of catecholamines from the circulation (Lund 1951 Whitby Axelrod and Weil-Malherbe 1961 Muscholl 1960 1961 Strömblad and Nickerson 1961) At physiological rates only small amounts of NA appear in the effluent from stimulated tissues (Celander 1954 Brown and Gillespie 1957) On the other hand the out flow can be greatly increased by drugs which depress uptake of NA into sympathetic nerves (Brown and Gillespie 1957 Brown 1965) These observations have led to the consideration that reuptake is the main mechanism for inactivation of NA released from sympathetic nerves (Paton 1960 Blakeley Brown and Geffen 1964 Stjärne 1964 Brown 1965 Haefely

Hürlimann and Thoenen 1965 Gillespie and Kirpekar 1965 Hedqvist and Stjarne 1966 1969 Geffen 1967 Folkow Häggendal and Lisander 1968)

The possibility that PGE_2 depresses NA outflow on nerve stimulation by facilitating reuptake of locally released NA, was studied in the cat spleen It was found that PGE_2 did not appreciably alter removal of tritium-labelled exogenous NA infused into the organ (Fig 3) Thus there is no reason to believe that action at this level can explain the observed prejunctional effects of PGE and PGE_2

7 *Physiological aspects on pharmacological interference with the effect of* PGE_1 and PGE_2.

a) *Interaction between* PGE_2 *and phenoxybenzamine (Paper 5)* Phenoxybenzamine (PBA) has been shown to cause a huge increase of the outflow of NA from the cat spleen in response to nerve stimulation (Brown and Gillespie 1957 Kirpekar and Cervoni 1963 Thoenen, Hürlimann and Haefely 1964 a, Hedqvist and Stjärne 1966) Since PBA inhibits the uptake of NA into sympathetic nerves (Hertting Axelrod and Whitby 1961 Axelrod, Hertting and Potter 1962, Farrant, Harvey and Pennefather 1964 Gillespie and Kirpekar 1965) inhibition of reuptake of NA released by nerve stimulation has been regarded as the main mechanism responsible for the increased outflow of NA in the presence of the drug (Thoenen Hürlimann and Haefely 1964 a) However cocaine and desmethylimipramine (DMI claimed to be at least equally potent and more specific as blocker of NA uptake (Iversen 1965 Gillespie and Kirpekar 1965 Malm for produce only a moderate increase or no change of NA efflux induced by nerve stimulation (Kirpekar and Cervoni 1963 Thoenen Hürlimann and Haefely 1964 b Geffen 1965) This has made it necessary to assume that the differences in effect are due to mechanical factors, the α-receptor blocking properties of PBA, by preventing the vascular responses to NA promoting washout of NA released while the intense vasoconstriction in the presence of cocaine and DMI counteracts effective washout of the NA released / Rosell Kopin and Axelrod 1963) In the case of phentolamine which is a rather weak inhibitor of NA uptake (Hertting Axelrod and Whitby 1961 almost the whole of its action on transmitter overflow may be related to the effect on blood flow (Hertting 1965) On the other hand α-receptor blockade *per se* has been reported to cause but a small increase of the NA outflow from the spleen in response to nerve stimulation (Thoenen Hurlimann and Haefely 1964 a)

This may justify the search for additional levels of action of PBA besides

inhibition of NA reuptake and blockade of α receptors, to explain the large outpouring of NA in the presence of the drug

In the dog spleen, nerve stimulation causes the simultaneous appearance of NA and PGE_2 in the effluent from the organ. In the presence of PBA is the outflow of NA markedly increased while that of PGE_2 is completely abolished (Davies, Horton and Withrington 1967) This observation seems particularly interesting since the present study provides good evidence that exogenous PGE_2 depresses the release of NA from sympathetic neurons in response to nerve stimulation and also counteracts the potentiating effect of PBA on this process, leading to NA output figures close to those obtained during nerve stimulations in the absence of PBA and PGE_2 (Fig 1)

It is thus conceivable that PBA, in addition to causing α receptor blockade and inhibition of NA uptake, promotes increased transmitter outflow in response to nerve stimulation by preventing the local release of endogenous PGE_2 possibly normally triggered by contraction of smooth muscle, and representing a braking mechanism controlling the continued release of NA from the sympathetic neurons. Such an action might well explain the striking differences between the effects of PBA, and of cocaine and DMI on the outflow of NA in response to nerve stimulation.

An interaction between PGE_2 and PBA is of particular interest because it provides support for the hypothesis that endogenous PG s of the E series may act as feed back inhibitors of neurotransmitter release from sympathe tic nerve terminals.

b) *Interaction between PGE and atropine (Paper 3 4 6)* Using crude prostaglandin extract, Euler (1934) found its action on rabbit blood pressure and intestinal smooth muscle to be resistant to administration of atropine. Similar results have been obtained with pure PGE Thus atropine does not inhibit the blood pressure reducing action or the contractile effect on intestinal smooth muscle of PGE_1 in the rabbit (Bergström *et al* 1959 a) Nor is the contractile response of the rat uterus to PGE_1 or the relaxation of isolated vascular strips caused by PGE altered by atropine (Paton and Daniel 1967 Strong and Bohr 1967)

In the present study atropine was found to counteract or in some cases to abolish the inhibitory action of PGE on the contractile response to post ganglionic nerve stimulation in the guinea pig vas deferens preparation, while the contractile effects of nerve stimulation or of exogenous NA were only very slightly affected. However atropine did not alter the effects of PGE_2 in spleen and heart. Atropine also appears to be devoid of effect on the inhibitory action of PGE_1 on NA release and on the effector responses

to sympathetic nerve stimulation in the rabbit heart (Hedqvist and Wennmalm 1970). Species differences or differences in nerve supply (*cf.* Sjöstrand 1965) may possibly account for this discrepancy.

C. Possible role of PGE_1 and PGE_2 in sympathetic neuromuscular transmission (Paper 1, 2, 3, 4, 5)

Already 1936 it was supposed that the strong smooth muscle stimulating properties of prostaglandin could be of importance for the emptying of the male accessory genital glands (Euler 1936). Further studies led to the hypothesis that prostaglandin acts by facilitating passive sperm transport in the uterus by a local action (Eliasson 1959). The discovery that prostaglandin is not a single substance but rather a family of biologically highly active compounds with a broad distribution in animal tissues has led to the proposal of several other functions.

PGs have been suggested to act as transmitters or transmitter modulators in the central nervous system (Horton and Main 1967). The experimental basis is that PGs are natural constituents of the brain and the spinal cord (Samuelsson 1964 b, Coceani and Wolfe 1965, Horton and Main 1967), that they are released from the central nervous system both spontaneously and in response to electrical and chemical stimulation (Coceani and Wolfe 1965, Ramwell and Shaw 1966, Ramwell, Shaw and Jessup 1966), and that they upon administration produce distinct effects (Horton 1964, Wanzuno, Bradley and Wolstencroft 1966, Hoffer, Siggins and Bloom 1969). Basically the same type of experimental evidence has led to the proposal that PGE_1 by an action on the adenyl cyclase—cyclic AMP system may modulate lipolysis and gastric secretion (Bergström 1967, Horton 1969).

PGE and PGE have been shown to be present in many sympathetically innervated tissues (Ramwell and Shaw 1967, Karim, Sandler and Williams 1967, Karim, Hillier and Devlin 1968). As to their cellular distribution *information is still incomplete*. In the spleen it appears that PGE_2 may be released from smooth muscle cells (Gilmore, Vane and Wyllie 1968). However some drugs have been reported to cause the release of PGE_2 from the spleen in the absence of smooth muscular contraction, indicating that PGE may be derived from other sources than the muscle cells (Gilmore, Vane and Wyllie 1969). PG or PG-like material has also been demonstrated in several types of nerve tissue (Kataoka, Ramwell and Jessup 1967, Karim, Hillier and Devlin 1968). Thus the possibility should no be overlooked that some PGE and PGE_1 may be located in sympathetic nerve ter-

minals, and become activated by mechanisms involved in transmitter release.

In the present study PGE and PGE_2 were found to markedly and reversibly inhibit the sympathetic neuromuscular transmission in the cat spleen, in the guinea pig vas deferens and in the rabbit heart. In the cat spleen the release of NA from the sympathetic neurons was markedly reduced by exogenous PGE_2 in concentrations comparable to those which may occur as result of release of endogenous PGE_2 from the dog and cat spleen in response to nerve stimulation (Davies, Horton and Withrington 1967 1968 Gilmore, Vane and Wyllie 1968) PBA causes a large increase of the outflow of NA from the spleen in response to nerve stimulation (Brown and Gillespie 1957) and simultaneously prevents the release of PGE_2 (Davies, Horton and Withrington 1967) Administration of PGE_2 was found to counteract the action of PBA on transmitter overflow leading to NA output figures close to those obtained in the absence of PGE_2 and PBA.

On the basis of their natural occurrence and availability for release, as well as the demonstrated effects of exogenous PGE and PGE_2 it is tempting to assume that endogenous PGE and PGE_2 may play a physiologically significant regulatory role in sympathetically innervated tissues, especially in view of the low concentrations needed to depress the effect of sympathetic nerve stimulation. This homeostatic action of PGE_1 and PGE_2 possibly but not necessarily triggered by the mechanical response to nerve stimulation, appears to be exerted by inhibition of NA release from the sympathetic neurons and, to some extent by inhibition of the effector response to NA released. However direct proof of this hypothesis cannot be given at present, and may probably be obtained only when specific inhibitors of PG synthesis and action are available.

to sympathetic nerve stimulation in the rabbit heart (Hedqvist and Wennmalm 1970). Species differences or differences in nerve supply (*cf* Sjöstrand 1965) may possibly account for this discrepancy.

C. Possible role of PGE_1 and PGE_2 in sympathetic neuromuscular transmission (Paper 1, 2, 3, 4, 5)

Already 1936 it was supposed that the strong smooth muscle stimulating properties of prostaglandin could be of importance for the emptying of the male accessory genital glands (Euler 1936). Further studies led to the hypothesis that prostaglandin acts by facilitating passive sperm transport in the uterus by a local action (Eliasson 1959). The discovery that prostaglandin is not a single substance but rather a family of biologically highly active compounds with a broad distribution in animal tissues has led to the proposal of several other functions.

PG's have been suggested to act as transmitters or transmitter modulators in the central nervous system (Horton and Main 1967). The experimental basis is that PG's are natural constitutents of the brain and the spinal cord (Samuelsson 1964 b, Coceani and Wolfe 1965, Horton and Main 1967), that they are released from the central nervous system, both spontaneously and in response to electrical and chemical stimulation (Coceani and Wolfe 1965, Ramwell and Shaw 1966, Ramwell, Shaw and Jessup 1966) and that they upon administration produce distinct effects (Horton 1964, Avanzino, Bradley and Wolstencroft 1966, Hoffer, Siggins and Bloom 1969). Basically the same type of experimental evidence has led to the proposal that PGE by an action on the adenyl cyclase—cyclic AMP system may modulate lipolysis and gastric secretion (Bergström 1967, Horton 1967).

PGE and PGF have been shown to be present in many sympathetically innervated tissues (Ramwell and Shaw 1967, Karim, Sandler and Williams 1967, Karim, Hillier and Devlin 1968). As to their cellular distribution information is still incomplete. In the spleen it appears that PGE_2 may be released from smooth muscle cells (Gilmore, Vane and Wyllie 1968). However some drugs have been reported to cause the release of PGE_2 from the spleen in the absence of smooth muscular contraction, indicating that PGE may be derived from other sources than the muscle cells (Gilmore, Vane and Wyllie 1969). PG or PG like material has also been demonstrated in several types of nerve tissue (Kataoka, Ramwell and Jessup 1967, Karim, Hillier and Devlin 1968). Thus the possibility should not be overlooked that some PGE and PGE_2 may be located in sympathetic nerve ter-

outflow in response to nerve stimulation. In the same preparation the NA releasing action of TA was not affected by PGE_2. The fact that NA release induced by nerve stimulation is critically calcium—dependent, while that by TA is not, indicates that PGE and PGE_2 might interfere with transmitter release by inhibition of calcium influx induced by depolarization, or by preventing calcium from reaching specific reactive sites in the interior of the neuron. However the observation that the calcium—dependent secretion of catecholamines from the adrenal medulla is not affected by PGE_1 and PGE_2 might appear to make the calcium hypothesis less likely.

In bovine splenic nerves PGE_2 did not alter the amplitude of action potentials elicited by electrical stimulation of the nerves. While this observation indicates that the compounds do not act as blockers of impulse conduction in sympathetic nerve trunks, it does not exclude the possibility that PGE_1 and PGE_2 may inhibit the propagation of nerve impulses in the fine fibres of the sympathetic ground plexus.

The striking difference in action of PGE and PGE_2 on transmitter release from sympathetic nerves versus catecholamine secretion from the adrenal medulla, as well as the definite differences in secretory properties between the two tissues were discussed, and it was tentatively suggested that the two compounds might act prejunctionally by interfering with the transport of NA into the extracellular space.

In the cat spleen a definite interaction was observed between PGE_2 and PBA. Since PBA is known to abolish the efflux of endogenous PGE_2 from the spleen in response to nerve stimulation and since the potentiating action of PBA on NA outflow to nerve stimulation in the same tissue seems difficult to explain only in terms of its α-receptor blocking and uptake inhibiting properties, it was suggested that part of the action of PBA on transmitter release from the spleen may be due to inhibition of local release of PGE_2 acting as an endogenous braking mechanism on transmitter release.

Atropine was found to counteract the inhibitory action of PGE_1 on the contractile response to nerve stimulation in the vas deferens preparation. However a similar action of atropine could not be established when PGE_2 was used in the spleen and heart experiments. It was suggested that species differences or differences in nerve supply might account for this discrepancy.

On the basis of previous information of their natural occurrence and availability for release from sympathetically innervated tissues, as well as the demonstrated effects of PGE_1 and PGE_2 in the present study it was suggested that the two compounds may play a physiologically significant regulatory role in sympathetically innervated tissues. This homeostatic ac-

tion of PGE_1 and PGE_2 appears to be mediated both by inhibition of NA release from the nerve terminals and by inhibition of the effector response to NA released.

The differences in tissue distribution of PGE_1 and PGE_2 as well as the quantitative differences between them, with respect to the observed predominance of pre or postjunctional effects, invites the more general speculation that the spectrum of prostaglandins, specific for each individual tissue, might serve the function of controlling different neuroeffector junctions, possibly including those with transmitters other than catecholamines, and make the motor responses rapidly or slowly adapting

CHAPTER I

Aim of the study

In spite of the great number of data available on respiratory and cardiovascular adaptation to exercise (Asmussen and Nielsen 1955 Asmussen 1965 Bevegård and Shepherd 1967) it remains to be established what factors normally limit aerobic work capacity Some authors seem to consider the cardiovascular system the limiting factor (*cf* Bevegård and Shepherd 1967) although evidence against this assumption is also found in the literature (Doll, Keul and Marwald 1968 Jöbsis and Stainsby 1968)

The present study is an attempt to supply further experimental data to elucidate the problem. The basic assumption was, that if the ability of the cardiovascular system to furnish the exercising muscles with oxygen is the main limiting factor for aerobic work capacity an increase in arterial oxygen content should increase the aerobic muscle performance. If, on the other hand, any step in the substrate metabolism and the electron transport chain is limiting the maximal oxygen utilization rate, an increase in arterial oxygen content should not significantly alter muscle performance.

A substantial increase in arterial oxygen content is possible only by oxygen breathing in a hyperbaric environment, when about 20 ml O_2/l blood is added in physical solution per atmosphere oxygen pressure. In the first part of the present study the influence on work performance of oxygen breathing at hyperbaric pressure (3 ata) was investigated.

To establish the relative importance of the oxygen amount supplied to the active muscle by the blood, a comparison with the effect of a decreased arterial oxygen content during exercise at decreased inspiratory oxygen pressure was also made. Furthermore, to test the significance of metabolic factors as limiting for muscle performance the effect of a decrease in temperature of the active muscles, presumed to retard the maximal metabolic rate, was studied.

The possibility exists that the circulatory system is more important as a limiting factor for aerobic work capacity when large muscle groups are utilized and a large demand is placed on the central circulation, than when work is performed with small muscle groups. Consequently it was considered of interest to study the adaptation to work with a small (the fore arm) as well as a large (the legs) muscle group.

CHAPTER II

Possible limiting factors for aerobic work performance

The energy for heavy muscle activity of short duration is derived from the hydrolysis of high energy phosphate, available to the contractile system in the active muscle cell (Lundsgaard 1930, Lohmann 1934, Margaria 1968). For a continuous muscle activity a resynthesis of high energy phosphate must occur. During limited periods of time, up to 1-3 minutes, the major part of the energy needed for the resynthesis may be yielded by anaerobic glycolysis. For longer exercise times the maximal rate at which exercise can be performed depends on the rate of aerobic metabolism.

The aerobic work capacity in the present study, defined as the capacity for work of 5-10 minutes duration, is dependent on oxygen supply by 1) ventilation of the lungs, 2) diffusion of oxygen between the lung alveoli and the blood in the lung capillaries, 3) the cardiac output, 4) blood perfusion of the muscle tissue, 5) diffusion from the capillaries to the muscle cells and 6) the substrate metabolism and the electron transport in the respiratory chain. A short survey will be given of the possible role of the different steps as rate limiting for aerobic muscle performance.

1. Dimensions of the respiratory and circulatory organs

Significant correlations have been demonstrated between the aerobic work capacity and dimensional measurements of the lungs and the cardiovascular system (Kjellberg *et al.* 1949, Åstrand 1952, Spostrand 1967, Åstrand *et al.* 1963, Holmgren and Åstrand 1966). These correlations are to be considered more as an indication of the morphological adaptation of the oxygen transport system to increased demands by the body than as evidence that cardiovascular or lung function limits the oxygen transport.

2. Pulmonary function

[illegible] at an intensity corresponding to the maximal oxygen uptake. [illegible] Healthy individuals [illegible] less than ½ of his maximal [illegible] Dripps, Freedman 1970). How-

ever the maximal voluntary ventilation is usually measured during 10-15 sec The largest lung ventilation which can be maintained for longer periods is far less (Zocche, Fritts and Cournand 1960 Freedman 1970) According to Freedman the maximal ventilation possible for 4 minutes is 70-75 per cent of the maximal voluntary ventilation. However this seems to be enough to yield an adequate alveolar ventilation during maximal work of 5-10 minutes duration

Diffusion

During exercise up to intensities corresponding to about 50 per cent of the maximal oxygen uptake the lung diffusing capacity increases, as first shown by M Krogh (1915) Differing opinions prevail regarding the increase in diffusing capacity above the work intensity mentioned (cf. Boje 1933 Filley MacIntosh and Wright 1954 Riley *et al.* 1954 Linderholm 1959 Freyschuss and Holmgren 1965 Holmgren 1965) However the arterial oxygen saturation does not even during exhaustive work, decrease significantly (Lilienthal *et al* 1946 Holmgren and Linderholm 1958 Asmussen and Nielsen 1960 Holmgren and McIlroy 1964) Thus, under ordinary atmospheric conditions, the diffusing capacity of the lungs seems not to limit the maximal oxygen uptake.

3. Cardiovascular function

Central circulation

An increased supply of oxygen to the working muscles is brought about by an increased blood flow and an increased oxygen extraction per unit blood (see reviews by Asmussen and Nielsen 1955 Asmussen 1965 Bevegård and Shepherd 1967)

In spite of the ample knowledge on the adaptation of blood flow to exercise the importance of the cardiovascular system as a limiting factor for the maximal rate of oxygen uptake is not well delineated. Many authors consider it of main importance (cf Bevegård and Shepherd 1967) However not even during heavy exercise with large muscle groups have any signs of impaired function of the central circulation been reported in healthy subjects as judged from arterial pressure or stroke volume. (Holmgren 1956 Åstrand *et al* 1964 Ekblom and Hermansen 1968)

Peripheral circulation

Krogh (1929) stated that the volume of capillary blood in relation to the

tissue volume and the diffusion of oxygen from blood to tissue was probably the crucial factor limiting tissue oxygen uptake. Chance *et al* (1962) have calculated that cell respiration does not decrease until the Po_2 is less than about 1 mm Hg. Staunsby and Otis (1964) and Staunsby (1966) calculated the lowest oxygen tension of the venous blood ("critical oxygen tension") to furnish the interior of the muscle cell with oxygen at a sufficient pressure to be about 10 mm Hg in dog leg muscle preparations. In man Doll *et al* 1968 found an oxygen tension in the femoral vein during heavy exercise of about 20 mm Hg. Consequently oxygen transport by the blood circulation should not limit the maximal oxygen uptake in the active muscle. However the venous blood may not come exclusively from active muscle tissue but partly from tissue with a lower oxygen utilization rate. In that case the described findings are less valid as evidence, that the circulation does not limit the aerobic work capacity.

4 Muscle metabolism

Using the microfluorimetric technique on the exposed *sartorius* muscle of pithed *bufo marinus* Chance and Jobsis (1959) concluded that by electrical stimulation it was possible to increase the oxidative phosphorylation to a rate limited by the blood flow. On the other hand in experiments on electrically stimulated dog *gastrocnemius* and *gracilis* muscles with the same fluorimetric technique Jobsis and Stainsby (1968) concluded that the blood circulation did not limit the respiratory metabolic activity. In that case the oxygen utilization system inside the muscle should be the limiting factor for aerobic performance.

Higher activities of respiratory enzymes are generally found in muscles performing prolonged heavy work than in less active muscles (Paul and Sperling, 1967; Lawrie 1953). Holloszy (1967) showed an increased activity of respiratory enzymes in the hind limb muscles of rats after physical training. The described relations suggest that the oxygen utilization system may be a limiting factor for oxygen uptake.

Metabolic changes in the internal milieu of the active muscle cell may contribute to limit the maximal rate of cell respiration. One obvious intracellular change during muscle activity is the increased H^+ concentration. Evidence for a pH dependence of the oxidative phosphorylation of importance in the physiological pH range has been given by Myers and Slater (1957). Also the function of the contractile system seems to be impaired by a pH decrease of the same order of magnitude as that inside the muscle cell during maximal exhaustive exercise (Bendall 1960).

5 Conclusions

As no significant decrease in arterial oxygen saturation is seen during exhaustive exercise, *pulmonary function* cannot possibly be a limiting factor for aerobic work capacity

Neither seems available data in literature prove the often repeated statement that oxygen uptake is limited by the *cardiovascular function*

Increasing evidence, however points at the possibility that the *oxygen utilization system* in the muscle cell should limit aerobic work capacity

Part B. PRESENT INVESTIGATIONS

CHAPTER I

General procedures and methods

1 Modes of exercise

Dynamic forearm work

For the study of work with a small muscle group, rhythmic dynamic forearm work on a spring loaded hand ergometer was chosen. This mode of exercise makes it possible to quantitate the work intensity and to sample blood from veins, which during work almost exclusively drain muscle tissue (Cooper Edholm and Mottram 1955 Coles *et al* 1958 Idbohm and Wahren 1964

The same kind of ergometer was used in all experiments. On one of the ergometers, the handle was connected to a linear motion potentiometer the output of which could be visualized on an oscilloscope (Tectronix, type 30). Hence the time course of the individual contractions could be followed. The number of contractions was counted with a mechanical counting device.

In all experiments (except a pilot study see below) a constant contraction distance (10 mm) and a constant contraction frequency (60 contractions/min) was used. The work intensity was varied by varying the length or the number of springs. The shortest spring length, measured in the mid contraction position, was 36 cm. Hence the largest variation from mean length and mean tension during one contraction was ±4.5 per cent.

All work tests were performed in the sitting position. The active forearm rested on a pillow on a table in the horizontal position, the elbow flexed at about 90°, the back of the hand upwards. The height of the table was adjusted to correspond to the level of the fourth intercostal space.

No standardized procedure for the determination of dynamic forearm work capacity is described earlier. Hence it was considered eligible in certain experiments to study the possibility of its determination (Chapter II).

Dynamic leg work

Dynamic leg work was performed on a mechanically braked cycle ergometer (Cykelfabriken Monark, Varberg, Sweden). The pedalling fre-

quency governed by a metronome, was in all tests 60 cycles/min. The choice of the mechanically braked instead of an electrodynamic cycle ergometer was due to the potential fire hazards with electrical equipment when handling oxygen at hyperbaric pressures.

The work capacity of the subjects was prior to the experiments determined as the work intensity which they could perform in relative steady state at a heart rate of 170 beats/min (Sjostrand 1947 Wahlund 1948)

The maximal work experiments were performed as exhaustive work for durations similar to those used in the Tornvall test (Tornvall 1963) According to Tornvall the performance time for exhaustive work is well correlated to the maximal oxygen uptake.

In some of the maximal work experiments also the oxygen uptake was measured

When two work tests were performed on the same day at least 4 hours elapsed between them.

2. The pressure chamber

Forearm and leg exercise during oxygen breathing at hyperbaric pressure as well as leg exercise with decreased oxygen pressure in the inspiratory air was performed in a pressure chamber Forearm work at decreased inspiratory oxygen pressure was performed during breathing of hypoxic gas mixtures. Decreased ambient pressure was preferred to hypoxic mixtures during the low oxygen leg work experiments as it offered the possibility of disconnecting the volunteer from the mouthpiece without much affecting P_{O_2} in the inspiratory air

The pressure chamber consisted of a main chamber internal length 320 cm and internal height 210 cm, and connected to the main chamber an air-lock chamber of smaller dimensions. The total volume was 16 3 m^3 During the experiments a communication was always open between the two chambers. The exercise test was performed in the main chamber and the instruments for blood gas analysis were placed in the air-lock chamber

For the *hyperbaric experiments* the chamber was pressurized from a compressed air supply The volunteers breathed oxygen via a low resistance valve (Collins Triple J dead space about 180 ml) from a Douglas bag, which could be continuously refilled from an oxygen supply placed outside the chamber In order not to increase the oxygen concentration in the chamber air the expiratory air was collected from the exhaust side of the breathing valve in a second Douglas bag. This bag could be continuously evacuated via a connection to the outside of the chamber Alternatively

times are needed however before lung function changes can be detected

The potential risk of oxygen toxicity called for special care to be taken. At 3 ata toxical manifestations of oxygen seldom occur during exposure periods of less than 60 minutes (Foster 1965) The interindividual and also the day to-day intraindividual variation is large however (Donald 1947) Furthermore toxical symptoms are considered to appear earlier during exercise than at rest.

The present investigations and the pilot studies include 75 oxygen exposure periods at rest and 65 oxygen exposure periods during work at 3 ata. In a few pilot experiments volunteers were exposed to oxygen for periods up to 30 minutes at rest (range 5-30 minutes only 10 exposure periods were longer than 15 minutes) During exercise the exposure periods ranged between 6 and 13 minutes.

In the main experiments no instance of oxygen toxicity was experienced However in a preceding pilot experiment a member of the laboratory staff developed convulsions after 19 minutes of oxygen breathing at 3 ata at rest Furthermore in another pilot experiment on submaximal leg exercise another member of the laboratory staff complained of dizziness after 13 minutes of O breathing at 3 ata. Exercise and oxygen breathing were discontinued as the symptoms could have been attributed to oxygen toxicity In both instances the subjects recovered without further complications.

From the author's experience and reports in the literature it was considered advisable to keep the times for continuous oxygen exposure below 30 minutes at rest and 12 minutes during work.

4 Catheterization procedures

Arterial catheterization was performed percutaneously by the Seldinger technique Seldinger 1953 In most experiments and in all experiments in which arterial pressures were measured, the brachial artery was catheterized A teflon catheter was used, with an outer diameter of 1 45 mm and an inner diameter 1 0.5 mm, and with the catheter tip adapted to a nylon guide line diameter 0.8 mm The length of the catheter was 60 cm. In some experiments, when no pressure recordings were performed the radial artery was preferred For the radial artery a teflon catheter was used with an outer diameter of 1 15 mm and an inner diameter of 0 75 mm and the tip adapted to a nylon guide line with a diameter of 0 6 mm.

The *deep venous system* in the forearm (forearm exercise experiments) was catheterized with the same kind of catheters as used for the brachial

artery Via a puncture of vena mediana cubiti the catheter was advanced 4-8 cm in the distal direction into the deep venous system The catheter position was checked by palpation.

The *right heart* and the *pulmonary artery* were catheterized with a Gensini Positrol catheter size 6.5 (United States Catheter & Instrument Corp.) The catheter was introduced percutaneously via the cubital vein in the left arm by the Seldinger technique and advanced under fluoroscopic guidance to the pulmonary artery The catheter tip was placed about 3 cm out in the right branch of the pulmonary artery and kept in position with a cutaneous suture. When the volunteer was sitting on the cycle ergometer in the pressure chamber the catheter position was checked by studying the shape of the pressure recording

The *femoral vein* in the right leg (maximal leg exercise experiments) was catheterized with a teflon catheter of the same outer and inner dia meter as used for the brachial artery It was introduced percutaneously advanced about 5-6 cm in the proximal direction and sutured to the skin.

5. Methods

Blood analysis

Po_2 was measured with a polarographic electrode and Pco_2 with a glass electrode according to Severinghaus (Instrumentation Laboratory blood gas analyzer mod. 113) in the pressure chamber The chamber pressure at the time of analysis was the same as that at which the samples were obtained. The electrodes were kept at a constant temperature of 37 C.

With the exception of the experiments described in Chapter VI no correction was made for the difference in temperature between the measur ing instrument and the blood at the site of sampling The reasons for this were multiple. 1 Most conclusions were based on comparisons between work at corresponding loads and almost corresponding durations at two experimental conditions (*e g* 1 ata and 3 ata) The temperature differences between the two conditions may be assumed to be small. 2 The quite short exercise periods resulted in moderate temperature increases. In control experiments the rectal temperature increased by 0 1 -0.2 C during leg work at a heart rate of 120 beats/min. During maximal work for 6 minutes the rectal temperature increased by 0 5 1 0 C, and the temperature in the femoral vein by 0.9 1 5 C reaching 37.3 -38 0 C at exhaustion. The temperature in the deep vein of the forearm increased by 0 2 -0 6°C during exhaustive forearm work, the final temperature being 32.9 36 3 C

The electrodes were calibrated before and after the blood gas deter minations. When series of blood samples were taken the calibration was

checked at about 15 minutes intervals. For blood samples obtained during oxygen breathing a calibration gas containing approximately 80 per cent O 5 per cent CO_2 and 15 per cent N_2 was used, for samples taken during air breathing a calibration gas containing approximately 15 per cent O_2 5 per cent CO 80 per cent N_2. The linearity of the instrument for the analysis of O pressures up to about 2 200 mm Hg and CO pressures up to about 120 mm Hg was checked by analysing gas mixtures of known Po and Pco at 3 ata (Figs. 1 and 2). The same correction factor for the

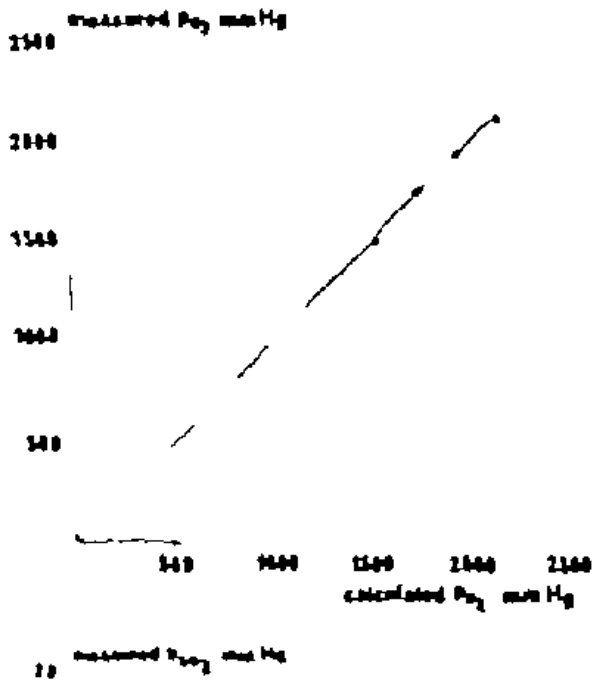

Fig. 1 Linearity for Pox measurements at 3 ata. Each filled circle represents a dublicate determination. × (the fifth point from below) denotes the calibration gas. Test gases analysed by the Scholander technique.

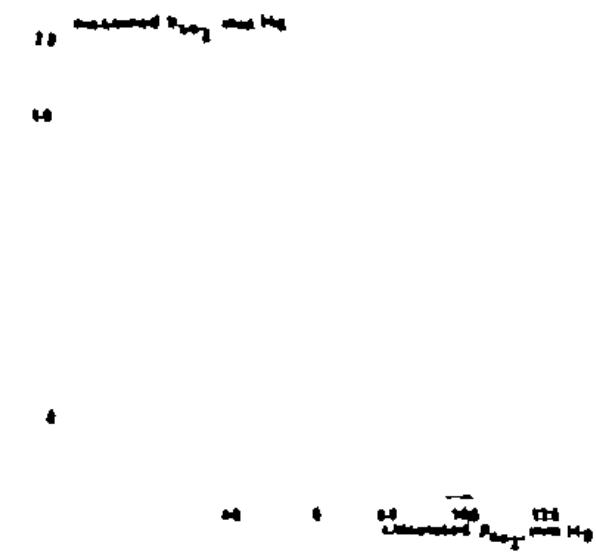

Fig. 2 Linearity for P on measurements at 3 ata. Each filled circle represents a dublicate determination. × (the fourth point from below) denotes the libration gas.

difference between calibration with gas and with tonometered blood 1 015 was used in all experiments. The factor was determined at 1 ata.

The *Haemoglobin concentration* was determined spectrophotometrically as oxyhemoglobin

The *oxygen saturation* was considered 100 per cent when the oxygen tension exceeded 350 mm Hg At lower oxygen tensions the saturation was determined spectrophotometrically according to the method described by Drabkin (1950) as modified by Holmgren and Pernow (1959)

The *oxygen content* was calculated from the hemoglobin oxygen saturation, the hemoglobin concentration and the oxygen tension, assuming 0 031 ml O in physical solution per mm Hg and liter of blood at the temperature of the Po_2 electrode.

pH was measured with a micro-Astrup equipment outside the chamber The syringes with blood samples were chilled with ice till the end of the experiment and analysed immediately thereafter

Lactate was analysed by an enzymatic method according to Hohorst (1962) Lundholm Mohme Lundholm and Varnos (1963) as modified by Wahren (1966)

Pyruvate was analysed by the enzymatic method described by Segal Blair and Wyngaarden (1956) and Bücher *et al.* (1962)

Blood temperature in the study of the effects of muscle temperature variations was measured at the site of blood sampling with a thermocouple introduced in the deep vein via the catheter and registered by a mirror galvanometer (Ellab TE 3) The same instrument was used for intravascular temperature measurements in control experiments (see under Po_2 and Pco_2)

Gas analysis

The *oxygen uptake* during air breathing and the *CO_2 elimination* were measured by sampling expired air in Douglas bags. Gas concentrations were analysed by the Scholander technique. During oxygen breathing no direct measurements of oxygen uptake were made. Possible techniques for its measurement should premise quite long breathing times to reach a steady state in gas exchange, and this would introduce the risk of toxic effects of oxygen. In the heart catheterization study the oxygen uptake during oxygen breathing was calculated from the cardiac output and the arterio-venous oxygen difference.

Heart rate intravascular pressures and cardiac output

The *heart rate* was measured by ECG recorded on an ink jet recorder (Mingograf 81 Elema-Schönander) In most exercise tests the leads CH_5 and CH were recorded

Intravascular pressures were measured with capacitative transducers (EMT 34 and 35 Elema-Schönander) and recorded on the Mingograf 81

As reference point the articulation of the fourth rib with the sternum was taken.

The cardiac output was determined by the dye dilution technique 5 mg of Indocyanin green (Cardio-green Hynson Westcott & Dunning) was injected from a 1 ml syringe into the catheter system and rapidly flushed into the pulmonary artery Arterial blood was continuously withdrawn at a rate of 18 ml/min from the brachial artery through a cuvette densitometer Gilford mod. 103-IR) Dye curves were recorded on a pen recorder Electro Instruments) The time for 10 cm deflection for a square-wave transient fed into the recorder was 0 23 second. One calibration curve was made for each subject using pooled blood withdrawn during light and heavy work. For each calibration curve three dye concentrations were used. The response was linear within the concentration range applied

During air breathing, the cardiac output was also determined according to the direct Fick technique A comparison was made between the two methods Fig 3) Above 18 l/min slightly higher values of cardiac output

TABLE 1 Errors for a single determination as estimated from duplicate determinations.

Variable	Range	Number of duplicate determinations	Mean value	Error $\sqrt{\frac{\Sigma d^2}{2n}}$	Error in per cent of the mean value

6. Definitions, symbols and abbreviations

Chamber pressure

Environmental pressure is expressed in hyperbaric experiments in atmospheres absolute pressure (ata) in hypobaric experiments in mm Hg

630 mm Hg corresponds to an altitude of about 1,500 m.

560 mm Hg corresponds to an altitude of about 2,500 m.

Air at 560 mm Hg has approximately the same P_{O_2} as a gas mixture containing 15 % O_2 at 760 mm Hg

Blood and gas symbols

For blood and gases the symbols and abbreviations are those proposed by Pappenheimer *et al.* (1950)

Physical working capacity

W_{170} = work at heart rate 170 in steady state during leg work on a cycle ergometer

W_{max} = maximal work intensity a subject can sustain for 6 minutes with the muscle group and mode of exercise stated.

CHAPTER II

Control experiments on the determination of forearm work capacity and its reproducibility

It is of importance to define the work intensity not only in absolute values, but also in relation to the work capacity of the subject for the specific mode of work studied. During steady state leg work the heart rate gives information on the relative work intensity During forearm work no such easily measured indicator of the relative load is obtainable.

Grosse Lordemann and Müller (1937) and Müller (1938) found that the relation between maximal performance time for exhaustive work and work intensity on a cycle ergometer could be expressed by the equation $\log T = a \times \log N + b$, where T = the performance time to exhaustion and N = the work intensity Tornvall (1963) studied this relation in greater detail and showed that for exercise times between 1 and 18 minutes log performance time was linearly related to log work intensity He suggested a test of physical work capacity in which the maximal performance time was measured at one arbitrarily selected heavy work load. From the correlations stated above the work capacity could then be expressed as the maximal work load which the subject could sustain for 6 minutes, $W_{max'}$ This was shown to be well correlated to the maximal oxygen uptake ($r = 0.94$)

To see whether the same kind of determination of work capacity could be used for dynamic forearm work on a hand ergometer the relation between work intensity and maximal performance time for exhaustive dynamic work of durations between 1 and 25 minutes was studied. The reproducibility of the measured performance times at various work levels was also determined.

The work intensity can be varied by varying the spring tension, the contraction distance or the contraction frequency The mode by which the work intensity is varied may influence the measured value of forearm work capacity by influencing blood flow or mechanical efficiency (*cf* Wahren 1966) For that reason the performance times at constant work intensities achieved with different contraction frequencies were measured in pilot experiments.

For volunteers not familiar with the hand ergometer the reproducibility

of the performance time at a given work load is low. This may be because they often perform the contractions in a manner that differs from test to test. The hand is kept in a contracted position for an unnecessarily long time if it is not relaxed completely between the individual contractions, and hence static work of a varying and unknown magnitude is added to the dynamic work. To minimize this source of error the subjects were instructed to initiate the contraction as fast and to relax as rapidly as possible after the end point of the contraction path was reached. The subjects were also given plenty of time to practice with the ergometer before the investigation. The influence of different relations between contraction and relaxation time was also studied in pilot experiments.

Subjects

Four male volunteers of average physical fitness, two students and two members of the laboratory staff aged 18-32 years, took part in the investigation.

Procedure

Dynamic forearm work to exhaustion was performed on a spring loaded hand ergometer (see Chapter 1).

Pilot experiments

Performance times at constant work intensities ranging between 17.5 and 30.0 kpm/min, achieved with different contraction frequencies, 40-80 contractions/min, were measured in two of the subjects. In these experiment the contraction distance was kept constant 40 mm.

A comparison between the performance times when the contraction was maintained for 150 msec and for 500 msec was performed in one subject. This could be done by watching the time course of the contraction on the oscilloscope. Ten tests of each mode of work were made.

Main experiments

All experiments were performed with 60 contractions/min and a contraction distance of 40 mm. Each of the four subjects performed exhaustive work at four work intensities with each hand. To determine the reproducibility each subject performed a repeated work test at one higher (performance time 4 minutes) and one lower performance time 4-8 minutes) work intensity.

Results

Pilot experiments

The average performance time was 22 1 per cent shorter (SE 9 1 $P < 0.05$) with 80 contractions/min compared to 40 contractions/min (Fig 4)

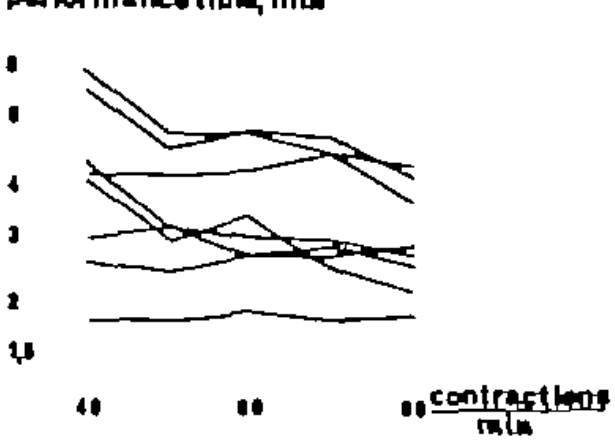

Fig 4 The effect of varying contraction frequency on performance time t exhaustion. Logarithmized y-axis.

Between 50 and 70 contractions/min no significant differences were found.

The performance time when the contraction was maintained for 500 msec in each contraction cycle was for times between 2 and 4 min 65 0 per cent (SD 5.5) and for times between 4 and 8 min 57 0 per cent (SD 5 1) of the performance time with the contraction maintained for 150 msec.

Performance time/work intensity relation

Within the time range 1-8 min, log work intensity was well correlated to log performance time (Fig 5) The coefficient of correlation for the individual subjects varied between 0.98 and 0 99 The calculated W_{max} ranged between 13.3 and 23.9 kpm/min, average value 17 9 kpm/min for the right and 15 0 for the left hand (Table II)

When the work intensity was decreased and performance times longer than about 8 minutes were achieved, the time increased far more than was calculated from the log/log correlation. At a work intensity of about 80 per cent of W_{max} the time was often doubled by a 3-6 per cent decrease in work load. When the performance time exceeded 25 minutes the test was in most cases interrupted by the experimenter All subjects reached this point at a load 0,5 kpm/min lower than the lowest load presented in Fig 5

Reproducibility

The reproducibility calculated from a duplicate determination as the standard error of a single determination was 10.9 per cent in the performance time range 2-4 min and 9 2 per cent in the range 4-8 min.

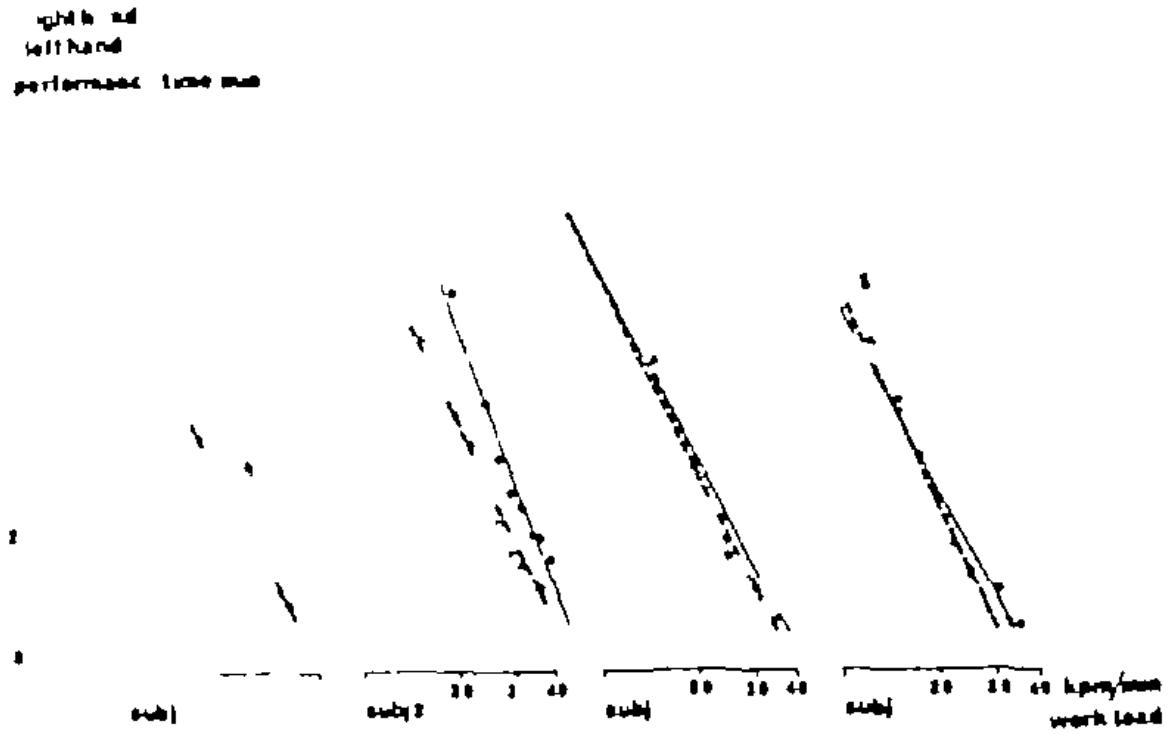

Fig. 5. Relationship between log performance time and log work load for the individual subjects.

Discussion

The energy for heavy exhaustive work of short duration derives mainly from anaerobic sources whereas for exercise times longer than about 1-2 min aerobic processes are most important. The aerobic work output decreases very little with increased work time (Hill 1927, Margaria 1964).

From this it can be assumed that, if exhaustive exercise is performed at a heavy load, log maximal performance time will be approximately linearly correlated with log work intensity. On the other hand, when the work intensity is increased and a larger proportion of the energy is derived from oxidative regeneration of ATP, the performance time will increase more with decreased work intensity than calculated from the above mentioned correlation. This is actually what was found in the present study. Within the performance time range 1-8 min, a good estimation of W_{max} can be obtained from intra- or extrapolation on a log/log chart between performance times determined at two work intensities. For intensities lower than about ¼ of W_{max}, the relation between a change in work intensity and performance time was almost of the same order of magnitude as the decrease in maximal aerobic work output with increased performance times calculated by Margaria 1964. From this it can be assumed that

TABLE II Performance time/work intensity relationship and forearm work capacity for the individual subjects. t = performance time to exhaustion W = work intensity

	right hand	left hand
Subject 1	$\log t = -2.39 \times \log W + 3.85$	$\log t = -1.98 \times \log W + 3.06$
r	0.99	0.99
W_{max} kpm/min	19.3	14.1
Subject 2	$\log t = -2.90 \times \log W + 4.76$	$\log t = -2.21 \times \log W + 3.54$
	0.99	0.98
W_{max} kpm/min	23.9	17.9
Subject 3	$\log t = -2.0 \times \log W + 3.12$	$\log t = -2.12 \times \log W + 3.25$
	0.99	0.98
W_{max} kpm/min	15.0	14.6
Subject 4	$\log t = -1.99 \times \log W + 3.07$	$\log t = -2.14 \times \log W + 3.30$
	0.99	0.99
W_{max} kpm/min	15.3	15.5

the maximal aerobic work capacity of the forearm is of the order of magnitude ⅗ ¾ of W_{max}

Conclusions

1 It is possible with reasonably good reproducibility to determine a subject's forearm work capacity as W_{max} by intra or extrapolation between two values of maximal performance time in the range 1-8 min This statement is valid provided that the subject has been allowed to become familiar with the exercise technique.

2. The aerobic work capacity can be assumed to be about ⅗-¾ of W_{max}

3 Measurement of maximal performance time seems to provide a fairly good estimate of the aerobic work capacity if work intensities yielding performance times of about 5 min are chosen as evidenced by Tornvall (1963)

CHAPTER III

Control experiments for the study of the adaptation to leg work during normoxia at 3 atmospheres

When exercise is performed during oxygen breathing in a hyperbaric milieu factors other than the increased oxygen tension, *e.g.* the increased gas density may influence the adaptation to work. The exercise heart rate during air breathing at 4.5 ata was reported to be decreased compared to air breathing at 1 ata (Hesser, Fagraeus and Linnarsson 1968). It cannot be concluded at present whether this is an effect of the increased nitrogen pressure or whether other factors are more important. Thus in experiments during saturation exposures to helium-oxygen mixtures at 31.3 ata, yielding an inspiratory oxygen pressure slightly above the normal atmospheric a heart rate decrease of a corresponding magnitude was recorded (Salzano, Rausch and Saltzman 1970). The investigations mentioned also report a decreased lung ventilation during exercise at increased ambient pressure. The reason for this is probably the increased air density (Millic-Emili and Tyler 1963). The O_2 uptake at corresponding loads was slightly higher at increased pressure. This was considered due to a larger work of breathing.

Before discussing the effect of oxygen breathing at 3 ata, it was considered necessary to investigate whether the heart rate and the lung ventilation change during normoxic exercise at the same ambient pressure.

Subjects

Four male volunteers, aged 22–39 years, were studied. Three of them belonged to the laboratory staff, two were students. Their average physical working capacity measured as W_{170} was 1170 kpm/min (range 1000–1350 kpm/min).

Procedure

Exercise was performed in a mechanically braked cycle ergometer in the pressure chamber. The subjects started to work for 6 minutes at a load yielding a heart rate of about 130 beats/min and continued for 6 minutes

at a load yielding a heart rate of about 160 beats/min Comparisons were made between air breathing at 1 ata and breathing a gas mixture containing about 8 per cent O and 92 per cent N_2 yielding an inspiratory Po_2 of about 190 mm Hg at 3 ata.

Measurements

The heart rate was recorded at rest and continuously during work. Lung ventilation, respiratory frequency O uptake Co_2 elimination and the pressure variations in the mouthpiece were recorded during the last minutes of each exercise period.

TABLE III Heart rate, respiratory rate, tidal volume, total lung ventilation and mouthpiece inspiratory to expiratory pressure variation during 8 per cent O_2 breathing (PIo_2~190 mm Hg) at 3 ata and air breathing at 1 ata.

Results

The results are summarized in Table III.

No significant differences between 3 and 1 ata were found in heart rate lung ventilation respiratory frequency O_2 uptake or CO_2 elimination neither at the lower nor at the higher work load ($P>0.05$). At the higher load, however the average respiratory frequency was slightly lower 4 breaths/min at 3 ata ($P<0.05$). The average inspiratory to expiratory pressure variation in the mouthpiece, that is the pressures needed to overcome the resistance in the breathing equipment, was 7.7 mm Hg at 3 ata compared to 3.3 mm Hg at 1 ata during expiratory air sampling at the higher work load with a lung ventilation of about 75 litres/min.

Conclusions

The ambient pressure used in the present study 3 ata, was apparently too low in itself to cause significant changes in heart rate, lung ventilation or O uptake. The pressure variations in the breathing mouth piece were also at rather large lung ventilations moderately increased at 3 ata.

CHAPTER IV

Adaptation to exercise during oxygen breathing at 3 atmospheres

Introductory remarks

Nielsen and Hansen (1937) reported that the maximal oxygen uptake measured by the Douglas bag technique increased considerably when the oxygen fraction of the inspiratory air was augmented. The increase in oxygen uptake was larger than the calculated increase in arterial oxygen content. The CO production, on the other hand, did not increase. Margaria *et al.* (1961) found by the closed circuit spirometer technique a 10 per cent increase in maximal oxygen uptake during oxygen breathing Asmussen, von Döbeln and Nielsen (1948) Miller (1952) and Bannister and Cunningham (1953) reported an improved performance time for exhaustive work during 66-100 per cent oxygen breathing Miller however stated that the increase was very small and concluded that the major part of the effect could be attributed to suggestion. Asmussen and Nielsen (1955) reported a decrease in heart rate at corresponding work intensities of about 6 per cent during oxygen breathing whereas no measurable difference in cardiac output could be detected

Several authors, for example Asmussen and Nielsen (1946 1958) Bannister and Cunningham (1953) and Dejours (1959) have described a reduction in pulmonary ventilation during heavy exercise when breathing oxygen, whereas the effect is more uncertain during light exercise.

To sum up oxygen breathing during exercise at atmospheric pressure seems to reduce the pulmonary ventilation, at least at heavy loads. On the other hand the effect on the cardiovascular adaptation and aerobic work performance is small or even doubtful (Miller 1952)

The cardiovascular effects of hyperbaric oxygen breathing have been studied mainly at rest. Whalen *et al.* (1965) found a decrease in heart rate and cardiac output with unchanged stroke volume and arterial pressure. Decreases in cerebral, renal and forearm blood flows have also been reported (Lambertsen *et al* 1953 Jacobson, Harper and McDowall 1963 Rennie and Knox 1964 Hahnloser *et al.* 1966 Bird and Telfer

1965) However little is known about the adaptation to exercise during oxygen breathing at hyperbaric pressure. In the dog Waxman *et al.* (1968) reported a 17 per cent decrease in cardiac output at 3 ata compared to at corresponding work loads during air breathing at 1 ata. Weglicki *et al* 1966) found a decreased lactate production in dogs exercising during and after oxygen breathing at 3 ata. The work intensities studied were low however

In man the heart rate during moderately heavy exercise has been shown to decrease slightly whereas the arterial blood pressure is unchanged while breathing oxygen at 2 ata as compared to air breathing at 1 ata (Salzano *et al* 1967) Also the lung ventilation has been found to decrease during oxygen breathing at 2 ata (Lambertsen *et al* 1959) as well as 3 ata (Telfer and Jennett 1965) compared to air breathing The decrease, 12 15 per cent, during moderately heavy exercise, is of the same order of magnitude as that found during oxygen breathing at atmospheric pressure (Asmussen and Nielsen 1946)

When studying exercise during hyperbaric oxygen breathing it is important to state whether the effects recorded are the result of an increased arterial oxygen supply or of toxic metabolic changes. Numerous enzymes, the sulfhydryl enzymes in particular are inhibited by high pressures of oxygen (Haugaard 1946) Stadie, Riggs and Haugaard (1954 a, b) and Dickens (1946 a, b) found *in vitro* that tissue respiration was inhibited by high oxygen pressure the brain being more rapidly affected than other tissues. Chance Jamieson and Coles (1965) and Chance, Jamieson and Williamson (1966) demonstrated in brain tissue an inhibition in the electron transfer pathways and the oxidative phosphorylation. The comparatively low sensitivity of muscle tissue (Dickens 1946 b) to high oxygen pressure and the high oxygen utilization rate in the active muscle makes it less probable however that toxic effects of oxygen might change the muscle metabolism during short exposure times at 3 ata.

The ambient pressure in the present study 3 ata, was chosen to yield a substantial increase in arterial O content and still permit exposure times long enough for meaningful measurements without toxic manifestations. Some of the results have been presented in preliminary reports (Kaijser 1969 a, b 1970)

I. Adaptation to dynamic forearm work

Subjects

Seven male volunteers, aged 21 27 years, and three female volunteers, aged 25-31 years, were studied. Five of the subjects were students, two were

conscripts and the three female subjects were nurses at the laboratory. Prior to the experiment their forearm work capacity was determined as W_{max}. The average value for the male subjects was 14 kpm/min (range 10-18 kpm/min) for the females 8.5 kpm/min (range 8-9 kpm/min). The values are, according to the author's experience, normal for subjects with sedentary occupations, who do not take part in competitive sports engaging the forearm muscles.

Procedure

Two sets of experiments were performed. In both the subjects were studied during oxygen breathing at 3 ata and for comparison during air breathing at 1 ata.

In the *first investigation* the influence of varying loads was studied. Six male volunteers worked at stepwise increasing work loads 4 minutes at 50 per cent of W_{max}, 4 minutes at 100 per cent of W_{max}, and until exhaustion at 150 per cent of W_{max}. The aim in the selection of work loads was that the first load should be well below the maximal aerobic capacity of the forearm and the last load should lead to exhaustion within about 2 minutes.

In the *second investigation* the adaptation to a somewhat longer work time at a constant load was investigated. Three of the male and the three female subjects were studied during 20 minutes work at ⅔ of W_{max}. After 20 minutes exercise the work load was increased to that corresponding to W_{max}, and the subjects worked until exhaustion. In general, the subjects were exhausted after 2–3 minutes.

During all experiments arterial blood was sampled from a catheter in the brachial artery of the resting arm, and muscle vein blood from a catheter in a deep vein of the active forearm.

Measurements

P_{O_2} was measured in arterial blood, and O saturation, P_{CO_2}, pH, lactate and pyruvate concentrations in arterial and venous blood. In the study of stepwise increased load, blood was sampled at rest and during the last 30 seconds of each work load. In the study of constant load, blood was sampled at rest and after 5, 10, 15 and 20 minutes of work, as well as at exhaustion. Also the performance time to exhaustion at the highest load was measured.

For methodological details see Chapter I.

Results

1 *Stepwise increased load*

The results are summarized in Table IV and Fig 6

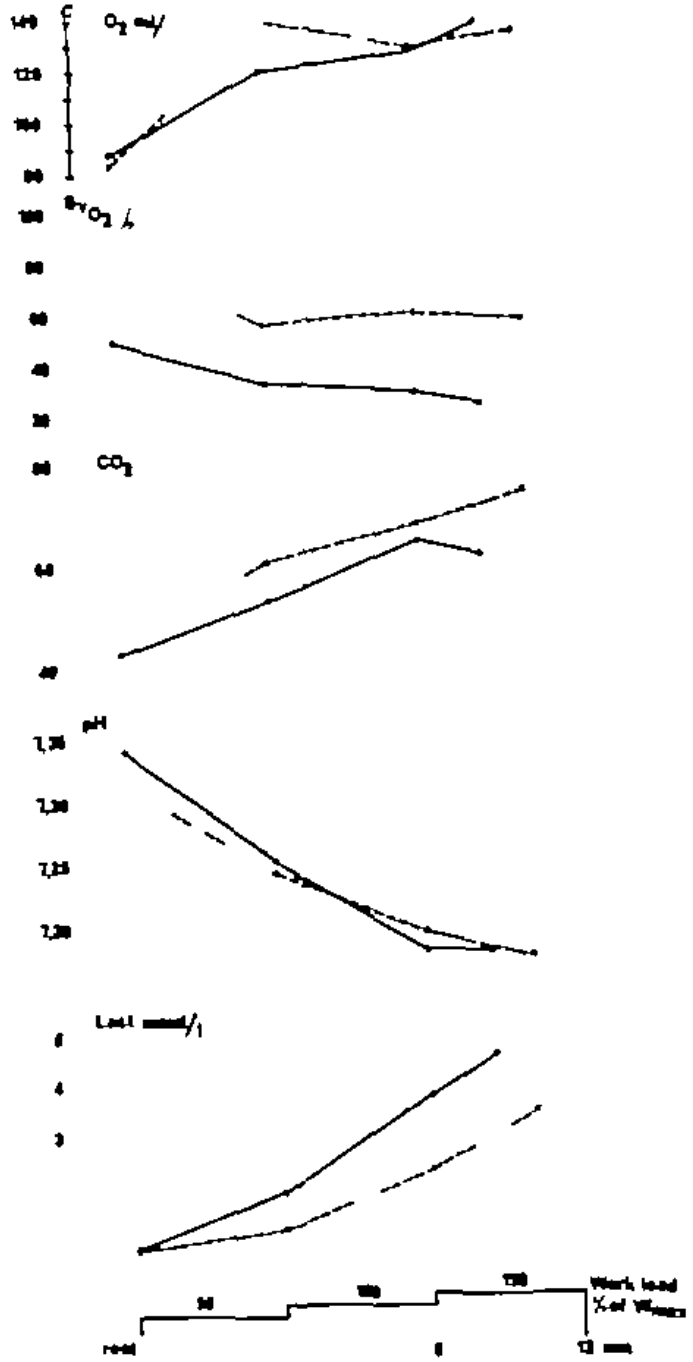

Fig 6 Arterial-deep venous O_2 difference and O_2 saturation Pco_2, pH and lactate concentration in the deep vein of the active forearm during work stepwise increased loads. Average values (n = 6) at rest, after 4 min at the first and the second load, and at exhaustion. Continous lines denote air breathing at 1 ata, dashed lines oxygen breathing at 3 ata.

Air breathing at 1 ata

Arterial blood In arterial blood no significant changes in *Po* *Pco*$_2$ *pH* or *pyruvate* concentrations appeared during the exercise period. The *lactate* concentration increased slightly being 1 11 mmoles/l at exhaustion compared to 0 68 at rest ($P<0.01$)

Table IV. A. Data obtained during forearm work at stepwise increased loads during oxygen breathing at 3 ata and air breathing at 1 ata. Blood was sampled from the brachial artery and the deep vein of the active forearm at rest, after 4 min at the two lower loads and at exhaustion at the highest load. Mean ± SD. n = 6.

No difference in *hemoglobin* concentration was found between arterial and venous blood The hemoglobin concentration was higher at exhaustion, 14 38 g/100 ml than at rest 13 36 ($P<0.05$) or at the lowest load, 13 87 ($P<0.05$)

Deep vein blood The *O_2 saturation* was 50 1 per cent at rest. During work at the lowest load it decreased to 34 5 per cent ($P<0.01$) At exhaustion it had decreased further to 27 2 per cent ($P<0.05$)

As no major changes in arterial O_2 saturation occurred the *arterio-venous O difference* increased from an average of 87 7 ml/l at rest to 120 9 ml/l at the lowest work load ($P<0.01$) At the highest load it had increased further to 140 4 ml/l ($P<0.05$)

Pco increased from an average resting value of 43.2 mm Hg to 54 8 mm Hg at the lowest and 63 5 mm Hg at the highest load The differences between rest and the lowest and between the lowest and highest work loads were significant ($P<0.01$)

The deep vein lactate concentration was 0 85 mmoles/l at rest. At the first work load it had increased to 1 99 mmoles/l ($P<0.05$) It increased markedly with further increase in work intensity being 4 76 mmoles/l at exhaustion.

The deep vein pyruvate concentration was at rest 0 083 mmoles/l At the lowest work load it had increased to 0 134 mmoles/l ($P<0.05$) It increased further to 0 181 mmoles/l ($P<0.01$) at exhaustion. The lactate/pyruvate ratio in venous blood was almost unchanged at the lowest load, 16 4 (S D 7.8) compared to 12.4 (S D 4.5) at rest. It increased at the second load to 30 0 (S D 8 3) but was in four out of five subjects slightly lower at exhaustion, average value 23 5 (S D 4 9)

pH decreased with increased work load from 7 342 at rest to 7 185 at exhaustion ($P<0.001$)

The average *performance time* to exhaustion at the highest work load was 110 seconds.

Oxygen breathing at 3 ata. At rest

After oxygen breathing for 4 minutes the average *arterial Po* was 1840 mm Hg The *deep vein O saturation* was substantially higher than during air breathing in all subjects. The average saturation was 85 9 per cent. The arterio-venous O_2 difference was 80 0 ml/l. It was not significantly different from that during air breathing ($P>0.05$) Compared to air breathing the arterial *Pco_2* and *pH* were unchanged ($P>0.05$) No diffe-

rences in deep vein Pco_2 *pH lactate* or *pyruvate* concentrations between oxygen breathing at 3 ata and air breathing were found ($P>0.05$)

Oxygen breathing at 3 ata During exercise

Arterial blood Po_2 at the end of the first load was 1958 mm Hg the amount of physically dissolved oxygen being about 60 ml/l. Po_2 decreased slightly during the exercise period being 1892 mm Hg at exhaustion ($P<0.05$) No significant differences in arterial *Pco pH lactate* or *pyruvate* concentrations were found between oxygen breathing at 3 ata and air breathing at 1 ata.

Deep vein blood The *O saturation* was decreased during exercise as compared to rest ($P<0.05$) At the lowest work load it was 56.7 per cent. It remained on the same level at all work loads, being 59.7 per cent at exhaustion. The O_2 saturation was in all subjects, at all work loads, substantially higher during oxygen than air breathing The difference compared to air breathing was higher at exhaustion than at the lowest work load ($P<0.05$)

The *arterio-venous O difference* was at the lowest work load 21.4 ml/l higher during oxygen than air breathing ($P<0.001$) It did not change significantly with increased work intensity At exhaustion the arterio-venous O difference was 137.9 ml/l. This value did not differ from that during air breathing ($P>0.05$)

Pco_2 was generally higher during oxygen than air breathing at low and high work loads.

The lactate concentration was lower during oxygen than air breathing It increased more, however from the second load to exhaustion, and the value at exhaustion was not significantly lower than during air breathing

The *pyruvate concentration* was lower than during air breathing at the lowest load ($P<0.05$) but did not differ at the higher loads.

The lactate/pyruvate ratio did not differ significantly from that during air breathing at any level of work.

The performance time to exhaustion at the highest load was prolonged in two subjects and almost unchanged in four during oxygen breathing at 3 ata as compared to air breathing The average performance time was 153 seconds during oxygen breathing The average difference compared to air breathing, 43 seconds, was not statistically significant ($P>0.05$)

2. *Prolonged work at constant load*

The results are summarized in Fig 7

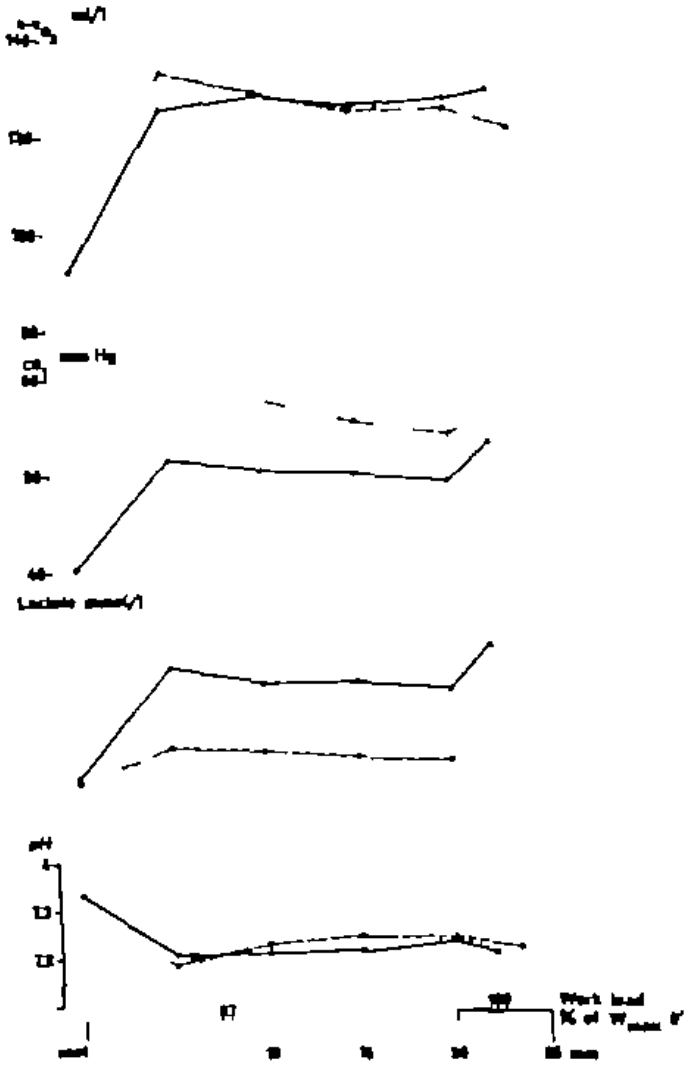

Fig. 7 Arterial-deep venous O_2 difference and P_{CO_2}, lactate concentration and pH in the deep vein of the active forearm during 20 min work at a load corresponding to 67 per cent of W_{max}, followed by work to exhaustion at 100 per cent of W_{max}. Average values ($n = 6$) at rest, after 5, 10, 15 and 20 min at the lower load and at exhaustion at the higher load. Continuous lines = air breathing at 1 ata, dashed lines = oxygen breathing at 3 ata.

Air breathing at 1 ata

Arterial blood The *lactate concentration* increased slightly from 0.47 mmoles/l (SD 0.20) at rest to 1.06 mmoles/l (SD 0.59) after 20 minutes work and 1.05 mmoles/l (SD 0.30) at exhaustion. The difference between exhaustion and rest is significant ($P < 0.01$). No other significant changes occurred during work.

Deep vein blood The *O_2 saturation* decreased significantly from 48.8 ml/l at rest to 31.5 ml/l after 5 minutes work ($P < 0.05$). It remained on the same level throughout the work at $\frac{2}{3} \times W_{max}$ and did not either change during the terminating exhaustive work ($P > 0.05$). The *arterio-venous O_2 difference* was 125.2 ml/l after 5 minutes' work. It was unchanged after 20 minutes, 127.4 ml/l, as well as at exhaustion, 123.3 ml/l ($P > 0.05$).

P_{CO_2} was 40.0 mm Hg at rest. It increased to 51.7 mm Hg after 5 minutes work ($P < 0.05$) and remained on the same level to the 20th

minute. It increased slightly to 53 7 mm Hg at exhaustion after the increase in work load ($P<0.05$)

The *lactate concentration* was 3 05 mmoles/l after 5 minutes. It was not significantly changed after 20 minutes, 2 60 ($P>0.05$) At exhaustion it had increased in four subjects and remained almost unchanged in two the average value being 3 50 mmoles/l and not significantly different from that after 20 minutes ($P>0.05$) The veno-arterial concentration difference was not changed between 5 and 20 minutes ($P>0.05$)

The *pyruvate concentration* was 0 068 mmoles/l at rest. It increased to 0 121 mmoles/l after 5 minutes work ($P<0.05$) and remained unchanged throughout the work period.

The *pH* decreased from 7 384 at rest to 7 212 after 5 minutes work ($P<0.01$) It increased slightly during the constant load work, being 7 245 after 20 minutes ($P<0.05$) At exhaustion it was 7.226 which is not significantly lower than after 20 minutes.

The *performance* time to exhaustion after increasing the load was 1 '8 seconds (SD 68)

Oxygen breathing at 3 ata

Arterial blood Po_2 was 1778 mm Hg (SD 74) at rest. After 5 minutes' work it was 1837 mm and it remained on the same level throughout the work period. The *lactate concentration* was 0 44 mmoles/l at rest and increased slightly to 0 66 mmoles/l ($P<0.05$) at exhaustion. No other changes of importance occurred in the arterial blood

Deep vein blood The *O saturation* at rest, 76 3 per cent, was significantly higher than during air breathing ($P<0.01$) It decreased to 59.5 per cent after 5 minutes' work and did not change significantly during work ($P>0.05$) During the whole work period it was significantly higher during oxygen than air breathing The *arterio-venous O difference* did not differ significantly from that during air breathing neither at rest nor at the beginning nor at the end of the work period ($P>0.05$)

Pco was after 5 minutes work 58 2 mm Hg, that is 6.5 mm Hg higher than during air breathing ($P<0.05$) It decreased slightly throughout the work period to 52 0 mm Hg after 20 minutes ($P<0.05$) and did not increase significantly during the exhaustive work ($P>0.05$)

The *lactate concentration* was 1.37 mmoles/l after 5 minutes' work. It had not changed significantly after 20 minutes ($P>0.05$) During the constant load work it was slightly lower during oxygen than air breathing ($P<0.05$) During the terminating exhausting work it increased signi-

ficantly ($P<0.05$) and the value at exhaustion, 2.46 did not differ significantly from that during air breathing ($P>0.05$). The veno-arterial concentration difference was not significantly changed between 5 and 20 minutes ($P>0.05$).

The *pyruvate concentration* was at rest 0.072 mmoles/L. It had increased slightly after 5 minutes work ($P<0.05$) and remained unchanged throughout the work period, being 0.099 mmoles/l at exhaustion. The pyruvate concentration during work was slightly lower during oxygen than air breathing ($P<0.05$).

pH was 7.304 (SD 0.029) at rest. After 5 minutes it had decreased to 7.219 ($P<0.05$). It thereafter increased significantly to 7.256 after 20 minutes ($P<0.05$). It decreased slightly to 7.237 at exhaustion at the higher load ($P<0.05$). There was no difference compared to 1 ata.

The *performance time* at the higher work load was increased in 3 decreased in 2 and unchanged in 1 subject. The average performance time, 172 sec (SD 98) did not differ significantly from that during air breathing ($P>0.05$).

Discussion

Stepwise increased load

Submaximal work. At the lowest work load, which from an oxygen uptake point of view was submaximal, the arterio-venous O difference was about 15 per cent higher during oxygen than air breathing. The increase corresponds to about 1/3 of the increase in arterial oxygen content. If the oxygen uptake in the active muscle is assumed to be the same at corresponding submaximal work intensities during oxygen and air breathing, the forearm blood flow can be calculated to be about 15 per cent lower during oxygen breathing.

The difference in calculated blood flow is caused by a difference in vascular resistance, as oxygen breathing at 3 ata does not change the arterial pressure significantly during resting conditions (see heart catheterization study p. 47). The difference in resistance may partly be caused by a direct effect of the oxygen pressure on the arteriolar tonus (Carrier Walker and Guyton 1964).

Numerous other factors probably contribute to the difference in blood flow and their relative importance cannot be established from the present data. Of interest is the observation that pyruvate has a vasodilating effect (Molnar *et al.* 1963) although the direct effect is considered weak in physiological concentrations. The difference in calculated blood flow between oxygen and air breathing is in the present study correlated to the

difference in deep vein pyruvate concentration ($r = 0.90$). However the number of observations are too few to permit definite conclusions about its role in blood flow regulation.

Maximal work. During air breathing the arterio-venous O difference increased slightly with increased work intensity. Corresponding findings are reported in studies of the femoral venous oxygen saturation during work of increasing intensity (Donald *et al.* 1957, Pernow *et al.* 1965). Wahren (1966) on the other hand did not find any increase in arterial-deep [illegible] O_2 difference with increasing work load during dynamic forearm work probably because only rather low work intensities were studied.

During oxygen breathing the arterio-venous O_2 difference did not increase with increased work load. At exhaustion the same arterio-venous O_2 difference was found during oxygen and air breathing. If the oxygen uptake in the active muscles is limited by the local blood circulation the increased blood oxygen content during oxygen breathing should have made possible an increased O uptake by an increased O_2 extraction per unit blood volume. Consequently the unchanged arterio-venous O difference during oxygen breathing indicates that the oxygen uptake is unchanged by oxygen breathing. Hence the oxygen supply by the circulation should not limit oxygen uptake. This is further evidenced by the lack of significant increase in performance time during oxygen breathing.

The deep vein blood was at exhaustion more than 50 per cent O_2 saturated, *i.e.* more than twice as high as during air breathing with a calculated Po_2 of 40-50 mm Hg during oxygen compared to about 20-25 mm Hg during air breathing. Hence not either diffusion of oxygen from the blood to the interior of the muscle cell seems to limit the maximal oxygen uptake during work with small muscle groups.

In spite of the evidence mentioned of a sufficient oxygen supply in the muscle tissue, the deep vein lactate concentration was quite high during oxygen breathing, actually not significantly lower than during air breathing at the time for exhaustion. Apparently a substantial lactate production—or a high lactate/pyruvate ratio—should not be taken as evidence of anaerobic conditions in active muscles in the sense of lack of oxygen (*cf.* Doll *et al.* 1968, Jöbsis and Stainsby 1968). It may rather be taken as an indicator that the limit for the capacity of the oxidative metabolism is approached. With normal arterial O_2 saturation and normal circulation this limit seems to be set by the oxygen utilization system in the muscle cell.

Among factors contributing to limit the maximal aerobic capacity of a muscle, the intracellular pH must be considered. As the deep vein pH at

exhaustion was the same during oxygen and air breathing, and as the deep vein lactate concentration did not significantly differ during oxygen breathing from that during air breathing the intracellular pH was probably the same under the two conditions.

Prolonged work

When, in the present study the subjects worked for 20 minutes at a load assumed to be slightly below that corresponding to the maximal aerobic work capacity no change in arterio-venous O difference with time occurred. The increase in deep vein pH during oxygen breathing closely paralleled corresponding changes during air breathing No significant change in lactate concentration or veno-arterial difference with time ocurred This is in accordance with earlier findings by other authors for the time intervals and work intensities studied (Bang 1936 Saiki Margaria and Cuttica, 1967)

When exhaustive work was performed following the submaximal the lactate concentration increased significantly during oxygen breathing The lactate concentration at exhaustion was slightly lower than during the earlier experiment, probably because of the somewhat longer work time (Åstrand *et al* 1963) The findings render it probable that enzyme inhibition induced by the high oxygen pressure did not change the muscle metabolism significantly under the conditions studied The results seem not to confirm the findings by Weglicki *et al.* (1966) in the dog and Banister *et al* (1969) during leg work in man that the lactate production is markedly inhibited by high oxygen pressure. However at least the result by Banister *et al* may be explained by the long oxygen exposure time at rest preceding the work period.

In agreement with the findings during the shorter work at stepwise increased loads the performance time was not significantly prolonged by oxygen breathing

Comment

Although oxygen breathing did not increase the work performance time significantly there are obviously interindividual variations in the influence of oxygen breathing on performance time. This is partly caused by the error of measurement. However the relation between circulatory and metabolic capacities may differ between the subjects. This statement may be supported by the apparent correlation between the changes in performance time and maximal arterio-venous O difference induced by oxygen breathing (Fig 8)

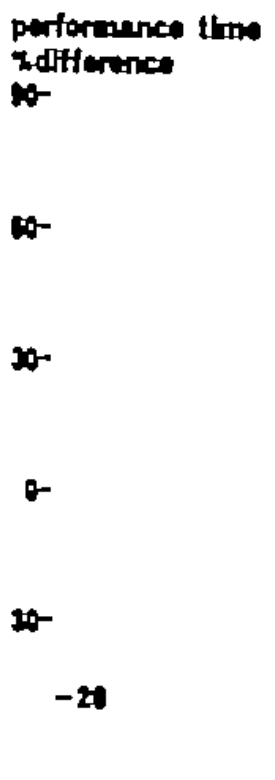

Fig. 8. Relation between the individual changes in performance time and in maximal arterio-venous O_2 difference during submaximal forearm exercise breathing air at 1 ata. Data from different sets of experiments (see text): pilot experiments (filled circles) and experiments according to W_{max} (open circles). $n = 14$, $r = 0.62$, $SD = 24.0$, $P < 0.05$.

Conclusions

1) During oxygen breathing at 3 ata the arterial O_2 content is increased about 30 per cent. During submaximal forearm work about ⅓ of this increase was utilized.

2) The aerobic work capacity was not influenced by the increased blood oxygen content at 3 ata, as evidenced by the unchanged maximal arterio-venous O_2 difference and performance time. Hence oxygen supply by the local blood flow is not limiting for maximal local O_2 uptake, apparently not either under normal atmospheric conditions.

3) At exhaustion during oxygen breathing at 3 ata the deep vein lactate concentration was not significantly lower than during air breathing in spite of the much higher P_{O_2}. This indicates that a large lactate production cannot be taken as evidence for lack of oxygen in the active muscles.

4) The deep vein pH reached at exhaustion the same level during oxygen breathing at 3 ata as during air breathing. Hence tissue acidity may be a limiting factor for aerobic muscle performance.

2. Adaptation to submaximal leg work

As little is known about the adaptation to exercise at hyperbaric oxygen pressures, it was considered necessary to make a comprehensive study of the adaptation to submaximal work before maximal work tests were performed.

The heart catheterization procedure may influence the cardiovascular adaptation to exercise For that reason the heart rate reaction during exercise, breathing oxygen at 3 ata, was studied in preliminary experiments without heart catheters. During work under normal atmospheric conditions a correlation is found between heart rate and arterial lactate concentration. Therefore, also blood lactate was determined.

The cardiovascular and ventilatory adaptation to exercise was then studied in greater detail by means of heart catheterization in the main experiment.

Preliminary study of heart rate and blood lactate

Subjects

Eight male volunteers, aged 19-31 years, were studied. Their average work capacity determined as W was 1240 kpm/min (range 1150-1400 kpm/min) By the author's experience they were of average physical fitness.

Procedure

Exercise was performed during oxygen breathing at 3 ata and for comparison during air breathing at 1 ata. Each subject exercised at a lower load selected to yield a heart rate of about 120 beats/min for 5 minutes, rested for 10 minutes and exercised at a higher load selected to yield a heart rate of about 160 beats/min for 5 minutes. During the oxygen breathing tests resting values were recorded after 4 minutes of oxygen breathing and each exercise period was preceded by about 4 minutes of oxygen breathing

Measurements

The heart rate was recorded at rest and continuously during work. Blood for lactate determination was sampled at rest and during the last 30 seconds of each exercise period from a catheter in an antecubital vein.

For methodological details, see Chapter I

Results

The results are summarized in Table V

The average heart rate at rest in the sitting position on the cycle ergometer was 7 beats/min lower during oxygen than air breathing ($P>0.05$) Throughout the exercise periods, both at the lower and the higher work load the heart rate was in all subjects lower during oxygen than air

TABLE V Heart rate and blood lactate during submaximal leg work breathing oxygen at 3 ata and air at 1 ata.

	air 1 ata mean ± S D			O_2, 3 ata mean ± S D			Difference 3 ata — 1 ata, mean ± standard error of the mean.

breathing The average difference was 16 beats/min after 5 minutes at the lower work intensity and 16 beats/min after 5 minutes at the higher work intensity Both differences are highly significant ($P<0.001$)

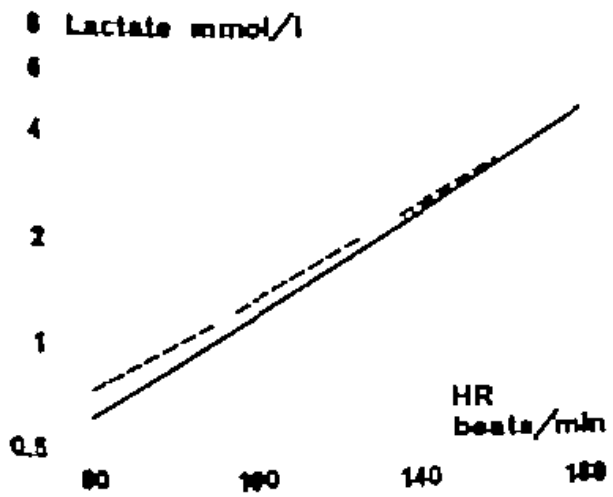

Fig 9 Relation between log lactat and heart rate t submaximal work loads. ——— regression line, air breathing t 1 ata. log lactate = 0.0073 HR — 0 65 —0,87 SD = 0.154
regression line, oxygen breathing t 3 ata. log lactate = 0 0066 HR — 0,53 —0.82, SD = 0 152.

At the lower work load the lactate concentration was not significantly different from that during air breathing ($P>0.05$) At the higher work load it was 0 86 mmoles/l lower during oxygen breathing ($P<0.05$) The relation between heart rate and lactate concentration followed almost the same course during oxygen and air breathing (Fig 9)

Discussion

The difference in heart rate between oxygen breathing at 3 ata and air breathing was of the same order of magnitude at the higher and the lower

work load It was larger than the difference in heart rate between oxygen breathing at 1 ata and air breathing reported by Asmussen and Nielsen (1955)

Although there does not seem to be any significant difference between mixed venous and arterial lactate concentrations during exercise (Holmgren 1959) the concentration in an arm vein may differ from that in arterial blood because of an uptake in the forearm muscles (Carlson and Pernow 1959) However the relation between log lactate concentration and heart rate during air breathing was the same as earlier described for arterialized capillary blood by Strandell (1964) in healthy young men The relation between log lactate and heart rate was the same during oxygen as during air breathing It may be tempting to interprete the correlation as an indication that the difference in production of acid metabolites between oxygen and air breathing is one factor determining the difference in heart rate However the concentration differences are very small in relation to the heart rate differences, and in the individual subjects no correlation between the magnitude of heart rate difference and lactate difference between oxygen and air breathing can be found.

Cardiac output intravascular pressures and blood gases studied by means of heart catheterization

Subjects

Eight male volunteers, aged 19-26 years, were studied. Seven of them were students, one was a teacher Their average working capacity determined as W_{170} was 1280 kpm/min (range 1150-1650 kpm/min) the highest value was recorded for a subject who takes part in competitive cross-country skiing With the latter exception, the subjects were considered of average physical fitness.

Procedure

A Gensini catheter was introduced through an antecubital vein and advanced to the pulmonary artery A teflon catheter was introduced about 15 cm in the proximal direction in the brachial artery Exercise was performed during oxygen breathing at 3 ata and for comparison during air breathing at 1 ata. Each subject exercised for 7-8 minutes at a work load yielding a heart rate of about 120 beats/min rested for 10 minutes and then exercised at a work load yielding a heart rate of about 160 beats/min The resting measurements during oxygen breathing were made after 4 minutes of oxygen breathing Between the different measurement periods

(rest, load I load II) the subject was disconnected from the oxygen breathing system to keep the continuous oxygen exposure times short Each oxygen breathing exercise period was preceded by 4 minutes of oxygen breathing

Measurements

Pressure measurements in the brachial and pulmonary artery were performed at rest and after 3-4 minutes of exercise. Samples of arterial and mixed venous blood were taken for measurement of Po_2 oxygen saturation, Pco_2 and pH, expired gas was collected for determination of total lung ventilation, CO_2 elimination and O_2 uptake (during air breathing) and cardiac output was determined between 4½ and about 7 minutes of work. During oxygen breathing cardiac output was determined with the dye dilution technique, during air breathing as well with the Fick method.

For methodological details, see Chapter I

Results

The results are summarized in Table VI A and B and Fig 10

Air breathing at 1 ata

The *stroke volume* was significantly larger at the lower work load than at rest in the sitting position ($P<0.001$) It did not increase significantly with increased work intensity ($P>0.05$)

The *arterio-venous O difference* increased substantially from an average value at rest of 60.5 ml/l to 111.4 ml/l at the lower load ($P<0.001$) It increased slightly further with increased work intensity in all subjects to an average value at the higher work load of 134.7 ml/l ($P<0.05$)

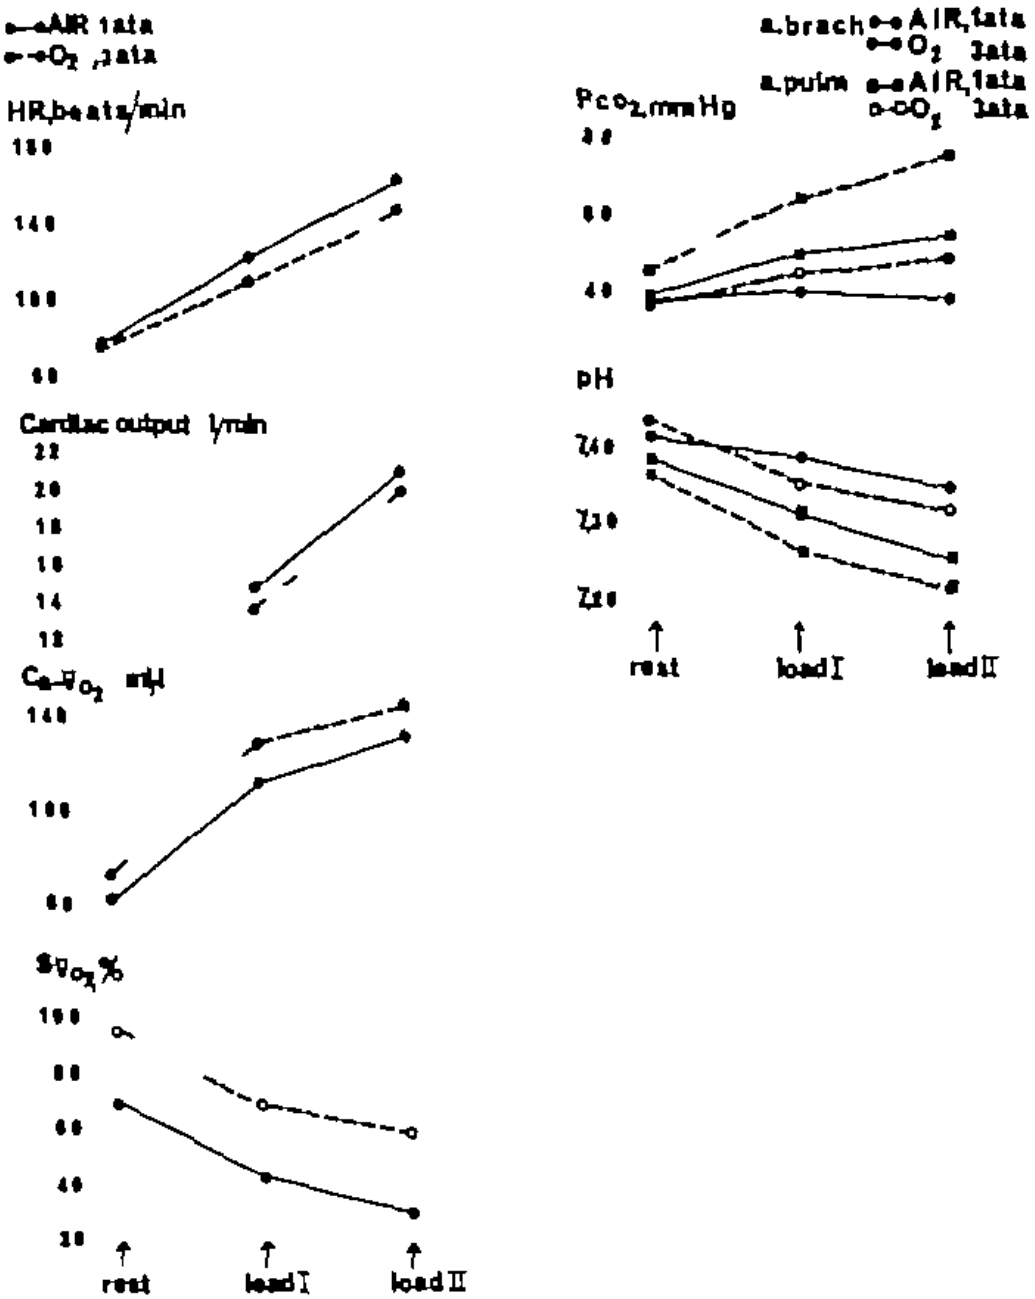
The *arterial Pco* was 38.3 mm Hg at rest and remained on a constant level at both work loads. The *arterial pH* decreased from 7.413 at rest to 7.348 at the highest work load ($P<0.05$)

The mixed venous Pco_2 increased moderately from 39.6 mm Hg at rest to 54.5 mm Hg at the highest work load ($P<0.01$) The *mixed venous pH* decreased from 7.384 at rest to 7.252 at the highest work load ($P<0.01$)

The integrated mean pressure in the *brachial artery* increased approximately linearly with increased heart rate. The *pulmonary artery* mean pressure increased moderately with increased work load and heart rate

Oxygen breathing at 3 ata. At rest

The arterial Po_2 was 1808 mm Hg The *heart rate* was the same during



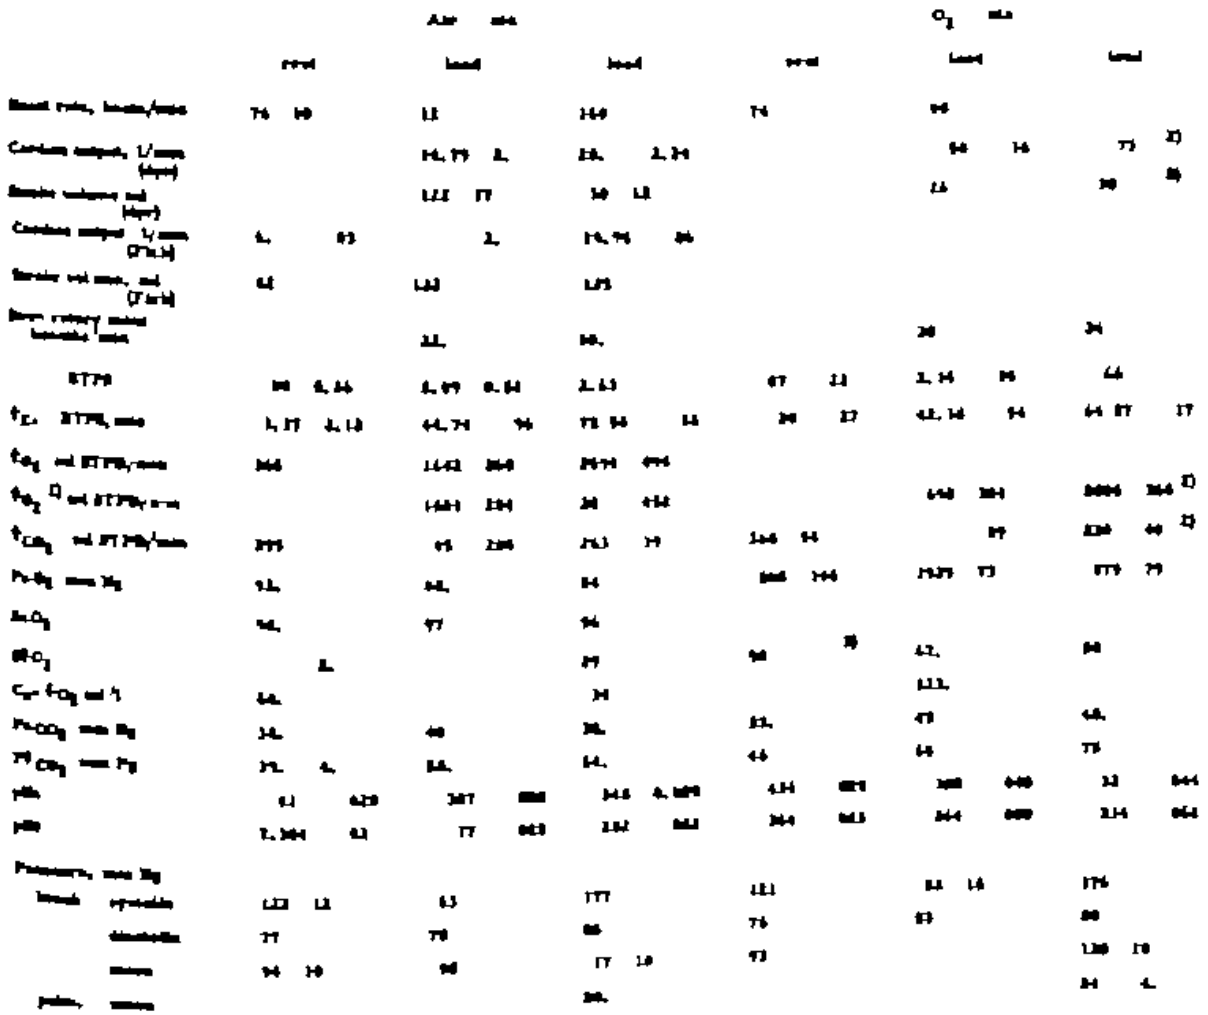


Fig 10 Heart rate cardiac output, arterio-venous O_2 difference and mixed venous (= pulmonary artery) O_2 saturation. P_{CO_2} and pH in the brabcial artery and pulmonary artery A erage values t rest and after about 6 min at the lower and the higher load *during air breathing* t 1 ta *and oxygen breathing at 3 ata.* = 8 *except for* cardiac output, load II (n = 5)

oxygen as during air breathing The *arterio-venous O difference* was 71 0 ml/L 11 ml larger than during air breathing ($P<0.01$) The *CO_2 elimination* and the *lung ventilation* were significantly larger during oxygen than air breathing ($P<0.01$) whereas the *arterial Pco* was unchanged. The *mixed venous O saturation* was 92 4 per cent, that is substantially higher than during air breathing ($P<0.001$) No significant differences in *arterial*

Table VI A. Heart catheterization data, obtained at rest in the sitting position and at light (500—850 kpm/min) and a moderately heavy (1000—1400 kpm/min) work load during air breathing at 1 ata and oxygen breating t 3 ata. Mean ± SD n = 8.

1) Calculated from cardiac output and arterio-venous O_2 difference
2) = 5. In 3 subjects the dye curves at 3 ata were not technically satisfactory
3) n = 7

or *mixed venous pH* were found compared to air breathing ($P>0.05$) The *systolic diastolic* and *mean pressures* in the *brachial* and the *pul monary artery* were the same during oxygen as during air breathing ($P>0.05$)

Oxygen breathing at 3 ata. During exercise

Pao was 1929 mm Hg at the lowest load. At the highest load it was slightly lower 1879 mm Hg ($P<0.05$)

At the lower work load no significant difference in *lung ventilation* was found between oxygen and air breathing At the higher work load, how ever the ventilation was on the average 18 per cent lower during oxygen than air breathing ($P<0.01$) The difference was caused by a difference

Table VI B. Difference between oxygen breathing at 3 ata and air breathing. Mean ± standard error of the mean. n = 6.

1) Calculated from cardiac output and arterio-venous O_2 difference.

in respiratory frequency the tidal volume being the same during oxygen as air breathing

The calculated *oxygen uptake* at corresponding work intensities was the same during oxygen as air breathing ($P > 0.05$)

Compared to air breathing the *heart rate* and the *cardiac output* were

about 10 per cent lower whereas the *stroke volume* was not significantly changed by oxygen breathing

The *O_2 saturation* of mixed venous blood at corresponding work intensities was substantially higher during oxygen than air breathing ($P<0.001$)

The *arterio-venous O difference* at the lower load was 12 4 ml/l larger during oxygen than air breathing ($P<0\,001$) whereas at the higher load no statistically significant difference was found the interindividual variations were large.

The *arterial Pco_2* was at the lower load 4 6 mm Hg higher during oxygen than air breathing ($P<0\,05$) and at the higher work load 10 5 mm Hg higher ($P<0\,001$)

The magnitude of the difference in $Paco_2$ between oxygen and air breathing was fairly well correlated to the difference in lung ventilation.

At the lower work load no significant difference in *arterial pH* was found ($P>0\,05$) whereas at the higher load the arterial pH was slightly lower during oxygen than air breathing ($P<0\,05$) The *mixed venous pH* was lower during oxygen breathing at both work loads ($P<0\,05$) reaching 7.214 at the higher load. The difference was caused by a higher *mixed venous Pco_2* during oxygen breathing both at the lower ($P<0\,001$) and at the higher work load ($P<0\,01$)

At the lower work load a slightly higher *diastolic* ($P<0\,05$) as well as integrated *mean pressure* ($P<0\,001$) in the *brachial artery* was found during oxygen compared to air breathing The difference was small, 5 0 mm Hg. At the higher work load no significant difference was found ($P>0\,05$) however The *systemic vascular resistance* calculated from the arterial pressure and the cardiac output was significantly higher during oxygen breathing at both work loads ($P<0\,001$) At the higher load a linear correlation between the increase in vascular resistance and the increase in arterial Pco_2 induced by oxygen breathing was found (Fig 11) At the lower load no corresponding correlation could be demonstrated.

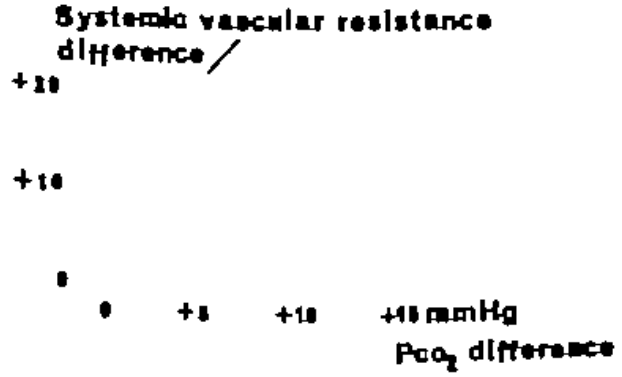

Fig 11 Relationship between the difference in systemic vascular resistance and the difference in arterial Pco_2 between oxygen breathing at 3 ata and air breathing at 1 ata at the highest load. The systemic vascular resistance is calculated as brach. artery mean pressure / cardiac output

At the lower work load the *mean pressure* in the *pulmonary artery* was the same during oxygen as during air breathing At the higher work load the pressure was significantly higher during oxygen than air breathing in spite of the smaller cardiac output. The pressure difference was not correlated to either of the factors, P_{CO_2} and pH in the pulmonary or brachial artery

Discussion

Stroke volume cardiac output and arterio-venous O_2 difference

The cardiovascular adaptation to exercise during air breathing in the present study agrees with earlier reports from the same laboratory concerning exercise in the sitting position (Bevegård, Holmgren and Jonsson 1960 Holmgren Jonsson and Sjöstrand 1960 Ekelund and Holmgren 1967)

The stroke volume was the same during oxygen as air breathing Consequently changes in exercise heart rate, induced by exposure to oxygen at 3 ata, reflect changes in cardiac output. This is important to establish if conclusions concerning the maximal aerobic work capacity are to be drawn from data obtained during hyperbaric oxygen breathing The possibility of toxic manifestations of oxygen on the myocardium has been proposed both during oxygen breathing at 3 ata (Kioschos *et al* 1969) and during oxygen breathing at normal atmospheric conditions (Daniell and Bagwell 1968) Both investigations were performed in resting dogs. In the light of the present study it seems much more likely that the decrease in stroke volume during oxygen breathing was caused by the labile stroke volume of dogs under differing experimental conditions (Rushmer and Smith 1959)

During oxygen breathing the arterial oxygen content was increased by about 30 per cent. With the moderate decrease in cardiac output and increase in arterio-venous O difference, less than 20 per cent of the increase in arterial oxygen content was utilized Consequently the mixed venous blood was comparatively highly saturated also during rather heavy work.

Gas exchange lung ventilation and blood gases

No difference in oxygen uptake at corresponding work loads between oxygen and air breathing were found This is in agreement with earlier reports concerning oxygen breathing at 1 ata (Asmussen and Nielsen 1955) The possibility that the oxygen uptake rate at a given mechanical work intensity can be decreased by prolonged exposure to high oxygen pressure has been proposed by Banister (1969) The sparse data in Banister's preliminary communication makes it impossible at present fully

to interpret them. Salzano *et al.* (1967) on the other hand found a larger oxygen uptake during oxygen breathing at 2 ata than during air breathing at 1 ata at corresponding work loads. They considered it most probably caused by the increased air density. The present data concerning exercise at 3 ata during air breathing apparently contradict this explanation (Chapter II).

Although the oxygen uptake did not differ during oxygen as compared to air breathing the CO_2 elimination was decreased during oxygen breathing. As both arterial and mixed venous P_{CO_2} was increased during oxygen breathing this is probably due mainly to an accumulation of CO_2 in the body. The compartmentalization for CO_2 in the body is not so well known, that it is possible to calculate whether a decreased tissue respiratory quotient also contributes to the decreased CO elimination. The higher CO elimination at rest during oxygen as compared to air breathing may be explained by an increased metabolic rate or at least partly by hyper ventilation. Oxygen is earlier reported to stimulate ventilation at rest (Asmussen and Nielsen 1946, Lambertsen *et al.* 1953).

In agreement with earlier investigations at 1 ata (Asmussen and Niel sen 1946, 1958, Lambertsen *et al.* 1953, Åstrand 1954, Dejours 1959) a decrease in lung ventilation during oxygen compared to air breathing was found at the heavier load, whereas at the lower load no differences were recorded. The decrease in ventilation during oxygen breathing at the higher load, 18 per cent, is of the same order of magnitude as that found by Telfer and Jennett (1965) during oxygen breathing at 3 ata, Lambertsen *et al.* (1959) at 2 ata and by Åstrand (1954) and Asmussen and Nielsen (1958) during oxygen breathing at 1 ata. The mechanisms behind the decrease in ventilation are less well known (Asmussen and Nielsen 1946, 1958, Bannister and Cunningham 1954, Dejours *et al.* 1959). As proposed by Dejours (1959) a reduced or ceased impulsive activity from the chemoreceptors may be the most probable explanation. In that case it seems likely that the activity from the chemoreceptors ceases at a P_{O_2} not higher than 1 atmosphere, as the ventilation decrease by oxygen is the same at 3, 2 and 1 ata.

Intravascular pressures

The difference in mean brachial artery pressure between oxygen and air breathing at corresponding work loads was small. Only at the lower load was a significant although small, increase in pressure found during oxygen breathing. On the other hand, in relation to the cardiac output and the heart rate the pressure was higher during oxygen breathing, the calculated

vascular resistance being therefore higher Partly this seems to be the effect of the higher arterial P_{CO_2} as the difference in resistance between oxygen and air breathing at the highest load is correlated to the difference in Pa_{CO_2} (Fig 11) Other factors, such as the direct effect of oxygen on vascular tone, must contribute, however Thus also at the lower load, where Pa_{CO_2} during oxygen breathing was almost within the normal range, the vascular resistance was higher during oxygen breathing

Very small differences in pulmonary artery pressure were found between oxygen and air breathing at corresponding work loads, slightly higher pressures being found during oxygen breathing only at the higher work load. The reason for the pressure difference is not clear A decreased inspiratory oxygen pressure increases the pulmonary vascular resistance (von Euler and Liljestrand 1946) The effect of an increase seems to be more complicated. If the oxygen pressure in the pulmonary artery is increased, an increased vascular resistance will result (Moulder *et al.* 1964 Bain, Lancaster and Adams 1965) This factor does not seem to contribute to the pressure increase during oxygen breathing in the present study however as the oxygen saturation in the pulmonary artery was higher during oxygen breathing at rest and at the lower load when no pressure difference was found.

Conclusions

1 At submaximal work loads the cardiac output was lower and the arteno-venous O difference higher during oxygen breathing at 3 ata than during air breathing The differences were much smaller however than the difference in arterial oxygen content.

2 The stroke volume was found to be the same during oxygen as during air breathing

3 The pressures in the brachial and pulmonary artery were almost equal during oxygen and air breathing at corresponding loads. However in relation to the cardiac output they were higher during oxygen breathing

4 The lung ventilation during heavy exercise was decreased during oxygen breathing at 3 ata. The difference was of the same order of magnitude as that reported by other authors during oxygen breathing at 1 ata.

3. Adaptation to maximal leg exercise

Subjects

Twelve male volunteers, aged 19-25 years, were studied. Eleven of them

were students, one was a teacher Their average physical working capacity, determined as W_{170}, was 1240 kpm/min (range 1150-1350 kpm/min) In six subjects arterial and femoralvenous catheterization was performed five of them had taken part in the heart catheterization study earlier described. In the remaining six subjects only heart rate and performance time during exhaustive work were measured.

Procedure

In six subjects, percutaneous catheters were introduced in an artery (brachial artery in five, radial artery in one subject) and the right femoral vein. In the remaining six subjects only heart rate and performance time were measured.

Exercise was performed during oxygen breathing at 3 ata and for comparison during air breathing at 1 ata. The subjects first exercised for 5 minutes at a submaximal load selected to give a heart rate of about 120 beats/min (warm-up) After that they rested for 10 minutes and then worked until exhaustion at a work load which they could sustain for 5-6 minutes. The resting measurements during oxygen breathing were preceded by 4 minutes of oxygen breathing Also the exercise periods were preceded by about 4 minutes of oxygen breathing

Measurements

The heart rate was recorded continuously Arterial and venous blood (six subjects) for the determination of O saturation, P_{CO_2} pH, lactate and pyruvate concentrations, and arterial blood for P_{O_2} determination was sampled at rest, after 1 and 2 minutes and during the last 30 seconds of the exhaustive exercise period. P_{O_2} in the femoral vein was measured only at exhaustion.

Results

Heart rate and performance time

At rest the heart rate was 74 beats/min (SD 8) during air breathing and 70 beats/min (SD 9) during oxygen breathing at 3 ata. The difference is not significant ($P>0.05$)

During exercise breathing air the heart rate at the exhaustive load increased to 156 beats/min (SD 9) after 1 min. It increased further to 183 beats/min (SD 9) at exhaustion. During oxygen breathing it was throughout the work period in all subjects lower than during air breathing. The difference was largest in the early phase of work being 18 beats/min

after 1 minute and significantly lower 13 beats/min ($P<0.05$) after 4 minutes. The heart rate at exhaustion was 171 beats/min (SD 7)

The *performance time* was 6 15 min (SD 1 4) during air and 6 47 min (SD 2 1) during oxygen breathing The values are not significantly different ($P>0.05$) Of the individual subjects eight worked longer during oxygen and four during air breathing

Arterio-femoralvenous difference in blood gases and lactate
The results are summarized in Table VII and Fig 12

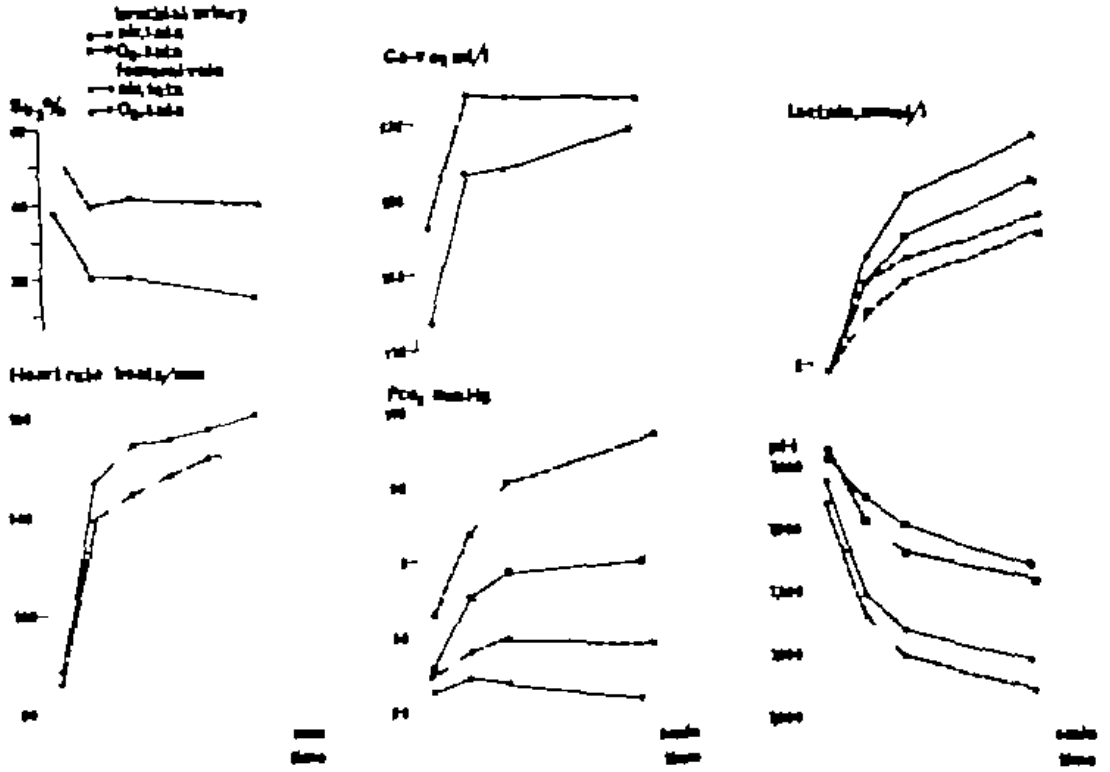

Fig 12 Femoralvenous O_2 saturation heart rate, arterial-femoralvenous O_2 difference arterial and femoral venous Pco_2, lactate concentration and pH. Average values (n = 6) at rest after 1 and 2 min, and immediately before the end of exhaustive work during air breathing at 1 ata and O_2 breathing at 3 ata. Continuous lines denote air at 1 ata, dashed lines oxygen at 3 ata. Pco_2, lactate and pH from the brachial artery squares, from the femoral vein circles.

The six subjects studied by femoralvenous catheterization did not differ from the rest of the group with respect to influence of oxygen on performance time or heart rate at rest and during work.

At rest
During air breathing the *O saturation* in the femoral vein was 37.3 per cent the *arterio-venous O difference* being 117 3 ml/l.

Table VII A. Data obtained at rest in the sitting position, after 1 and 2 min and at exhaustion at work loads ranging between 1450—1800 kpm/min during 1 breathing at 1 ata and oxygen breathing at 3 ata. Mean±SD n = 6.

During oxygen breathing the *arterial Po* was 1883 mm Hg The *venous O_2 saturation* was 54.5 per cent, which is significantly higher than during air breathing ($P<0.01$) The *arteno-venous O_2 difference* was 143 8 ml/l 26.5 ml/l higher than during air breathing ($P<0.05$)

Exhaustive work

Air breathing After 1 minute of exercise the *O saturation* in the femoral vein was 20 6 per cent. It decreased further during the exercise period and was at exhaustion 16 0 per cent ($P<0.05$) The corresponding *Po_2* was 17 8 mm Hg

The *arterial Pco* decreased slightly throughout the work period. The *femoralvenous Pco* increased from 60.5 mm Hg after 1 minute to 70.8 mm Hg at exhaustion

Both the *arterial* and *venous lactate* concentrations increased during exercise the veno-arterial difference not changing significantly from the first minute to exhaustion.

The *arterial pH* decreased to 7 241 and the *venous pH* to 7 092 at exhaustion

Oxygen breathing The *arterial Po* was 1892 mm Hg after 1 minute of work and remained unchanged. The *venous O_2 saturation* was 39 8 per cent after 1 minute It remained on the same level during the whole work period, being 41 1 per cent at exhaustion The *venous Po_2* at exhaustion was 65 8 mm Hg The *arteno-venous O difference* after 1 minute of work was 21 5 per cent higher than that during air breathing ($P<0.001$) No significant difference was found at exhaustion

The *art rial Pco* was higher during work than at rest ($P<0.01$) It did not change significantly from the first to the last minute of work. At exhaustion it was 48 8 mm Hg, *i.e* 14.5 mm Hg higher than during air breathing ($P<0.05$) *Pco_2* in the *femoral vein* increased from 77 3 mm Hg after 1 minute to 104.5 mm Hg at exhaustion ($P<0.01$) The value at exhaustion is 33 7 mm Hg higher than corresponding value during air breathing ($P<0.01$)

The *arterial lactate concentration* increased during work to 8.86 mmoles/l at exhaustion. Compared to air breathing this is significantly lower ($P<0.001$) However the value after 1 minute did not differ significantly from that during air breathing The *femoralvenous lactate concentration* increased to 9.93 mmoles/l at exhaustion, 4 25 mmoles/l less than during air breathing ($P<0.001$) The *veno-arterial lactate difference* was at exhaustion ($P<0.05$) but not after 1 and 2 minutes higher during oxygen than air breathing.

The *arterial pH* was at exhaustion slightly lower during oxygen than air breathing ($P<0.05$). Also the *venous pH* was at exhaustion lower than during air breathing ($P<0.01$).

Discussion

The heart catheterization study showed that the exercise stroke volume was the same during oxygen as during air breathing. Consequently the lower heart rate at exhaustion during oxygen breathing means that the cardiac output is lower than during air breathing. Thus the subjects were exhausted in spite of a lower calculated cardiac output and a higher femoralvenous O saturation than during air breathing. This gives evidence for that the O_2 transport is not limiting the oxygen uptake.

The intramitochondrial Po_2 is supposed to be about 1 mm Hg (Chance *et al.* 1962). In that case the O diffusion gradient from capillary blood to the mitochondrion was 3-4 times larger during oxygen than air breathing as judged from the venous Po_2. As, in spite of this, no sign of a significant increase in maximal oxygen uptake was found as judged from performance time arteriovenous O difference and maximal heart rate, not either diffusion from blood to muscle tissue seem to be limiting for aerobic work capacity in normal subjects.

The statement above is valid for the maximal muscular oxygen uptake rate. However even if it is not limiting for the maximal oxygen uptake an initial delay in cardiac output increase may limit oxygen uptake in the beginning of work (Margaria *et al.* 1965, Hughes *et al.* 1968). The higher femoralvenous O saturation after the end of the first minute of work than at exhaustion during air breathing may be taken as an indication that the oxygen transport by blood circulation does not either limit oxygen uptake in this quite early phase of work (*cf.* Hartley and Saltin 1969). However conclusions regarding the muscle oxygen supply at the onset of work premises still earlier measurements than in the present study.

In spite of the very high femoralvenous Po_2 during oxygen breathing the femoralvenous lactate concentration was only slightly lower than during air breathing. Consequently a high lactate production cannot be taken as evidence of a lack of molecular oxygen in the active muscle.

Both the arterial and the femoralvenous pH was slightly lower during oxygen than air breathing. It is not possible from these values to draw any definite conclusions regarding tissue pH. However as a high venous lactate concentration contributed relatively less to the low femoralvenous pH during oxygen than air breathing the pH difference between tissue and

blood is probably less during oxygen breathing (Diamant, Karlsson and Saltin, 1968) and the tissue pH may be the same under the two conditions.

Conclusions

1 The maximal aerobic work performance was not significantly increased by oxygen breathing at 3 ata.

2. As judged from the heart rate and the stroke volume, determined during submaximal work, the maximal cardiac output was not reached at exhaustion during oxygen breathing at 3 ata.

3 Po_2 in venous blood from the active muscles was 3-4 times higher during oxygen than air breathing

4 It was concluded that neither circulation nor diffusion in the active muscle are limiting for the muscle oxygen uptake.

5 The venous lactate concentration was lower during oxygen than air breathing although it was rather high in relation to the venous Po_2. The high lactate concentration cannot be taken therefore as evidence of a lack of molecular oxygen in the active muscles.

6 The femoralvenous pH at exhaustion was slightly lower during oxygen than air breathing

CHAPTER V

Adaptation to exercise at decreased inspiratory oxygen pressure

Introductory remarks

The data obtained during oxygen breathing at 3 ata demonstrated that the aerobic work performance is not significantly improved by an increase in arterial oxygen content. This seems to indicate that the oxygen transport capacity of the cardiovascular system is not the main limiting factor for aerobic work performance in healthy young subjects. To elucidate the problem further it was considered of interest to investigate to what extent a decreased arterial oxygen content could be compensated for by an increased O_2 desaturation of the venous blood.

The influence of a decreased arterial oxygen saturation on work performance in normal subjects has been described by numerous authors during sojourns at high altitude, during acute exposure to simulated altitude in low pressure chambers and during hypoxic gas mixture breathing (*e. g.* Dill 1938, Stenberg, Ekblom and Messin 1966). For a correct interpretation of results reported in the literature it is important to state under what conditions hypoxia is studied. Thus, during a prolonged sojourn at altitude, adaptation to hypoxia of the cardiovascular system as well as cell metabolism (see Hurtado 1965) take place. Some of these changes are very rapid indeed. Asmussen and Nielsen (1945) showed that the hemoglobin concentration was increased already after 24 hours exposure to simulated altitude because of a decrease in plasma volume. In unpublished experiments it was found that a major part of this concentration increase is completed within 30 minutes (Eklund and Kaijser). For the present discussion effects of short-time exposure to hypoxia are of dominating interest.

From investigations concerning acute exposure to a lowered inspiratory oxygen pressure during work, the general conclusion can be drawn that the maximal O_2 uptake is decreased by approximately the same amount (taken as a percentage) as the arterial oxygen content (Stenberg, *et al.*

1966 Hansen *et al* 1967 Ceretelli *et al.* 1967) However it is not well known if there exists a margin, by which the oxygen content may be reduced before the maximal oxygen uptake decreases, although it is discussed by Hughes *et al* (1968)

The cardiovascular adaptation to decreased inspiratory oxygen pressure is characterized by an increased heart rate at corresponding submaximal work intensities, a moderate increase in cardiac output and probably a somewhat decreased stroke volume. However the maximal heart rate, cardiac output and stroke volume seem not to be changed compared to normoxaemia, at least at simulated altitudes below 4 000 meters (Stenberg *et al* 1966 Hughes *et al* 1968)

1 Adaptation to dynamic forearm work

Subjects

Five male volunteers and one female, aged 22 24 years, were studied. Their average forearm work capacity determined as W_{max} was 13 6 kpm/min (range 9-18 kpm/min)

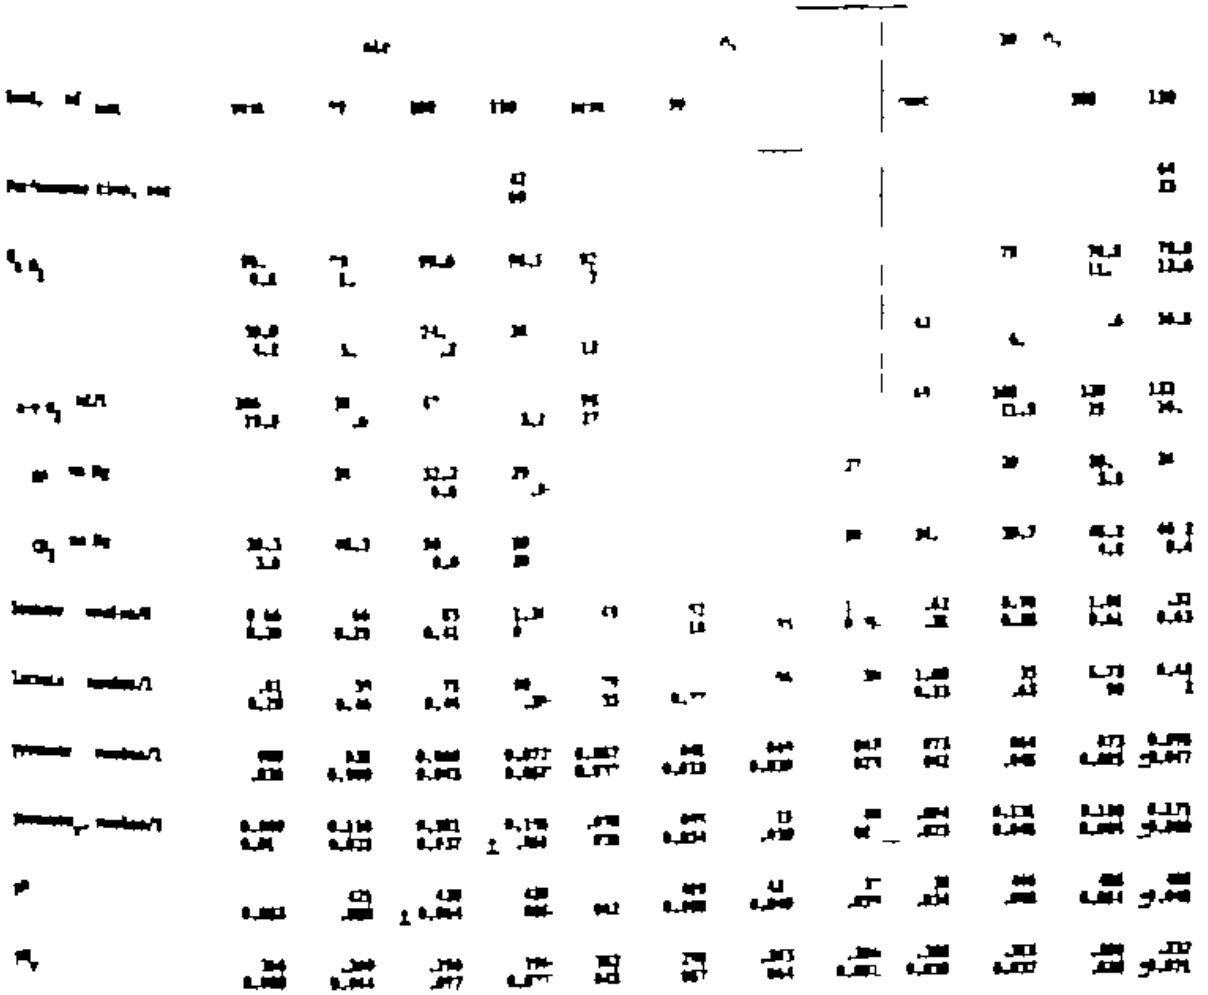
Procedure

Dynamic forearm work was performed at stepwise increasing loads 4 minutes at 50 per cent of W_{max} 4 minutes at 100 per cent of W_{max} and until exhaustion at 150 per cent of W_{max} *e g* the mode of exercise was the same as that used in the study of forearm work during hyperbaric oxygen breathing

The subjects were studied during 1) air breathing, 2) breathing 15 per cent O in N and 3) 10 per cent O in N_2.

A brachial artery and the deep vein of the active forearm were catheterized as described in Chapter I

Measurements



Sampling of arterial and deep venous blood was made at rest and at the end of each work period for the determination of oxygen saturation, P_{CO_2} pH, lactate and pyruvate concentrations. Also the maximal performance time at the highest load was measured.

For methodological details see Chapter I

Results

The results are summarized in table VIII A and B and Fig 13

Table VIII A. Data obtained during forearm work [illegible] stepwise in[illegible]d loads d[illegible]ring air 15 per cent and 10 per cent oxygen breathing [illegible]. Sample [illegible]ken at rest, after 4 min at the two lower loads and at exhaustion. Mean ± SD

Air breathing

Arterial blood The *O saturation* was 98 3 per cent at the lowest load No significant changes in O saturation, P_{CO_2}, *pH* or *pyruvate concentration* occurred during work as compared to rest.

The *lactate concentration* was 0 66 mmoles/l at rest and increased to 1.26 at exhaustion ($P<0.05$)

Venous blood The *O saturation* decreased from 39.9 per cent at rest to 31.8 per cent at the lowest work load ($P<0.05$) It decreased further to 24.9 per cent at the second load ($P<0.05$) and remained on the same level, 28 6 per cent at the highest load. The *arterio-venous O difference* increased from 106.5 ml/l at rest to 130 6 ml/l at the lowest load ($P<0.05$) and increased further to 140.9 ml/l at the highest work load ($P<0.05$)

Pco₂ increased from 38 3 mm Hg at rest to 48 3 mm Hg at the lowest load ($P<0.05$). It increased further to 58.5 mm Hg at the second load ($P<0.05$). It remained on the same level at exhaustion.

The *lactate concentration* increased with increasing work intensity from 0 81 mmoles/l at rest to 4 80 mmoles/l at the highest load ($P<0.001$)

The *pyruvate concentration* increased from 0 089 mmoles/l at rest to 0 156 mmoles/l at exhaustion ($P<0.05$)

pH decreased from 7 366 at rest to 7.269 at the lowest work load ($P<0.05$) and further to 7 196 at the highest load ($P<0.01$)

The *performance time* to exhaustion was 142 sec.

15 per cent oxygen breathing

Arterial blood The *O saturation* was 92 1 per cent at rest. It increased significantly to 94 4 per cent at the highest work load ($P<0.05$)

Pco₂ was 31 7 mm Hg at rest, and decreased slightly to 27 2 mm Hg at exhaustion ($P<0.05$)

The *lactate concentration* was 0 48 mmoles/l at rest, and increased to 1 11 mmoles at exhaustion ($P<0.05$)

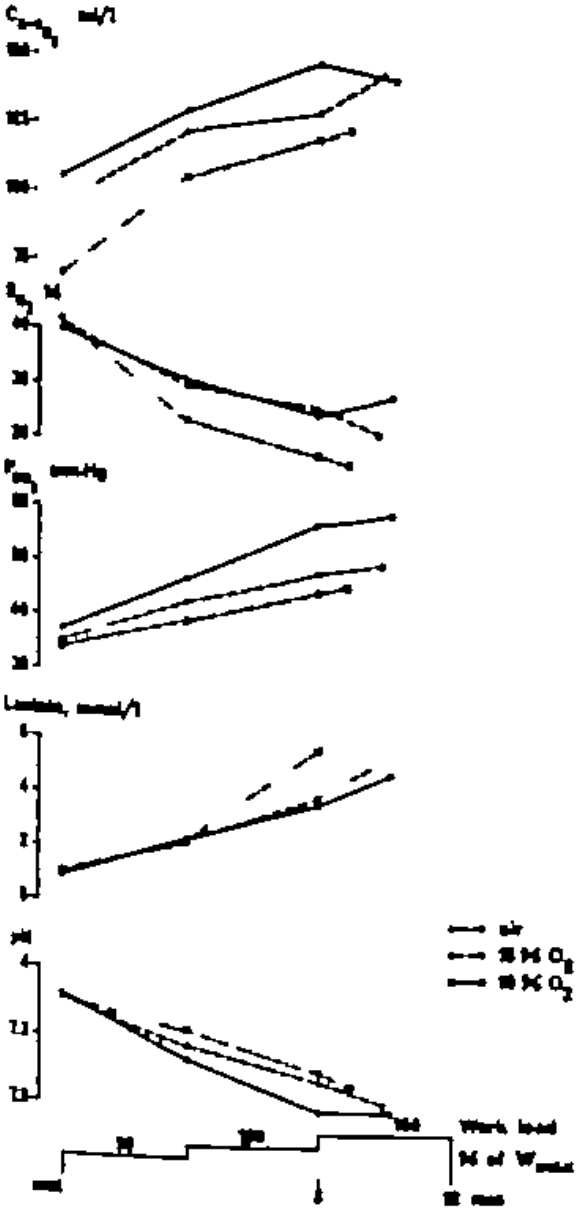

Fig 13 Arterial-deep venous O_2 difference and O_2 saturation, P_{CO_2}, lactate concentration and pH in the deep vein of the active forearm during work at stepwise increased loads. Average values ($n = 6$) at rest after 4 min at the first and the second load, and at exhaustion during air breathing, 15 per cent and 10 per cent oxygen breathing

The *pyruvate concentration* was 0.057 mmoles/l at rest, and did not change significantly during work.

pH was 7.418 at rest and did not change significantly during work ($P > 0.05$)

Venous blood The *O_2 saturation* decreased from 42.8 per cent at rest to 30.5 per cent at the lowest load ($P < 0.05$). It decreased further and was 21.9 per cent at exhaustion. The *O_2 saturation* was not significantly different from that during air breathing at the lower loads ($P > 0.05$) whereas at exhaustion it was 6.7 per cent lower than during air breathing ($P < 0.05$). The *arterio-venous O difference* was 95.7 ml/l at rest. It had increased to 125.6 ml/l at the second load ($P < 0.05$) and increased further to 143.7 ml/l at exhaustion ($P < 0.05$). It was slightly lower than during

air breathing in most subjects at the two lower work loads but at exhaustion it did not differ significantly from that during air breathing ($P>0.05$)

P_{CO_2} increased from 35.2 mm Hg at rest to 42.8 mm Hg at the lowest load ($P<0.05$) and increased further to 50.0 mm Hg at exhaustion. In most subjects it was lower than during air breathing on all work levels. If only the value at exhaustion is regarded, however it did not differ significantly from that during air breathing ($P>0.05$)

The *lactate concentration* increased from 0.79 mmoles/l at rest to 5.30 mmoles/l at exhaustion ($P<0.01$) Neither the *lactate* nor the *pyruvate concentration* differed from that during air breathing at corresponding loads.

The *pH* was 7.362 at rest. At the lowest load it was 7.295 or in most subjects higher than during air breathing The value at exhaustion, 7.207 did not differ from that during air breathing ($P>0.05$)

The *performance time* to exhaustion at the highest work load was 125 sec. It did not differ significantly from the performance time during air breathing ($P>0.05$)

10 per cent oxygen breathing

Arterial blood The *O saturation* was 78.7 per cent at rest. It did not change significantly during work ($P>0.05$)

P_{CO_2} was 31.0 mm Hg at rest and decreased to 24.5 mm Hg at exhaustion ($P<0.05$)

The *lactate concentration* was 0.62 mmoles/l at rest and increased to 1.31 mmoles/l at exhaustion ($P<0.05$)

The *pyruvate concentration* was 0.073 mmoles/l at rest and did not change during work.

pH was slightly high at rest, and did not change during work. At exhaustion it was 7.455

Venous blood The *O saturation* at rest was 42.4 per cent. It did not differ from that during air or 15 per cent O breathing It decreased to 24.2 per cent at the lowest work load ($P<0.05$) and decreased further to 16.5 per cent at the highest work load ($P<0.05$) It was at all work intensities lower than during air breathing ($P<0.05$) and at the two highest intensities lower than during 15 per cent O_2 breathing ($P<0.05$)

The *arterio-venous O difference* increased from 66.9 ml/l at rest to 105.7 ml/l at the first work load ($P<0.05$) and further to 120.2 ml/l at the second load ($P<0.05$) It remained on the same level at the highest load. It was lower than during air and 15 per cent O breathing at rest as well as at all work intensities.

P_{CO_2} was 34.5 mm Hg at rest and increased to 39 7 mm Hg at the first work load ($P<0.05$) It increased further to 45 2 mm Hg at the second load ($P<0.05$) and remained on the same level at exhaustion

The *lactate concentration* was 1 00 mmoles/l at rest and increased to 6 48 mmoles/l at exhaustion. It did not differ from that during air or 15 per cent O_2 breathing at rest or at the first two work loads. At exhaustion, how ever it was higher than during air as well as 15 per cent O breathing ($P<0.05$)

The *pyruvate concentration* was 0 094 mmoles/l at rest. It increased to 0.182 mmoles/l at the second work load ($P<0.05$) and 0 171 mmoles/l at exhaustion. It did not at any level of work differ from that during air or 15 per cent O_2 breathing

The *pH* was 7.358 at rest. It decreased to 7.318 at the lowest load, which is significantly higher than during air breathing ($P<0.05$) It de creased further to 7.237 at exhaustion. The value at exhaustion was not significantly different from that during air breathing ($P>0.05$)

The *performance time* to exhaustion at the highest load was 64 sec. It was significantly lower than corresponding values during 15 per cent O_2 and air breathing ($P<0.05$)

Discussion

Earlier investigations regarding the effect of low oxygen pressure in the inspiratory air on aerobic work performance concern heavy work with large muscle groups. The maximal oxygen uptake is generally found to decrease by an amount approximately corresponding to the decrease in arterial O_2 content (*cf* Stenberg *et al* 1966 Hansen *et al* 1967 Cerretelli *et al.* 1968)

The present study indicates that when work is performed with a small muscle group it is possible to compensate for a decrease in arterial O_2 saturation of about 5 per cent by a more complete oxygen desaturation of the blood perfusing the active muscles. This further underlines the con clusions drawn from the experiments with forearm work at hyperbaric oxygen pressure that the oxygen transport by the local blood circulation does not limit aerobic work capacity under normal conditions.

With a 20 per cent decrease in arterial oxygen saturation, the deep vein saturation can be reduced slightly further but not to a magnitude which makes possible an unchanged arteno-venous O difference and an unchanged performance time for exhaustive work.

The deep vein lactate concentration at exhaustion was higher during pronounced arterial hypoxaemia than under conditions of ordinary arterial

O saturation. Partly because of hyperventilation, partly because of the smaller O_2 extraction per unit blood during 10 per cent O breathing the deep vein P_{CO_2} is lower and the deep vein pH at exhaustion does not differ from that during air breathing

Conclusions

1 A decrease in arterial oxygen saturation of about 5 per cent did not decrease the arterio-venous O difference or the maximal performance time for exhaustive forearm work significantly
2 A decrease of about 20 per cent reduced the performance time and the arterio-venous O_2 difference significantly
3 The conclusion was drawn that there is a margin of at least 5 per cent in arterial O saturation before the maximal O_2 uptake is reduced.
4 At exhaustion the deep vein pH was the same during air 10 per cent and 15 per cent oxygen breathing

2 Adaptation to maximal leg work

In a first set of experiments work performance at an ambient pressure of 560 mm Hg was compared to that at 1 ata. In a second set of experiments four of the subjects were studied at 630 mm Hg as compared to 1 ata. The ambient pressure was selected with the results from the first set of experiments as guidance in an attempt to find the margin for decrease in arterial O content without a decrease in aerobic work performance

Subjects

Six male volunteers, aged 23-26 years, were studied. Their average work capacity determined as W_{170} was 1220 kpm/min (range 1150-1350 kpm/min)

Procedure

Percutaneous catheters were introduced in a brachial artery and the right femoral vein.

Exercise was performed in the first set of experiments at 1 ata and 560 mm Hg in the second set at 1 ata and 630 mm Hg ambient pressure. The subjects first worked for 5 minutes at a warm-up load, selected to give a heart rate of about 120 beats/min. The work intensity was then increased instantaneously to a load which the subjects were assumed to sustain for about 6 minutes.

Measurements

The *heart rate* was recorded continuously during the work periods. Arterial pressure was recorded at rest and after about 4 minutes at the submaximal and the maximal work load. Arterial and femoralvenous blood for the determination of Po_2, O_2 saturation Pco_2, pH, lactate and pyruvate concentrations was sampled at rest, after 4½ minutes at the submaximal and after 1 and 2 minutes as well as during the last 30 seconds at the maximal work load. Oxygen uptake was measured at rest and during repeated periods of about 1½ minute during maximal work.

For methodological details, see Chapter I

Results

1 Comparison between air breathing at 560 mm Hg and 1 ata

The results are summarized in Table IX and Fig. 14.

At rest

The *arterial O_2 saturation* was 98.5 per cent at 1 ata and 91.8 per cent at 560 mm Hg ($P<0.01$). No other significant differences between 560 mm Hg and 1 ata were recorded.

During exercise at 1 ata

The *heart rate* increased from 76 beats/min at rest to 118 beats/min at the submaximal work load and 182 beats/min at exhaustion at the maximal load.

The *arterial O_2 saturation* was 98.5 per cent at rest and decreased slightly to 95.0 per cent at exhaustion ($P<0.05$). The *femoralvenous O_2 saturation* was 46.9 per cent at rest and 30.3 per cent at the submaximal work load. It decreased to 21.5 per cent after 1 minute at the maximal load ($P<0.05$) and decreased further to 14.9 per cent at exhaustion ($P<0.05$). The *femoralvenous Po* decreased from 23.8 mm Hg at rest to 18.8 mm Hg at the submaximal work load ($P<0.05$). It remained on the same level in the beginning of the maximal work but decreased to 15.5 mm Hg at exhaustion ($P<0.05$). The *arterio-venous O_2 difference* increased from 98.1 ml/l at rest to 131.0 at the submaximal work load ($P<0.05$). It increased further to 148.7 ml/l after 1 minute at the maximal load ($P<0.05$) and was still higher 163.4 ml/l, at exhaustion ($P<0.05$).

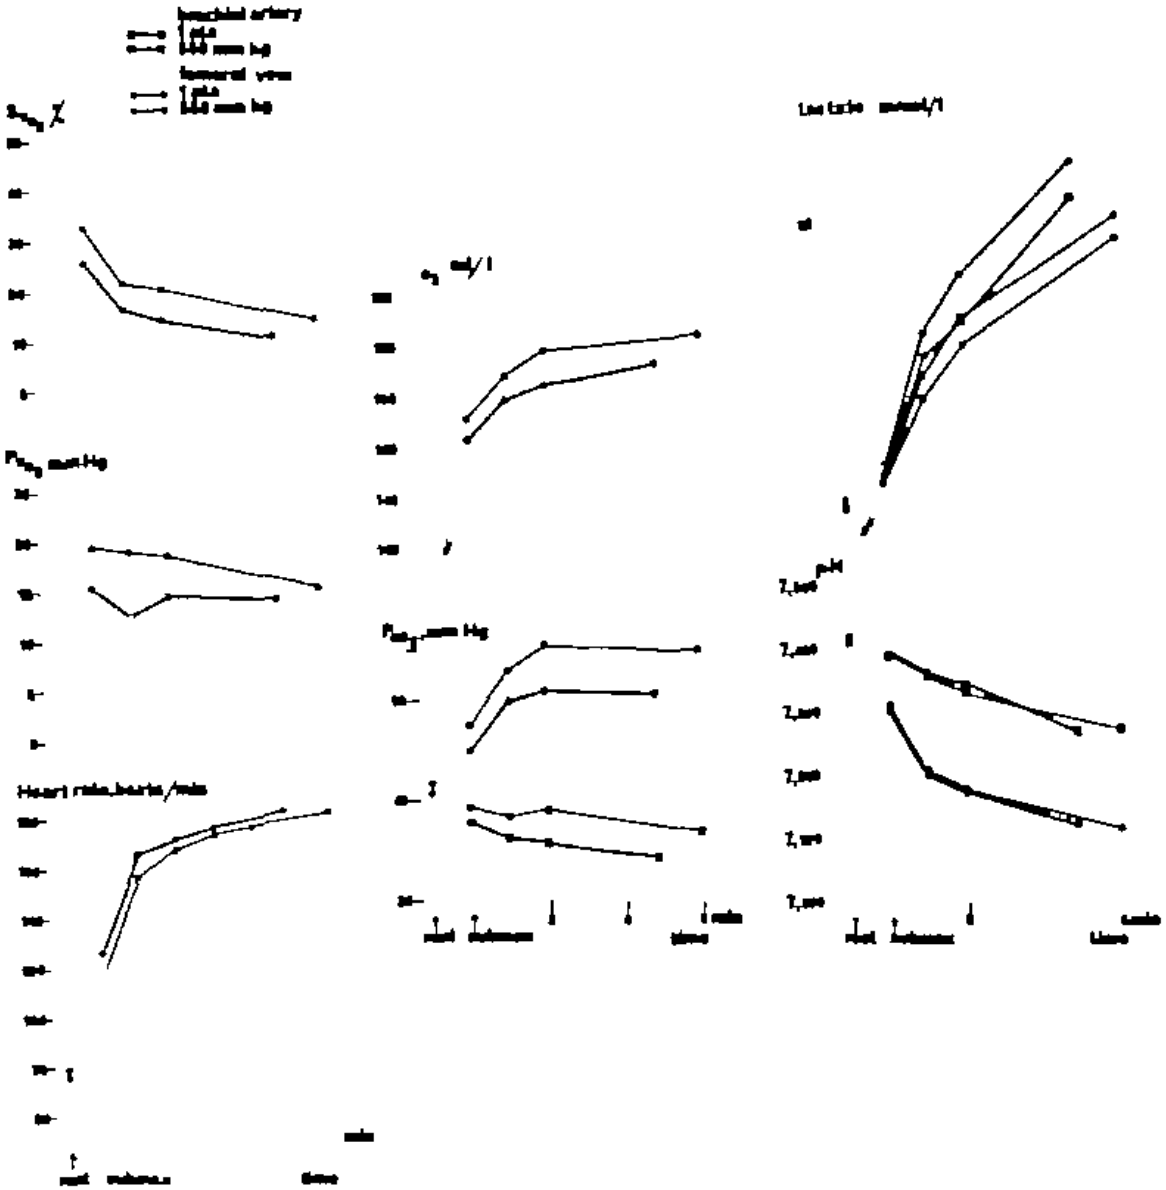

Fig. 14 Femoralvenous O_2 saturation, P_{O_2}, P_{CO_2}, lactate concentration and pH arterial-femoralvenous O_2 difference and heart rate at rest, during submaximal work, and after 1 and 2 min, and immediately before the end of exhaustive work. Average values ($n = 6$) at 1 ata and 560 mm Hg ambient pressure.

The *arterial Pco* was 36.7 mm Hg at rest. It remained on the same level during submaximal work and during the first two minutes at the maximal load but decreased significantly to 33.5 mm Hg at exhaustion ($P<0.05$). The *femoralvenous Pco* was 43.5 mm Hg at rest, increased to 54.3 mm Hg at the submaximal work load ($P<0.05$) and to 65.7 mm Hg after 1 minute at the maximal load ($P<0.05$). It increased further to 70.5 after 2 minutes ($P<0.05$) and remained at the same level until exhaustion.

The *arterial lactate concentration* increased from 1.04 mmoles/l at rest to 1.81 mmoles/l at the submaximal load ($P<0.05$) and increased con

Table IX A. Data obtained rest in the sitting position after 5 min a the submaximal work load and after 1 and 2 min and exhaustion t the maximal load during air breathing at 1 ta nd 560 mm Hg ambient pressure. Maximal loads anging between 1550—1700 kpm/min. Mean ± SD. n=6.

tinuously during work to 11 37 mmoles/l at exhaustion. No significant veno-arterial lactate difference was recorded at rest or at the submaximal work load. At the maximal load, however the venous concentration was higher than the arterial, reaching 12.26 mmoles/l at exhaustion. The *arterial pyruvate concentration* was 0 072 mmoles/l at rest, increased to 0 108 mmoles/l at the submaximal work load ($P<0.05$) It increased further to 0 196 mmoles/l at exhaustion ($P<0.01$) The *femoralvenous pyruvate concentration* did not differ from the arterial at rest or at the submaximal load but during maximal work it increased more than the arterial, reaching 0 226 mmoles/l at exhaustion. At the maximal work load the veno-arterial differences for lactate and pyruvate were significant, both after 1 minute ($P<0.05$) and at exhaustion ($P<0.01$) The veno-arterial differences were of the same order of magnitude at exhaustion as after 1 minute.

The *arterial pH* was 7 425 at rest, 7.394 at the submaximal work ($P<0.05$) and decreased continuously during the maximal work to 7.271 at exhaustion. The differences between the first and the second minute as well as between the second minute and exhaustion were significant ($P<0.05$)

The *mean pressure* in the *brachial artery* was 87 mm Hg at rest and 95 mm Hg at the ubmaximal work load. It increased significantly to 116 mm Hg shortly before exhaustion ($P<0.01$)

During exercis at 560 mm Hg ambient pressure

The heart rate at rest was the same at 560 mm Hg as at 1 ata. At the submaximal work it was almost unchanged compared to 1 ata in three subjects and increased in three, the average difference compared to 1 ata not statistically significant ($P>0.05$) During maximal work the heart rate increased faster at 560 mm Hg, the difference after 2 minutes being 4 beats/min ($P<0.05$) The maximal heart rate was the same under the two conditions.

The arterial O saturation was 91 8 per cent at rest, decreased slightly to 88 5 per cent at the submaximal load ($P<0.05$) and decreased further to 84 5 per cent at exhaustion ($P<0.05$) The *femoralvenous O saturation* at rest did not differ significantly from that at 1 ata. At the submaximal work as well as after 1 and 2 minutes and at exhaustion at the maximal work load it was lower than at 1 ata. The difference at exhaustion was 4 1 per cent ($P<0.05$) The *femoralvenous* Po_2 was not significantly lower than that at 1 ata at rest or at the submaximal work load but both after 1 and 2 minutes at the maximal work ($P<0.01$) At exhaustion no significant difference was found ($P>0.05$) The *arterio-venous O dif*

ference at rest and at the submaximal work load did not differ significantly from that at 1 ata ($P<0.05$). At the maximal work it was 9.4 ml/l smaller after 1 minute ($P<0.05$) and 10.7 ml/l smaller at exhaustion ($P<0.01$).

The *arterial* Pco_2 did not differ significantly from that at 1 ata, neither at rest nor at the submaximal nor after 1 minute at the maximal work load ($P>0.05$). After 2 minutes at the maximal work load it was significantly lower at 560 mm Hg ($P<0.05$) but at exhaustion the difference was insignificant ($P>0.05$). The *femoralvenous* Pco_2 did not differ significantly between the two conditions at rest, at the submaximal work or during the first two minutes of the maximal work. At exhaustion however it was 8.5 mm Hg lower at 560 mm Hg ambient pressure ($P<0.05$).

The *arterial lactate concentration* did not differ significantly between 560 mm Hg and 1 ata at rest, at the submaximal work or after 1 minute at the maximal work load. After 2 minutes at the maximal work load all subjects had higher arterial lactate concentrations at 560 mm Hg and at exhaustion five of the six subjects had higher lactate concentrations, whereas one did not differ between the two conditions. The *femoralvenous lactate concentration* was not significantly different between the two conditions at rest, at the submaximal work load or after 1 minute at the maximal work. After 2 minutes and at exhaustion however all subjects had higher lactate concentrations at 560 mm Hg. The arterial and femoralvenous pyruvate concentrations did neither at rest nor during submaximal or maximal work differ from that recorded at 1 ata.

The *arterial pH* was the same at the two environmental conditions at rest, at the submaximal work load and at exhaustion ($P>0.05$). *The femoralvenous pH* was at rest as well as at the submaximal and the maximal work load the same at 560 mm Hg as at 1 ata ($P>0.05$).

The *mean pressure in the brachial artery* was the same under the two conditions both at rest, at the submaximal and at the maximal work.

The *performance time* was in all subjects shorter at 560 mm Hg than at 1 ata, the average performance time being 4.83 min as compared to 5.97 min at 1 ata.

2. *Comparison between air breathing at 630 mm Hg and 1 ata*

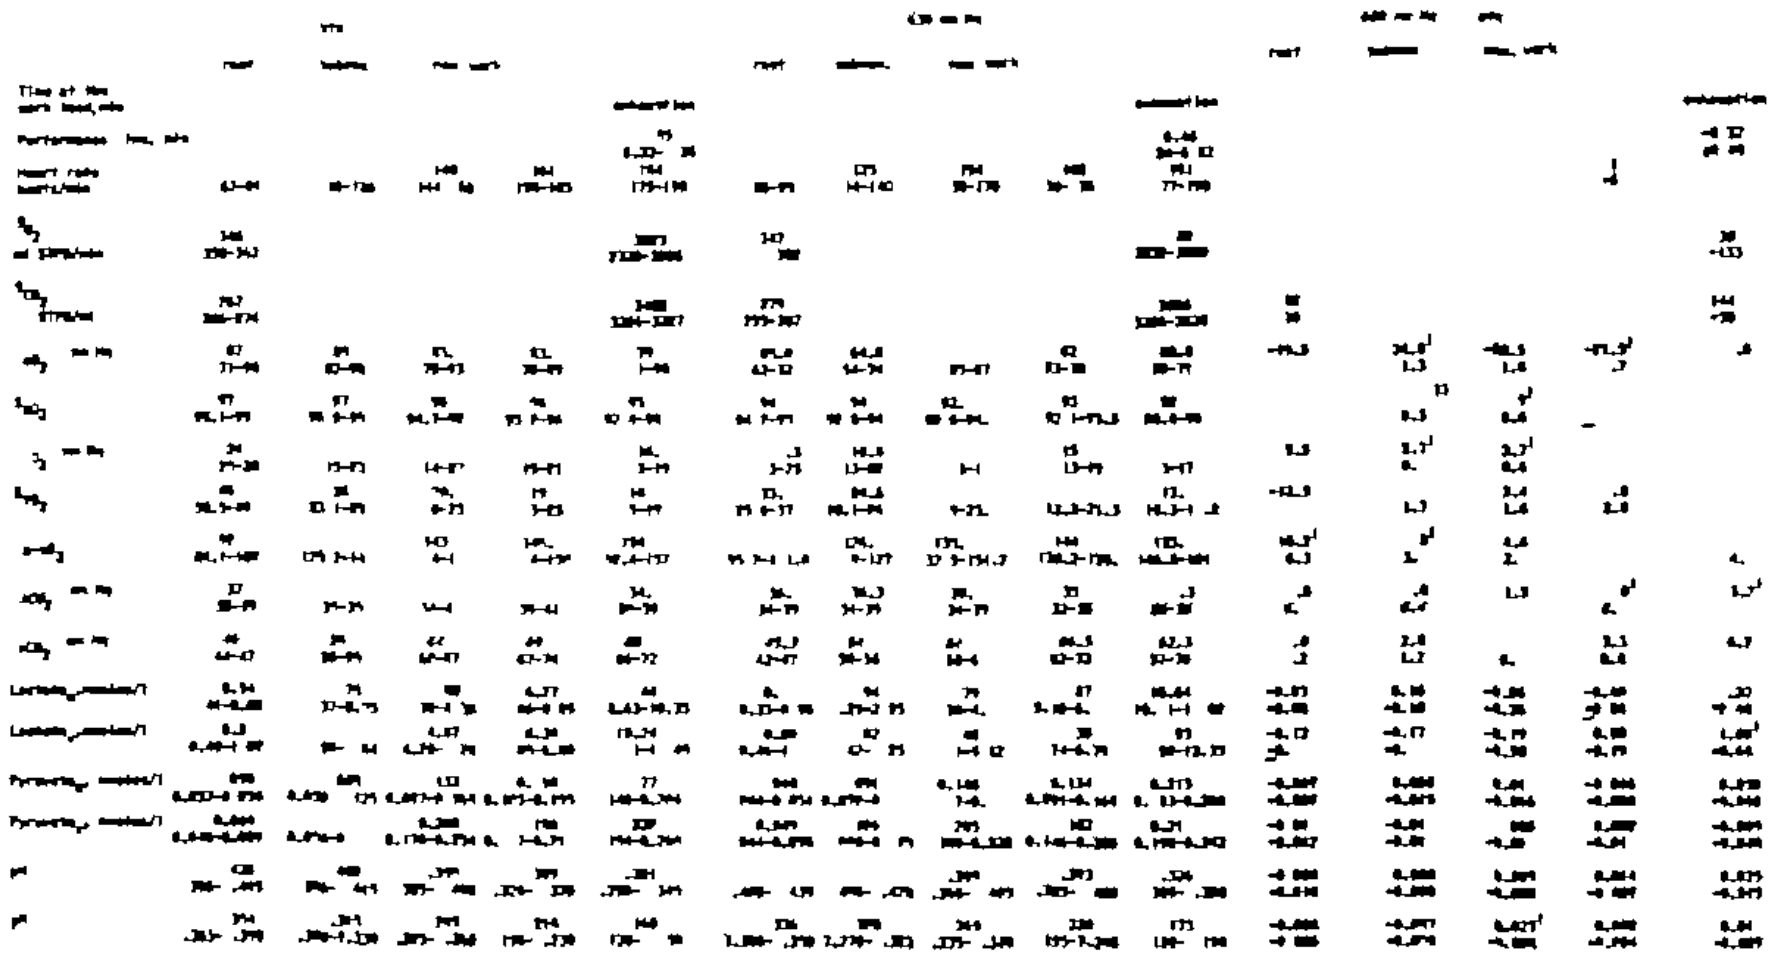
The results are summarized in Table X and Fig. 15.

1 ata

No major differences were recorded compared to corresponding values at 1 ata in the above reported experiments.

Table X. A. Data obtained t rest in the sitting position, after 5 min at the submaximal work load and after 1 and 2 min and at exhaustion at the maximal load during a breathing at 1 ata and 630 mm Hg ambient pressure. Maximal loads ranging between 1350—1700 kpm/min. Mean and range n = 4

B. Difference between values obtained t 630 mm Hg and 1 ta. Mean±standard error of the mean. n = 4 1) denotes that all individual differences are in the same direction.



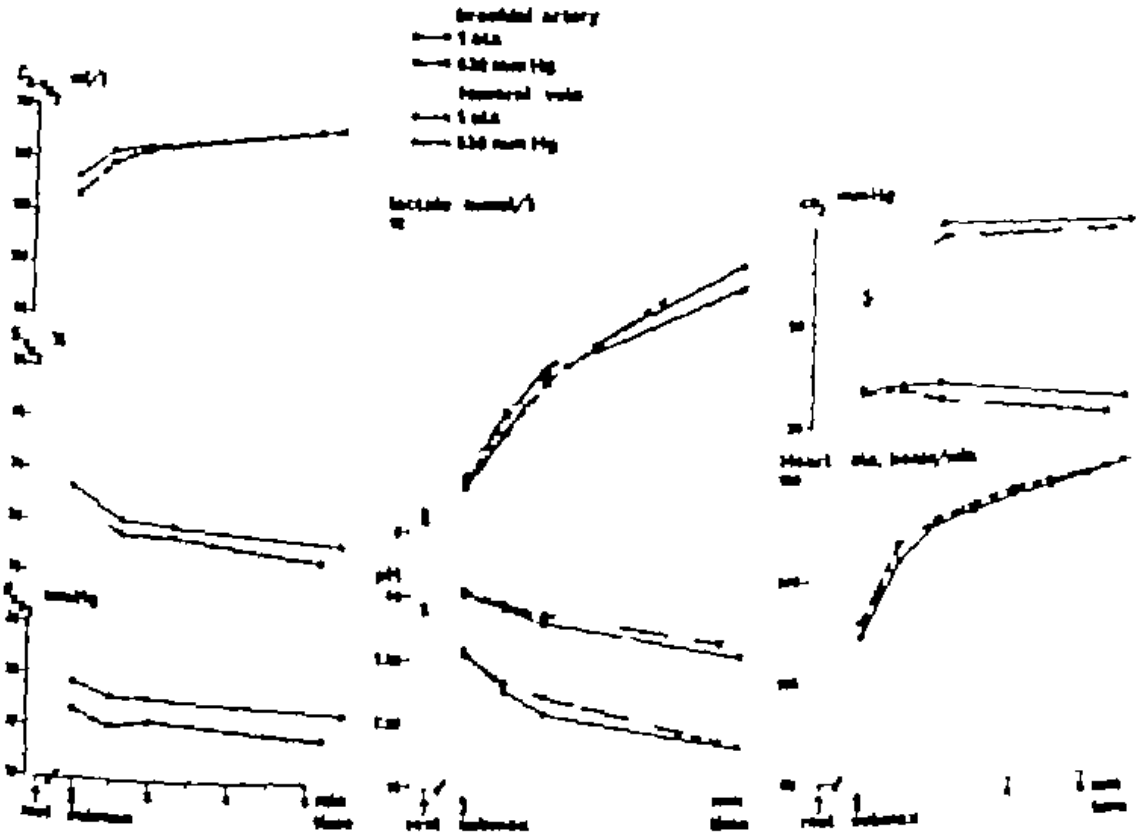


Fig. 15 Arterial-femoralvenous O_2 difference (extrac- tion, and P_{CO_2}, arterial and femoralvenous lactate concentration pH at rest, during submaximal work and after 1 and 2 min and before the end of exhaustive work. Average values (n = 4) during air breathing at 1 and 630 mm Hg ambient pressure.

Ambient pressure 630 mm Hg

The *arterial O saturation* was at rest 2.6 per cent lower than at 1 ata. Both at the submaximal work load and at exhaustion it was in all subjects lower at 630 mm Hg than at 1 ata, the average difference at exhaustion being 2.8 per cent. The *venous O saturation* was at rest lower than at 1 ata in all subjects, the average difference being 12.5 per cent. At the submaximal work no consistent difference was found, whereas at exhaustion three subjects had a lower and one an unchanged saturation at 630 mm Hg compared to at 1 ata. *The arterio-venous O_2 difference* did not differ consistently between 630 mm Hg and 1 ata neither at rest nor during submaximal work or at exhaustion.

No consistent differences in *arterial Pco* were found at rest or at the submaximal work load, whereas at the maximal work load both after 1 and 2 minutes and at exhaustion P_{CO_2} was lower at 630 mm Hg than at 1 ata in all subjects. *The femoralvenous Pco* did not either differ consistently between the two conditions at rest or at the submaximal work

load, whereas after 2 minutes and at exhaustion at the maximal work load, it was slightly lower in all subjects at 630 mm Hg than at 1 ata.

The *femoralvenous lactate concentration* did not differ between the two conditions at rest, at the submaximal work load or in the beginning of the maximal work but was at exhaustion in all subjects slightly higher at 630 mm Hg No consistent differences in *arterial* or *femoral venous pyruvate concentrations* were found.

No consistent differences in *arterial* or *femoral venous pH* were found at any time of work.

The *performance time* and the *maximal oxygen uptake* did not differ consistently between the two conditions.

Discussion

When the arterial oxygen content was decreased about 10 per cent at an ambient pressure of 560 mm Hg this was partly compensated by a more complete desaturation of the venous blood during exhaustive exercise. Hence, the O extraction from the blood was decreased to a lesser extent than the decrease in arterial O content. This is in accordance with Doll and Keul (1969).

The mentioned finding suggested that a certain decrease in arterial oxygen content should be possible without a decrease in aerobic work performance. This was confirmed in maximal exercise experiments at 630 mm Hg With a decrease in arterial O saturation of about 3 per cent the venous O saturation was decreased by the same magnitude. The arteriovenous O difference as well as the performance time to exhaustion and the maximal O uptake remained unchanged

It can be noted that under hypoxaemic conditions (560 mm Hg ambient pressure) the maximal work performance is reduced, although in no subject was the femoralvenous Po_2 as low as the so called "critical O pressure" of about 10 mm Hg (Stainsby and Otis 1964) Doll and Keul (1969) have recently reported Po_2 values in the femoral vein of about 10 mm Hg during heavy work breathing 12 7 per cent oxygen. However with 12.7 per cent oxygen in the inspiratory gas the arterial O_2 saturation was probably lower than in the present experiments. In the report by Doll and Keul nothing is stated about oxygen uptake or work performance. However the present experiments make it probable that the femoralvenous Po_2 below which the oxygen uptake is decreasing is higher than that calculated by Stainsby and Otis from experiments in dogs. The difference may however be caused by a difference in the fraction blood at the sampling site that drains active muscle tissue

Under hypoxaemic conditions the lactate concentration in the femoral-venous blood is significantly higher than under normal conditions. This is in accordance with findings reported by Keul and Doll (1969) At the same time the femoralvenous P_{CO_2} is lower during hypoxaemia and the venous pH is the same under the two conditions. This finding is valid both for the slight hypoxaemia at 630 mm Hg and the more marked hypoxaemia at 560 mm Hg This lends further support to the hypothesis that the increasing tissue acidity during exhaustive work is a limiting factor for muscle performance.

Also the arterial lactate concentration is higher during exhaustive work under hypoxaemic conditions. This is in accordance with the findings by Asmussen *et al.* (1948) although other authors have failed to show an increase in arterial lactate concentration during exhaustive work under hypoxaemic conditions (Edwards 1936 Stenberg *et al* 1966 Hansen *et al* 1967)

No difference in integrated mean pressure in the brachial artery was found between moderately hypoxaemic (at 560 mm Hg) and ordinary conditions. This is apparently not in agreement with the findings by Stenberg *et al.* (1966) However Stenberg's experiments were performed at a higher simulated altitude where probably the hyperventilation during work was more pronounced and the arterial P_{CO_2} lower (*cf* Chapter IV p 49)

Conclusions

1. A 3 per cent decrease in arterial oxygen content was found to be compensated for by a more complete oxygen extraction from the blood.
2. A more marked decrease in saturation, about 10 per cent, could only be partly compensated for and the maximal oxygen uptake decreased.
3. Thus there seems to be a margin of at least 3 per cent for lowering of the arterial oxygen content before the maximal oxygen uptake is influenced.
4. During exhaustive work under hypoxaemic conditions (Sa_{O_2}~85 per cent) the femoralvenous P_{CO_2} was lower than under normoxic conditions. The venous lactate concentration, on the other hand, was higher and the resulting venous pH at exhaustion was the same under the two conditions.
5. It was concluded that the decrease in pH could be a limiting factor for muscle performance.

CHAPTER VI

Adaptation to dynamic forearm work at decreased muscle temperature

Introductory remarks

To test the hypothesis that muscle metabolism is the limiting factor for aerobic work performance it was considered of interest to study muscle performance and oxygen extraction under conditions influencing the maximal metabolic rate In the following results of a preliminary study are reported.

The rate of enzymatic reactions usually increase with temperature up to a temperature where thermal inactivation of the enzymes occur Comparatively little is known about the optimum temperature for aerobic muscle metabolism. However Abramson *et al* (1957) found that the metabolic rate of the forearm was increased when the temperature was elevated above the normal resting level and Asmussen and Boje (1946) reported that the capacity for exhaustive leg work increased after prewarming of the active muscle Consequently it was assumed that a moderate decrease in muscle temperature of 2 3 C should reduce the maximal metabolic rate.

For the experiment to be conclusive from a metabolic point of view the temperature reduction should not interfere significantly with neuromuscular function or muscular blood flow Clarke, Hellon and Lind (1958) showed that the muscle temperature could be decreased to 27 C without a decrease in the rectified and integrated muscle action potentials at the end of an exhaustive sustained contraction. The same investigation also indicated that no major changes in muscle blood flow occurred

Hall Munoz and Fitch (1947) found the direct effect of heating of the cat gastrocnemius to be an increase in strength. Nukada and Müller (1955) reported an increased performance time for dynamic work and Nukada (1955) and Clarke *et al.* (1958) an increased performance time for sustained isometric contraction when the forearm temperature was reduced to 27 C. However Clarke *et al.* explained the findings by the assumption that during a sustained contraction, when the washout of

metabolites was impaired a decreased metabolic rate may be advantag eous.

Subjects

Four male volunteers, aged 23-27 years, were studied. Their average fore arm work capacity determined as W_{max} was 15.9 kpm/min (range 15-18 kpm/min)

Procedure

A catheter was introduced in the distal direction into a deep vein of the right forearm. The subjects performed dynamic forearm work on the hand ergometer described earlier for 5 minutes at a submaximal load correspond ing to 50 per cent of W_{max}, rested for 5 minutes, and worked until ex haustion at 150 per cent of W_{max}.

The forearm was chilled for 10-12 minutes by moist fabric packings filled with ice before the work test. For comparison exercise was performed at corresponding loads with the arm in room air. The order of the tests (warm-cold) was varied between the subjects.

Measurements

The blood temperature in the deep forearm vein was measured by a thermocouple introduced through the catheter. Blood was sampled at rest, after 5 minutes at the submaximal, and at exhaustion at the highest load for the determination of Po_2, O_2 saturation, Pco_2, pH, lactate and pyruvate concentrations.

For methodological details, see Chapter I.

Results

The results are summarized in Table XI and Fig. 16.

Room temperature

The average *temperature* in the deep forearm vein was 34.1°C at rest (range 31.6-36.0). It increased slightly to 34.8 at exhaustion (range 32.9-36.3).

The deep vein *O saturation* decreased from 44.7 per cent at rest (range 25.8-58.0) to 28.5 per cent at the lower load (range 24.3-34.3) and 28.6 per cent at exhaustion (range 22.6-35.6).

The deep vein *lactate concentration* increased from 0.88 mmoles/l (range 0.71-1.63) at rest to 2.08 mmoles/l (range 1.10-3.99) at the lower load, and 4.04 mmoles/l at exhaustion (range 3.08-4.94).

Table XI. Data obtained at rest, after 5 min at submaximal and at exhaustion at a maximal load during dynamic forearm work at room temperature and after cooling of the forearm. Mean and range. n = 4

	room temperature			cooled forearm		
	rest	load I	load II	rest	load I	load II

P_{vO_2} mm Hg	25.4 15–39	19.3 15–21	18.8 17–20	25.4 15–39	17.3 15–21	19.8 18–24
P_{vCO_2} mm Hg	40.0 35–44	48.5 45–53	59.3 46–70	35.8 30–43	45.3 41–53	50.0 46–57
$Lactate_v$ mmoles/l	0.86 0.71–1.63	2.08 1.10–3.99	4.04 3.06–4.94	0.89 0.56–1.66	2.46 0.87–4.47	3.96 2.89–6.06
$Pyruvate_v$ mmoles/l	0.076 0.055–0.109	0.078 0.057–0.099	0.107 0.078–0.141	0.055 0.035–0.070	0.092 0.078–0.109	0.112 0.094–0.127
pH	7.408 7.37–7.50	7.348 7.310–7.385	7.250 7.200–7.330	7.453 7.425–7.485	7.381 7.375–7.390	7.321 7.285–7.340

The *pyruvate concentration* was 0.076 mmoles/l at rest (range 0.055-0.105) 0.078 mmoles/l at the lower load (range 0.057-0.098) and 0.107 mmoles/l at exhaustion (range 0.078-0.141)

The *pH* was 7.408 at rest (range 7.375-7.430) 7.349 at the lower load (range 7.310-7.385) and 7.250 at exhaustion (range 7.200-7.330)

The average *performance time* to exhaustion was 290 seconds (range 209-363

Fig. 16. Differences between chilled forearm and forearm in room temperature. Values from the individual subjects of performance time at the highest load and O_2 saturation, P_{CO_2}, lactate concentration and pH in the deep vein of the active forearm at rest, at load I and at load II. n = 4

After cooling

After 10-12 minutes in ice packings, the average resting temperature in the deep forearm vein was 1·4 C lower than before cooling (range 0·7 3·0). The temperature increased moderately during exercise. The forearm vein temperature at exhaustion was 2·4 C lower than in the experiments conducted in room air (range 1·0-3·6).

At rest or at the lower work intensity no consistent difference in deep vein O_2 *saturation* was found between the cooled forearm and the forearm with ordinary temperature. However during work until exhaustion the O_2 saturation in the deep vein in all subjects decreased less after cooling than under ordinary conditions.

The *lactate concentration* did not differ consistently between the two conditions.

The *pyruvate concentration* was not consistently different after cooling compared to normal conditions at rest or at exhaustion. At the low work load however it was in all subjects slightly higher after cooling.

pH was higher after cooling in all subjects at rest in 3 subjects at the lower load and in all subjects at exhaustion.

The *performance time* to exhaustion was decreased in all subjects by cooling, the average difference being 95 seconds which corresponds to per cent.

Discussion

The experiment was not intended to be a comprehensive study of the relationship between muscle performance and muscle temperature but rather a qualitative confirmation that a decrease in maximal muscle metabolic rate directly influences maximal muscle performance.

A moderate decrease in muscle temperature, yielding a 2-3 C decrease in deep vein blood during exhaustive work, caused a 33 per cent reduction in performance time to exhaustion. At exhaustion the O saturation in the deep venous blood was higher after cooling than under normal conditions whereas the lactate concentration did not differ consistently suggesting that the most likely explanation of the decreased performance was a decreased aerobic metabolic rate.

Conclusions

1. A moderate decrease 2-3 C in muscle temperature was found to reduce the performance time for exhaustive dynamic forearm work.

2 The O_2 saturation in the deep vein at exhaustion was higher after cooling than under ordinary conditions.
3 The deep vein lactate concentration at exhaustion was the same after cooling as under ordinary conditions.
4 pH in the deep vein was higher after cooling than under ordinary condition.
5 The conclusion was drawn that the performance time was dependent on the muscle temperature and that this is due to an effect of temperature on the aerobic metabolic rate.

Part C. GENERAL DISCUSSION

1 The local blood perfusion as a limiting factor for aerobic work capacity

If the local blood flow limits the maximal oxygen uptake, variations in arterial oxygen content would directly induce changes in maximal oxygen uptake. Furthermore the altered oxygen uptake would be seen as a change in arteno-venous O difference During exhaustive forearm work the arte rio-venous O difference was not influenced by variations in arterial oxygen content between about 5 per cent below and 30 per cent above normal Since the maximal performance time was not significantly altered either it seems reasonable to conclude that the maximal oxygen uptake was not influenced Hence, the *local circulation* seems not to be a directly limiting factor for oxygen uptake (Fig 17)

The calculated Po_2 in the deep vein was at least twice as high when the arterial oxygen content was increased by oxygen breathing at 3 ata as when it was normal. This speaks against the assumption that the *oxygen diffusion* from the capillary blood to tissue is a limiting factor for oxygen uptake

If the arterial oxygen content is gradually decreased a level will be reached below which the oxygen supply to the active muscle tissue will limit aerobic work performance The magnitude of the decrease in arterial oxygen content which can be fully compensated for by a more complete oxygen extraction, seems to be somewhere between 5 and 10 per cent.

The muscle blood perfusion was not directly measured in the present study However from the arteno-venous O difference it can be calculated that at submaximal work loads a substantial increase (30 per cent) in arterial oxygen content decreased the blood flow although to a moderate degree A 20 per cent decrease in arterial O saturation from the normal

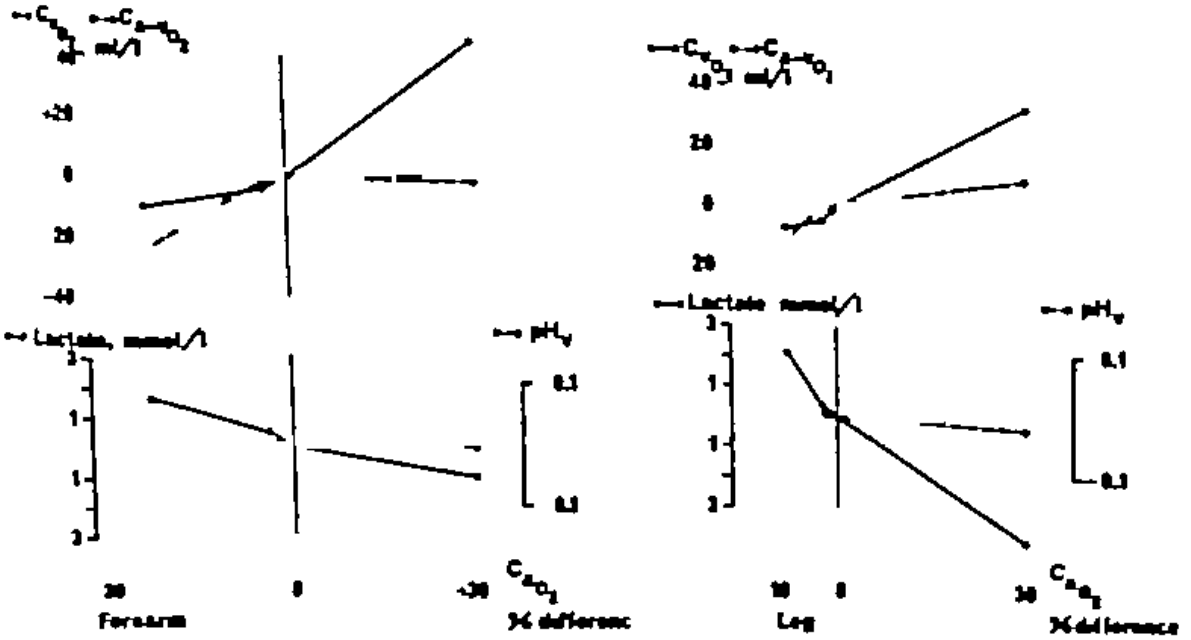

Fig 17 Left. Deviations in arterial-deep vein O_2 difference, deep vein O_2 content, lactate concentration and pH at exhaustion during dynamic forearm work from the values recorded under normoxaemic conditions as a function of changes in arterial O_2 content from normoxaemia.

Right. Deviations in arterial-femoral venous O_2 difference, femeral venous O_2 content, lactate concentration and pH at exhaustion during leg work from the values recorded under normoxaemic conditions as a function of changes in arterial O_2 content from normoxaemia.

level increased the blood flow somewhat. The direct effect of oxygen on vascular tone may partly explain the differences in blood flow (Carrier *et al* 1964) Nevertheless, factors associated with the muscle metabolism are generally supposed to be more important for the blood flow regulation. The hyperbaric oxygen experiments lend support to the hypothesis that the pyruvate concentration in muscle blood is at least one factor of importance.

During maximal exhaustive work the calculated blood flow was not influenced by changes in arterial oxygen content as evidenced by similar arterio-venous oxygen differences and similar performance times within a wide range of arterial oxygen pressures. Hence, blood flow seems not to be regulated by the local P_{O_2} under these conditions.

2. Central circulation as a limiting factor for aerobic work capacity

Work performed with large muscle groups, *e g* leg work on a cycle ergometer places a large demand on the central circulation. Under such condi-

tions central circulation could be limiting for aerobic work capacity although the local vessels permit an increased blood perfusion. In that case an increased oxygen utilizing muscle mass would not increase the maximal oxygen uptake. Findings in the literature are conflicting on this point, however Christensen and Högberg (1950) found a slightly higher maximal oxygen uptake during skiing and Åstrand and Saltin (1961) during treadmill running compared to cycling Taylor *et al* (1955) recorded a slightly larger maximal oxygen uptake during work with arms + legs than with only legs in contrast to Stenberg *et al* (1967)

When in the present study the arterial oxygen content was increased by oxygen breathing at 3 ata, subjects performing maximal work were exhausted when the cardiac output was calculated to be smaller than their maximal. Furthermore, at exhaustion, the femoralvenous oxygen saturation was much higher than during air breathing and the maximal performance time was not increased. Consequently the cardiac output seems not to limit the maximal oxygen uptake (Fig 17)

This is further supported by the observation that a small decrease in arterial oxygen content was possible without decreasing aerobic performance The margin was found to be above 3 and below 10 per cent. Probably it was not much larger than 3 per cent as the performance time was substantially reduced by a 10 per cent decrease in oxygen content. The decrease in femoralvenous saturation, 4 per cent may be regarded as the possible maximum for the margin

Regarding the cardiac output as a limiting factor for muscle oxygen uptake also the conditions at the start of heavy work must be discussed. It has been proposed by Margaria *et al* (1968) that the cardiac output will increase slower than the maximal possible oxygen utilization rate. The present findings do not support such a hypothesis, as the O_2 saturation in the femoral vein is higher after 1 minute of work than at exhaustion during maximal work with ordinary arterial oxygen content. However the present findings are not conclusive concerning the earliest phase of work, since this should have premised still earlier blood sampling

3 Muscle metabolism as a limiting factor for aerobic work capacity

The investigations concerning variations in arterial O content gave by elimination rise to the assumption that the maximal metabolic rate of the muscle under ordinary conditions in healthy young subjects is the limiting factor for aerobic work capacity In an attempt, by more direct means to find support for this conception, the effect of cooling the active muscles

during dynamic forearm work was studied A moderate decrease in forearm temperature reduced the performance time for exhaustive work substantially As, at the same time, the O_2 saturation in the deep vein was significantly higher than at ordinary temperature condition, whereas the lactate concentration in the venous blood was fairly unchanged it was concluded that the decreased performance was caused by a decrease in aerobic metabolism

4 The point of exhaustion

The point of exhaustion is settled by the contribution of several factors, among them *psychological factors* such as motivation tolerance of discomfort and pains. In the present study psychological factors may have influenced the performance time during exhaustive work to a larger or lesser degree in the individual subjects. In the group however they are probably at random. Furthermore, most volunteers took part in several experiments, and were well aquainted with the experimental situation, so minimizing the subjective influence on the point of exhaustion.

Physiological mechanisms determining the point of exhaustion may interfere with excitation, excitation-contraction coupling, the energy yielding processes or the function of the contractile elements. The effect may be due to factors such as an insufficient supply of substrate or oxygen, or it may be due to a change in the internal environment of the cell caused by metabolite accumulation.

The oxygen supply of the active muscle by blood perfusion and diffusion from blood to the muscle cell does not set the point of exhaustion This is obvious since wide variations in blood oxygen content and pressure did not influence the performance time. An exhausted substrate supply may be limiting for prolonged work but not for work of the durations in the present study (Bergström and Hultman 1966)

For many years the accumulation of lactic acid in the muscle cells has been looked upon as a main cause for muscle fatigue (Hill 1927) The present study does not lend support to the hypothesis that lactate accumulation *per se* determines the point of exhaustion, as the lactate concentration of the muscle vein blood varied under different conditions of arterial oxygenation. It is true that the lactate concentration in blood differs from that in the muscle cell during heavy exercise (Diamant *et al.* 1968) but as the conclusion in the present study rests on paired observations in the same subjects at corresponding work loads, differences in blood lactate probably reflect differences in tissue lactate.

In the experiments with varying arterial oxygen content the venous P_{CO_2} varied inversely with venous lactate concentration. As a result, the venous pH reached the same value at exhaustion within a wide range of conditions regarding arterial oxygen content during forearm work and with one exception also during leg work (Fig 17)

During leg work, breathing oxygen at 3 ata, the femoralvenous pH at exhaustion was slightly lower than under the other conditions studied. During oxygen breathing also the arterial pH was lower Furthermore, compared to air breathing the femoralvenous P_{CO_2} was substantially higher and the lactate concentration lower However during heavy work the lactate concentration in muscle tissue is higher than in blood (Diamant *et al.* 1968) whereas CO can be assumed to diffuse more readily from tissue to blood. Consequently the difference in femoralvenous pH may be explained without supposing a difference in tissue pH. Thus, although more definite conclusions should premise direct measurement in the tissue, the present study lends support to the hypothesis that the increased acidity in the muscle cell may set the point of exhaustion.

Of mechanisms by which acidity may exert its effects, the interference with the oxidative phosphorylation (Myers and Slater 1957) or processes more directly related to the contraction (Merton 1954 Bendall 1960) can be suggested from available reports in the literature.

In the cooled muscle, the point of exhaustion was reached at a higher venous pH than under ordinary conditions. This was due to a lower venous P_{CO_2} interpreted as the result of a retarded maximal aerobic metabolic rate However in contrast to the conditions during arterial hypoxaemia, an increase in lactate production did not occur Consequently a certain inhibition also of the anaerobic metabolism may have occurred. This is supported by determinations of the glycolytic flux at varying temperatures by Kohen, Kohen and Thorell (pers. comm.) On the other hand, the lower pH at exhaustion may be due to an altered pH sensitivity of any of the mechanisms underlying muscle contraction, induced by the decreased temperature. Our present knowledge of the processes leading to muscle contraction seem to be too incomplete to allow a more comprehensive explanation

5. The adaptation of oxygen transport capacity to metabolic capacity

The experiments with oxygen breathing at hyperbaric pressure indicated that the maximal oxygen uptake for the modes of exercise studied was achieved already under normal atmospheric conditions. The hypoxaemic

experiments showed that a small decrease in arterial oxygen content is possible without decreasing the oxygen uptake From the results it has been concluded that the oxygen transport *per se* does not determine the maximal oxygen uptake. However the conclusion must also be drawn that the margin between the maximal respiratory metabolic rate of the muscles and the maximal oxygen supply by local blood circulation (fore arm work experiments) as well as central circulation (leg work experiments) is small under ordinary conditions in ordinary young subjects.

It can be concluded that the capacity of the circulatory system in the ordinary subject is well adapted to maximal demands by the musculature. Findings by other authors have indicated that not either the lungs have an oxygen transport capacity which much exceeds that of the cardiovascular system (Blomqvist Jonson Jr and Saltin 1969 Freedman 1970) Thus significant correlations are found between measures of aerobic work capacity and dimensional and functional measures of the cardiovascular system and the lungs (Sjöstrand, 1953 1954 1962 Holmgren and Åstrand 1966)

Within the scope of the mentioned correlations large variations may exist, however The correlation between arterio-venous oxygen difference and performance time for dynamic forearm work (Fig 8) may indicate individual differences in relative capacity of the oxygen transport and utilization system. To judge from the experiency of this laboratory (*e g* Holmgren *et al.* 1960) as well as others (Saltin *et al.* 1968 Ekblom 1969) the earliest effect of physical training is an increased aerobic work capacity without an increase in cardiovascular dimensions. This is accomplished by a more complete oxygen extraction from the blood The phenomenon has often been ascribed to a more efficient vasoregulation but it might as well be caused by an increased capacity of the oxygen utilization system in the muscles. As a consequence, the margin for the capacity of the circulatory system in relation to the oxygen utilization system in the muscle cell should be smaller in the well-trained subject. Data are also reported in the literature, which indicate that the margin for oxygen transport by the lungs in relation to the overall oxygen transport capacity is decreased after training (Anderson and Shephard 1968)

Part D SUMMARY and CONCLUSIONS

The local circulation as a limiting factor for aerobic work performance was tested by varying the arterial oxygen content in forearm work experiments. Variations between 5 per cent below and 30 per cent above the ordinary arterial oxygen content did neither significantly influence the maximal

arteno-venous oxygen difference nor the performance time during exhaustive work. The oxygen saturation and the calculated oxygen pressure in the deep vein of the active forearm was 2 3 times higher during oxygen breathing at 3 ata than during air breathing It was concluded that neither the local blood perfusion nor the oxygen diffusion from blood to muscle cell limit the local maximum oxygen uptake.

To test if the central circulation could be a limiting factor for oxygen uptake when large muscle groups are utilized leg work was performed with varying arterial oxygen content. An increased arterial oxygen content was achieved by oxygen breathing at 3 ata. An analysis of the cardiovascular adaptation to steady state exercise at submaximal work loads during oxygen breathing at 3 ata revealed that the cardiac output is moderately reduced during oxygen breathing This was caused by a heart rate decrease, the stroke volume being unchanged. Only minor differences in pulmonary artery and brachial artery pressures were found between oxygen and air breathing Exhaustive work was performed with ordinary increased or decreased arterial oxygen content. With an increased arterial oxygen content by oxygen breathing at 3 ata, the subjects stopped because of exhaustion with a lower calculated cardiac output and a far higher femoral-venous oxygen saturation than during air breathing It was concluded that the cardiac output did not limit the maximal oxygen uptake during leg work. It was also found that it was possible to decrease the arterial oxygen content slightly without decreasing the aerobic work performance. The margin amounted to between 3 and 10 per cent, probably not much larger than 3 per cent, however

In spite of the 2-4 times higher venous oxygen pressure during oxygen breathing at 3 ata compared to air breathing, only a moderate reduction in venous lactate concentration was seen during forearm as well as during leg work. It was concluded that a high lactate production should not be taken as evidence for lack of molecular oxygen in the muscle tissue. It may however be taken as further evidence, that the capacity of the aerobic metabolism limits the oxygen uptake of a muscle.

In spite of varying venous P_{CO_2} and lactate concentration, the point of exhaustion seems to be reached at approximately the same venous pH under the different conditions. The finding was considered to support the hypothesis that the increased acidity in the muscle cell in healthy young subjects at work periodes of up to 10 minutes, sets the limit for its function.

The maximal rate of muscle metabolism as the limiting factor for aerobic work performance was supported by experiments with dynamic forearm work after cooling A ? 3 C decrease in muscle temperature, as evidenced

from measurement in the deep vein blood decreased the performance time for exhaustive work 33 per cent. The deep vein blood was at exhaustion less desaturated in the cooled arm than under ordinary conditions, whereas no difference in deep vein lactate concentration was found It was concluded that the decreased performance was caused mainly by a decrease of the aerobic metabolic rate

The final conclusion from work experiments with varying arterial oxygen content and muscle temperature is that oxygen transport by the blood circulation does not under ordinary conditions limit the aerobic work capacity However the different links in the transport and utilization systems for oxygen seem to be adapted to each other with rather small margins under ordinary conditions in healthy young subjects.

Acknowledgements

Professor Torgny Sjöstrand introduced me to basic scientific thinking and methodology. For his never ceasing interest and for the wealth of suggestions and encouragement received at every phase of this investigation I wish to express my sincere thanks.

The study had not been possible without collaborators. To all members of the laboratory staff who have assisted me in this work, no one mentioned no one forgotten, I owe a great debt of gratitude.

The data from the experiments should still have been lying on my shelves without the excellent secretarial help by Mrs. Gertrud Grönfarb. To her goes my warm thanks.

Finally I am much obliged to all those, who volunteered to be subjects in the investigation.

The study has been supported by grants from Karolinska Institutet (Reservationsanslaget) and the Swedish Sports Federation (Riksidrottsförbundets poliklinikkommitté).

1 Gas measurements.

a. Gas phase

I	= inspired gas
E	= expired gas
A	= alveolar gas
T	= tidal gas
D	= dead space gas
STPD	= standard temperature, pressure, dry (0 C., 760 mm Hg)
BTPS	= body temperature, pressure, saturated with water vapor
ATPS	= ambient temperature, pressure, saturated with water vapor
V	= volume, ml or l
V	= flow ml or l/min.
P	= pressure, mm Hg
F	= fractional concentration
R	= respiratory exchange ratio

b. Blood phase

a	= arterial
v	= venous
v	= mixed venous
S	= saturation, %

2. Other symbols used.

VC	= vital capacity l BTPS
FRC	= functional residual capacity l BTPS
RV	= residual volume, l BTPS
TLC	= total lung capacity l BTPS
$FEV_{1.0}$	= forced expiratory volume in 1 sec., l BTPS
$FEV_{\%}$	= $FEV_{1.0}$ in per cent of VC
MVV_{40}	= maximal voluntary ventilation at 40 breaths/min. l BTPS/min.
MVV_{free}	= maximal voluntary ventilation at a free respiratory rate, l BTPS/min.
$D_{L_{CO}}$	= pulmonary diffusing capacity for carbon monoxide, ml min.$^{-1}$ mm Hg^{-1}

V_E/V_{O_2} = ventilatory equivalent for oxygen $\frac{\text{l, BTPS/min.}}{\text{l, STPD/min.}}$

StB = standard bicarbonate, mEq/l

Sup = the patient in the supine position

Sitt = the patient sitting on a bicycle ergometer

Heart rhythm S = sinus

F = atrial fibrillation

BSA = body surface area according to DuBois formula, m^2

W_{150} = physical working capacity at heart rate 150 cpm, kpm/min.

W_{max} = "maximal working intensity kpm/min.

THb = total amount of hemoglobin, g

BV = blood volume, l

HV = heart volume, ml

3 Hemodynamic symbols

$\dot{Q}$ = cardiac output, l/min.

$\dot{Q}_s$ = cardiac output in systemic circulation, l/min.

$\dot{Q}$ = cardiac output in pulmonary circulation, l/min.

SV = stroke volume, ml

ΔSV = the relative change in stroke volume =

$$= \frac{SV_{sup} - SV_{sitt}}{SV_{sup}} \times 100 \ \%$$

HR = heart rate, cpm

AVD = arterio-venous oxygen difference, ml/l

AVD_P = AVD of the pulmonary circulation, ml/l

P = pressure, mm Hg

S = systolic

D = diastolic

M = mean

Ao = aorta

LV = left ventricle

PCV = pulmonary capillary venous

PA = pulmonary artery

RV = right ventricle

ed = end diastolic

RA = right atrium

SVC = superior vena cava

SVR = systemic vascular resistance = $\frac{P_{Ao}}{\dot{Q}_s}$ mm Hg/(l/min.)

PVR = pulmonary vascular resistance = $\frac{\bar{P}_{PA} - \bar{P}_{PCV}}{\dot{Q}_p}$ mm Hg /(l/min.)

4. Statistical symbols

p	=	probability
$\bar{x}$	=	mean value
d	=	difference
r	=	coefficient of correlation
SD	=	standard deviation
SD_d	=	standard deviation of the differences
C	=	coefficient of variation $= \frac{SD_d \cdot 100}{\sqrt{2} \cdot \bar{x}}$ %

Acknowledgements

The present investigation was carried out during the years 1967—1970 at the Department of Clinical Physiology Thoracic Clinics, Karolinska Sjukhuset. Clinical investigations, particularly of this type of study are the result of teamwork and many persons have been involved and have made it possible for me to realize this work. I therefore want to express my sincere gratitude to

My chief, Assistant Professor Alf Holmgren, who initiated me to the investigation and who has continously given me support and valuable advice.

My former chief Assistant Professor Bengt Jonsson, for introducing me to clinical physiology and for his interest and stimulating discussions.

Professor Torgny Sjöstrand, for his valuable and never failing support.

Assistant Professor Sture Bevegård, for stimulating and constructive criticism.

All my colleagues and the whole staff of the laboratory who have so generously helped me.

Miss Valborg Hagsand who skilfully made all the drawings, diagrams and assisted in some of the calculations.

Mrs Lena Kagger for her kind and excellent secretarial help

Dr R. H. T Edwards for correcting the English.

Finally I wish to thank my wife for her understanding and encouraging support throughout the whole study

This investigation was supported by grants from the Swedish National Association against Heart and Chest Diseases and Karolinska Institutet.

Introduction

The ability to perform exercise of short duration (5—10 min.) with large muscle groups is mainly determined by the oxygen transport capacity which is normally limited by circulatory factors.

In young and old individuals cardiac output increases as a linear function of oxygen uptake during submaximal work loads in both the supine and sitting positions (for references see Bevegård and Shephard 1967) The slope for the regression line of cardiac output on oxygen uptake varies little between normal individuals, while the intercept may vary markedly The average intercept for normal young subjects in the supine position is defined in the following to mean normokinetic circulation. If the level of the regression line is lower than normal, the circulation is said to be hypokinetic. In this state the oxygen transport is delivered with a smaller cardiac output than in the normokinetic state. In the presence of a hypokinetic circulation the peripheral oxygen utilization increases. In old subjects (above 60 years) the circulation has been described to be more hypokinetic than in young subjects (Strandell 1964) although the slope of the line is the same as in young individuals.

The level of the regression line is correlated with the size of the stroke volume in relation to the volume of the cardiovascular system. The circulation becomes hypokinetic on changing from the supine to the sitting position in normal young and old subjects. The slope of the regression line is, however unchanged. The cause of a lower stroke volume and cardiac output in the upright position is the lower filling energy available for the ventricles because of the gravitational shift of blood distribution (Sjöstrand 1941 Lagerlöf et al. 1951 Bevegård et al. 1960 Mc Gregor et al. 1961 Strandell 1964)

Patients with heart disease usually have a lower stroke volume in the supine position in relation to circulatory dimensions, such as heart volume and blood volume, than normal subjects (Sjöstrand 1953 Wade and Bishop 1962, Marshall and Shephard 1968) leading to a hypokinetic circulation. Several authors have reported a low cardiac output in patients with mitral stenosis (Eliasch et al. 1952, Holmgren et al. 1958 Bishop and Wade 1963, Granath 1965) Ikkos et al. (1966) described patients with tight pulmonary stenosis with a hypokinetic circulation at rest and during work.

Clinical experience suggests that patients with heart disease are less orthostatic than normal subjects. Several studies have dealt with the orthostatic response to change from the supine to the head up position at rest (McMichel and Sharpey Schafer 1944, Eliasch et al. 1961 Abelmann and Fareeduddin 1967 Lorentsen et al. 1967) Donald et al (1953) found a slight fall in cardiac output in patients

with heart disease, but there were marked interindividual variations. Lorentsen et al. (1967) reported a fall in cardiac output and stroke volume in most cases without, or with only a slight degree of heart failure. Patients in left ventricular failure showed the same response. Two patients with tricuspid valvular insufficiency even displayed an increase in cardiac output and stroke volume after changing from the supine to the sitting position.

Abelmann et al. (1969) found in 33 patients with heart disease that hemodynamic abnormalities characteristic of heart failure were associated with increased orthostatic tolerance, measured as the response of heart rate and diastolic blood pressure to change in posture. There are very few circulatory studies reported in cardiac patients during exercise in the upright position.

Epstein et al. (1969) pointed out that exhausting levels of exercise could be achieved in the upright position by patients with cardiac disease, with no evidence of pulmonary oedema appearing. They reported further that in patients with impaired cardiac function bicycle exercise in the supine position imposed a greater circulatory stress than when the same exercise was performed in the sitting position. This was manifested by a faster heart rate and higher systemic arterial pressures in the supine position. Details of the individual patients were not, however, given. Most clinical investigations on cardiac patients are performed in the supine position and these do not necessarily reflect the situation of the central circulation during ordinary daily activity.

The principal aim of this investigation was to study how changes in body position affect the central circulation, ventilation, alveolar gas exchange and pulmonary diffusing capacity at rest and during exercise in three different groups of patients. The *first group* was selected to represent low pulmonary blood flow (i.e. hypokinetic circulation) and high pulmonary vascular pressures, with an almost normal resistance in the pulmonary vascular bed, as found in patients with moderately tight mitral stenosis. The *second group* was selected to represent low blood flow and low pressure levels in the pulmonary circulation, as in patients with tight pulmonary stenosis. The *third group* represented high blood flow in the pulmonary circulation with almost normal pulmonary pressures, as found in patients with atrial septal defect.

Some of the patients in this last group were also investigated about 1 year after operation to study how decrease in pulmonary blood flow would affect ventilation, alveolar gas exchange and pulmonary diffusing capacity.

Methods

The week before heart catheterization the patients were thoroughly investigated with physical and x-ray examination, and determination of working capacity in the sitting and supine positions with simultaneous recording of a six lead electrocardiogram (Holmgren and Strandell 1961)

Exercise tests were performed on an electrically braked bicycle ergometer (Holmgren and Mattson 1954) with the work load increasing stepwise at the end of every six minutes. Using the approximately linear relationship between heart rate and work load working capacity at a fixed heart rate (150 beats/min) was obtained by inter or extra polation. The exercise test was usually stopped before the pulse rate had reached 150—170 beats/min. because of symptoms. This was particularly so in the patients with mitral stenosis, and in some patients with pulmonary stenosis and ASD Therefore, the concept "maximal work intensity introduced by Strandell (1964) has been used to express the working capacity

Maximal work intensity (W_{max}) was taken to be the highest work load that the patient could sustain for six minutes, with an increase proportional to the completed part of the period at the next higher load when symptoms prevented the patients from continuing the work for six minutes. An interval of 1—2 days elapsed between work tests in the sitting and supine positions

Total amount of hemoglobin (THb) was determined with the alveolar CO method of Sjöstrand (Sjöstrand 1948) with a reproducibility of 3 7 % (Normal values see Holmgren 1969)

Blood volume (BV) was calculated from THb and hemoglobin concentration of finger blood, and correction was made for the difference between body hematocrit and peripheral vessel hematocrit by a factor 0 91 (Ekelund 1965)

Heart volume (HV) was determined in the prone position according to the method described by Larsson and Kjellberg (1948) except that the angulation of the x ray tube was omitted.

Heart catheterization was performed as described earlier from this laboratory (Bevegård et al. 1960) A no 9 double lumen catheter was introduced percutaneously into an ante-cubital vein and passed into the pulmonary artery A teflon catheter was introduced in the right brachial artery by the percutaneous technique and advanced into the left ventricle through the aortic valve with the aid of a metal guide wire. In patients with mitral stenosis another teflon catheter was introduced percutaneously so that its tip was in the right atrium. In patients with atrial septal defect such a teflon catheter was placed with its tip in the superior vena cava. Blood sampled from this catheter was taken to represent approximately mixed venous blood from the systemic circulation (Dexter 1956)

Blood pressures were recorded with electrical transducers* the zero pressure reference level in the supine position being the midthoracic level and in the sitting position at the level of the sternal insertion of the fourth rib The tip of the double lumen catheter was moved to a wedge position in the lower part of the right lung and the tip of the teflon catheter in the right atrium was placed to be at approximately the same level, i.e. the sternal insertion of the fourth rib in supine position. During exercise in the sitting position the patient breathed through a fixed mouthpiece to maintain an approximately constant horizontal reference level.

Cardiac output (Q) was measured by the direct Fick method. Expired gas was collected in Douglas bags and was analysed for oxygen and carbon dioxide by the Scholander method (Scholander 1947) Gas volumes were measured with a spirometer and converted to BTPS *Blood samples* were drawn simultaneously from the pulmonary artery and the aorta for one minute in the middle of the gas collection period, which was 6 minutes at rest and 2—3 minutes during work.

Blood gas analysis Oxygen saturation and hemoglobin concentration were determined spectrophotometrically (Holmgren and Pernow 1959)

Partial pressure of carbon dioxide (P_{aCO_2}) was measured with a Severinghaus P_{CO_2} electrode (Severinghaus and Bradley 1958) and of oxygen (P_{aO_2}) with a Clark microcathode electrode in a stainless steel cuvette kept at 37 ° C. The reproducibility of measurement of P_{aCO_2} and P_{aO_2} was 0 5 and 1.2 % respectively

Standard bicarbonate base excess and *pH* were determined according to Siggaard Andersen et al. (1960)

Diffusing capacity of the lungs for CO (D_{LCO})

The methodology techniques and errors involved have been reported earlier (Holmgren 1965 Freyschuss and Holmgren 1965) therefore only brief information on methodology is included F_{O_2} and F_{CO_2} were analysed with the Scholander technique Gas volumes were measured with a spirometer *Carbon monoxide in the gas phase* was analysed with a hopcalite CO-meter as described by Linderholm and Sjöstrand (1956) *Carbon monoxide content* in blood was determined by the method described by Linderholm, Sjöstrand and Söderström (1956) The carbon monoxide capacity of blood was taken to equal 1 34 times the hemoglobin concentration. The reproducibility for measuring D_{LCO} during exercise in this laboratory is 7 2 %

Static spirometry with determination of total lung capacity and its subdivisions, was performed with helium dilution method in a closed system (Holmgren 1954) Normal values were those given by Grimby and Söderholm (1963)

Dynamic spirometry including forced expiratory volume in 1 sec., $FEV_{1.0}$ this volume related to the vital capacity FEV% maximal voluntary ventilation at a fixed respiratory rate of 40 breaths/min. and at free rate, MVV_{40} and MVV_{free} were

) Model EMT 34 and 35 Elema Schönander, Stockholm, Sweden.

determined with a Bernstein spirometer* Predicted normal values were those given by Berglund et al. (1963)

To study the reproducibility of the spirometric data over a longer period, the investigation was repeated with 2—120 days interval in the mitral stenosis group The coefficient of variation of the difference between the two measurements was for vital capacity 1.8 % for functional residual capacity 11 4 % for total lung capacity 4 3 % and for maximal voluntary ventilation 7 3 %

Calculations

The physiological dead space was calculated using the Bohr formula and assuming the alveolar carbon dioxide tension to be equal to the arterial carbon dioxide tension (Enghoff 1938, Riley and Cournand 1949)

Alveolar oxygen tension and alveolar ventilation were obtained from the alveolar gas equation (Riley et al. 1946) The *diffusing capacity* was measured by means of the steady state CO-method, calculated as the quotient between the carbon monoxide uptake (V_{CO}) and the driving pressure alveolar CO-tension minus mean capillary CO-tension ($P_{ACO}-\bar{P}_{cCO}$) The V_{CO} was calculated according to Filley et al. (1954) Assuming the same dead space for CO and CO_2, the P_{ACO} was calculated by means of the Bohr equation. The $\bar{P}_{CO}$ was calculated according to Lindeholm (1957)

All calculations concerning THb, alveolar gas exchange and D_{LCO} were performed by an IBM 7044 computer

Statistical methods

Statistical calculations were mainly performed according to Dahlberg (1940) and Snedecor (1959) Significance of differences between mean values were tested by Student s t-test. Differences between regression lines were tested with covariance analyses according to Hald (1960) The following probability (p) levels of significance were used.

$p<0.001$	=	highly significant	(***)
$0.001<p<0.01$	=	significant	(**)
$0.01<p<0.05$	=	probably significant	(*)

) Kifa, Stockholm, Sweden

V

Patients

Anthropometric and functional data are given in tables I—VI

The patients selected for this study were referred to the Thoracic Clinics for preoperative evaluation and/or surgical treatment. There were 38 patients in all, with ages ranging from 16 to 60 According to diagnosis they were placed into three groups.

MITRAL STENOSIS (MS) (Tables I—II)

This group consisted of 9 patients with mitral stenosis. There were 7 women and 2 men with a mean age of 50 years(range 42—59) The diagnosis was made on basis of typical physical findings, x ray examination, heart catheterization and later confirmed by surgery One patient (no 1) had an additional aortic stenosis of mild degree (peak systolic left ventricular aortic pressure difference of 20 mm Hg) With this exception and another patient (no 2) with very mild mitral regurgitation seen on angiocardiography all had pure mitral stenosis. Four of the patients had a history of rheumatic fever and two had been operated upon with commissurotomy 10 and 2 years respectively before the investigation, but had signs of restenosis (nos. 2 and 4)

According to the classification of the New York Heart Association (1955) (N Y H.A.) the patients belonged to functional group II—III and none had clinical signs of right heart failure. Four patients were in atrial fibrillation and the others in sinus rhythm. All except one (no 6) were digitalized and case no. 7 also had quinidine.

Heart volume (HV) in the prone position averaged 1108 ml (range 915—1320) All cases had moderately enlarged heart volumes in relation to the total amount of hemoglobin.

Total amount of hemoglobin (THb) was on an average 588 g SD ± 38 or 9 1 g/ kg body weight SD ± 0 6 These mean values do not deviate significantly from the normal range in the laboratory nor do they differ from those by Granath (1963)

Blood volume (BV) averaged 5.8 l SD ± 0 7 or 77.9 ml/ kg body weight SD ± 12 0 which is within the normal range.

Exercise test All patients stopped working because of dyspnea and general fatigue and these symptoms were more marked in the supine exercise test. The mean value of maximal working capacity (W_{max}) in the whole group was 468 kpm/min. (range 300—667) in the sitting and 383 kpm/min. (range 250—667) in the supine position. This mean postural difference of 85 kpm/min. was significant ($p < 0.01$) The mean value for the women was 414 kpm/min. in the sitting and

1	F	400	142	4	300	132	6	333	300
2	F	500	142	6	300	144	6	300	300
3	F	400	162	6	400	160	6	400	400
4	S	600	130	1	400	102	2	433	267
5	S	600	155	1.5	300	138	4	450	250
6	S	600	158	4	400	142	6	533	400
7	S	900	140	1	600	140	6	650	600
8	S	600	156	1 5	400	148	2	450	267
9	F	800	160	2	800	166	2	667	667

312 kpm/min. in the supine position. These values are low compared to those of normal subjects (Astrand 1956, Holmgren et al. 1957)

Stat spirometry The vital capacity and functional residual capacity were significantly decreased on an average to 84 % and 86 % respectively of the predicted normal value. The total lung capacity was decreased to 90 % of the normal value. The residual volume was not significantly changed from the normal value. The functional residual capacity and total lung capacity were diminished by the same degree and therefore the quotient between them was normal. Due to the diminished TLC the RV/TLC was slightly higher than normal (112 % $p<0.05$)

Dynamic spirometry The forced expiratory volume in 1 sec. ($FEV_{1.0}$) was significantly decreased to 82 % but the forced expiratory volume in relation to the

vital capacity (FEV %) was normal. The maximal voluntary ventilation at a fixed respiratory rate of 40 breaths/min (MVV_{40}) and at free rate (MVV_{free}) were decreased to 73 % and 69 % respectively of normal mean value

Comment None of the patients had a history of chronic bronchitis, and the spirometric data agree with what has been described earlier in mitral stenosis, i.e. a decreased vital capacity but a normal residual volume.

There were no signs of obstructive lung disease and the low maximal breathing capacity correlates with the decreased vital capacity following restrictive lung changes.

PULMONARY STENOSIS (PS) (Tables III—IV)

Five patients with congenital valvular stenosis were included in this group There were two men and three women with ages ranging from 36 to 60 years with a mean of 47 years. The diagnosis was based on physical findings, x ray examination with cineangiography of the right ventricle and heart catheterization. In 4 patients the diagnosis was verified at operation. None of the patients had other valvular disease or septal defect. The patients belonged to functional group I to II according to N.Y.H.A., and none had clinical signs of right ventricular failure. All were in sinus rhythm.

Heart volume (HV) varied between 590 and 1140 ml and was in all within the normal range in relation to total hemoglobin.

Total amount of hemoglobin (THb) varied between 390 g and 1011 g. In relation to body weight it was somewhat small in the three females, ranging from 6.3 to 6 9 g/kg body weight. For the males it was normal in one (10.0 g/kg body weight) and a little increased in one (12 6 g/kg)

Blood volume (BV) was as an average 3 7 l (range 3.0—4 6) or 55 0 ml/kg body weight for the women. This value is small compared to the normal range For the two men it was somewhat small in one (66 ml/kg body weight) and normal in the other

Exercise test All patients stopped the exercise test because of general fatigue and tiredness in the legs. Two patients (nos. 1 and 4) also complained of dyspnea. There was no main difference in symptoms between sitting and supine exercise. W_{150} was the same in both body positions in the three patients in whom it was possible to calculate. For the whole group W_{max} averaged 490 kpm/min. in the sitting and 460 kpm/min. in the supine position. The mean maximal heart rate observed in each individual was 155 beats/min. (range 140—170) and 153 beats/min. (range 124—180) in the sitting and supine positions respectively

Static spirometry The vital capacity functional residual capacity residual volume and total lung capacity were in all within the normal range.

Dynamic spirometry One patient (no 5) had a low $FEV_{1.0}$ and FEV % (73 and 78 % of predicted normal value) that could indicate an obstructive lung disease although he had no history of bronchitis or asthma. He had a normal MVV_{40}, however The other four patients were within the normal range.

ATRIAL SEPTAL DEFECT (ASD) (Tables V—VI)

The group with increased pulmonary blood flow was selected only to include patients with atrial septal defects and/or abnormal venous return. The group consisted of 24 patients, 14 women and 10 men with a mean age of 40 years (range 16—57) The diagnosis was based on physical findings, x ray examination, heart catheterization and in most patients the diagnosis was verified at operation. Two patients had an atrial septal defect of primum type, but none of these had signs of mitral insufficiency All the others had a defect of the secundum type and some of these also had partial anomalous pulmonary venous drainage.

The patients all belonged to functional group I—II according to the N.Y.H.A., i.e none had any symptoms at rest, and during ordinary physical activity some had symptoms dominated by dyspnea. None had clinical signs of heart failure. Two patients were in atrial fibrillation and the rest were in sinus rhythm.

) Heart volume in standing position.

Heart volume (HV) averaged 1222 ml (range 630—1840). In all patients, except one (no 17) it was abnormally increased in relation to total hemoglobin.

Total amount of hemoglobin (THb) was determined in 21 patients, 9 men and 12 women. The mean value for both sexes was within the variation of normal individuals. In female patients it was 567 g SD±93 corresponding to 8.7 g/kg body weight and in males it amounted to 715 g SD±111 or 10.5 g/kg body weight.

Blood volume (BV) was on an average 4.9 1 SD±0 7 corresponding to 75 ml/kg body weight for women and 5 6 1 SD±1.0 or 85 ml/kg body weight for men, and not significantly changed from the normal values.

Exercise tests in the sitting position was performed in 23 patients. Three of these

patients had no symptom or discomfort during the test and these three all worked to a pulse rate of 160 beats/min. One of these patients was 16 years old and the other two were over 40 years old.

The dominating symptom during the test was dyspnea in 12 patients (55 %) Tiredness of the legs was noticed in 6 (27 %) and general fatigue in 7 patients (32 %)

In 15 patients W_{150} could be calculated, according to the method described, in both the sitting and supine positions. The mean W_{150} in the sitting position was 592 kpm/min. (range 400—806) and in the supine position 617 kpm/min (range 413—850) The postural difference of 25 kpm/min. was not significant.

Static spirometry The vital capacity was below 2 SD of the mean normal value in 45 % of the patients. On an average the vital capacity was significantly reduced, being 85 % of the predicted normal mean value. Functional residual capacity and residual volume were normal both in absolute values and in relation to the total lung capacity

Dynamic spirometry The forced expiratory volume in 1 sec. ($FEV_{1.0}$) was significantly decreased to 85 % but the FEV % was normal and none of the patients fell outside 2 SD of the normal mean value The maximal voluntary ventilation at a fixed respiratory rate of 40 breaths/min. and at a free rate were significantly decreased to 76 % and 79 % respectively of the predicted normal values.

Comments No patients had signs of obstructive lung disease. The slight decrease of the vital capacity with 15 % fits well with the large material of Siltanen (1968) who found a 18 % decrease of the VC in patients with ASD The decrease in VC was not related to the pulmonary blood flow or to the age. Siltanen found in a postoperative follow-up study that significant improvement of VC correlated best with changes in heart volume, but there was generally no relation to the flow and pressure in the lung circulation. In the present study the group with abnormally small VC had a mean heart volume in the supine position that was 205 ml larger than that in the group with a normal VC, although the difference was not statistically significant.

VI

Procedures

MITRAL STENOSIS (MS)

All catheterizations were performed in the morning and the patients had only a light meal 2 hours before the investigation. Approximately 15 minutes after the catheters had been introduced, blood pressures (including the pressure difference across the mitral valve) and cardiac output were measured at rest in the supine position. Five of the patients were then studied during exercise in the supine position (nos 1 and 3 on two loads, the others on one load only). The highest work load during heart catheterization was on an average 85 % of W_{max} performed some days earlier in the supine position. After 30—45 minutes rest the patients were investigated on the bicycle in the sitting position. Pressures and flow were measured after 3—4 min. rest, and during the 4th—6th min. at work on the same loads as in the supine position. The other four patients were studied in the same way in the sitting position before the exercise in the supine position. Also in these cases the time interval between exercise periods in the two positions was 30—45 min. and at the end of a similar period all patients were studied once more supine at rest. There were no complications of exercise either in the supine or sitting postures and no patient complained of dizziness or fainted while sitting at rest on the bicycle. The total amount of blood that was withdrawn from the patient during the heart catheterization varied between 110 and 150 ml.

In all patients the diffusing capacity was measured 2 or 3 days after the heart catheterization also in the morning. The same work loads were chosen in both body positions as during the heart catheterization.

PULMONARY STENOSIS (PS)

The heart catheterizations were all done in the morning and performed as described earlier. In all patients the central pressures and the cardiac output were first measured at rest in the supine position. Two patients were then moved over to a bicycle and were studied at rest and during exercise in the sitting position first and then during work in the supine position. The other three patients exercised in the supine position first and then in the sitting position (case no. 4 and 5 on two loads, the others on one load). The time interval between the two investigations was 30 to 45 min. In three patients the diffusing capacity was determined some days after the heart catheterization, and the same work loads being used for the two investigations

ATRIAL SEPTAL DEFECT (ASD)

In seventeen patients the heart catheterizations were performed at the Thoracic Clinics as described. Cardiac output and central pressures were measured first at rest and then during work in the supine position. Seven of these patients were also investigated in the sitting position at the same work load as that used in the supine position. In two patients exercise in the sitting position was performed before the work in the supine position, in the other five the order was reversed. Seven patients had been investigated preoperatively in other hospitals. In these only diffusing capacity and alveolar gas exchange were studied in the supine and sitting positions.

VII

Postural effects on the central circulation and respiration at rest and during exercise in patients with MITRAL STENOSIS

Nine patients with MS, described in Chapter V were selected to represent low blood flow and high pressure in the pulmonary vascular bed but with normal vascular resistance to flow. The patients had moderately tight stenosis with a valve area of 1.2—2.3 cm^2 calculated according to Gorlin and Gorlin (1951).

RESULTS

Hemodynamic data

Mean values during exercise are given in Table VII.

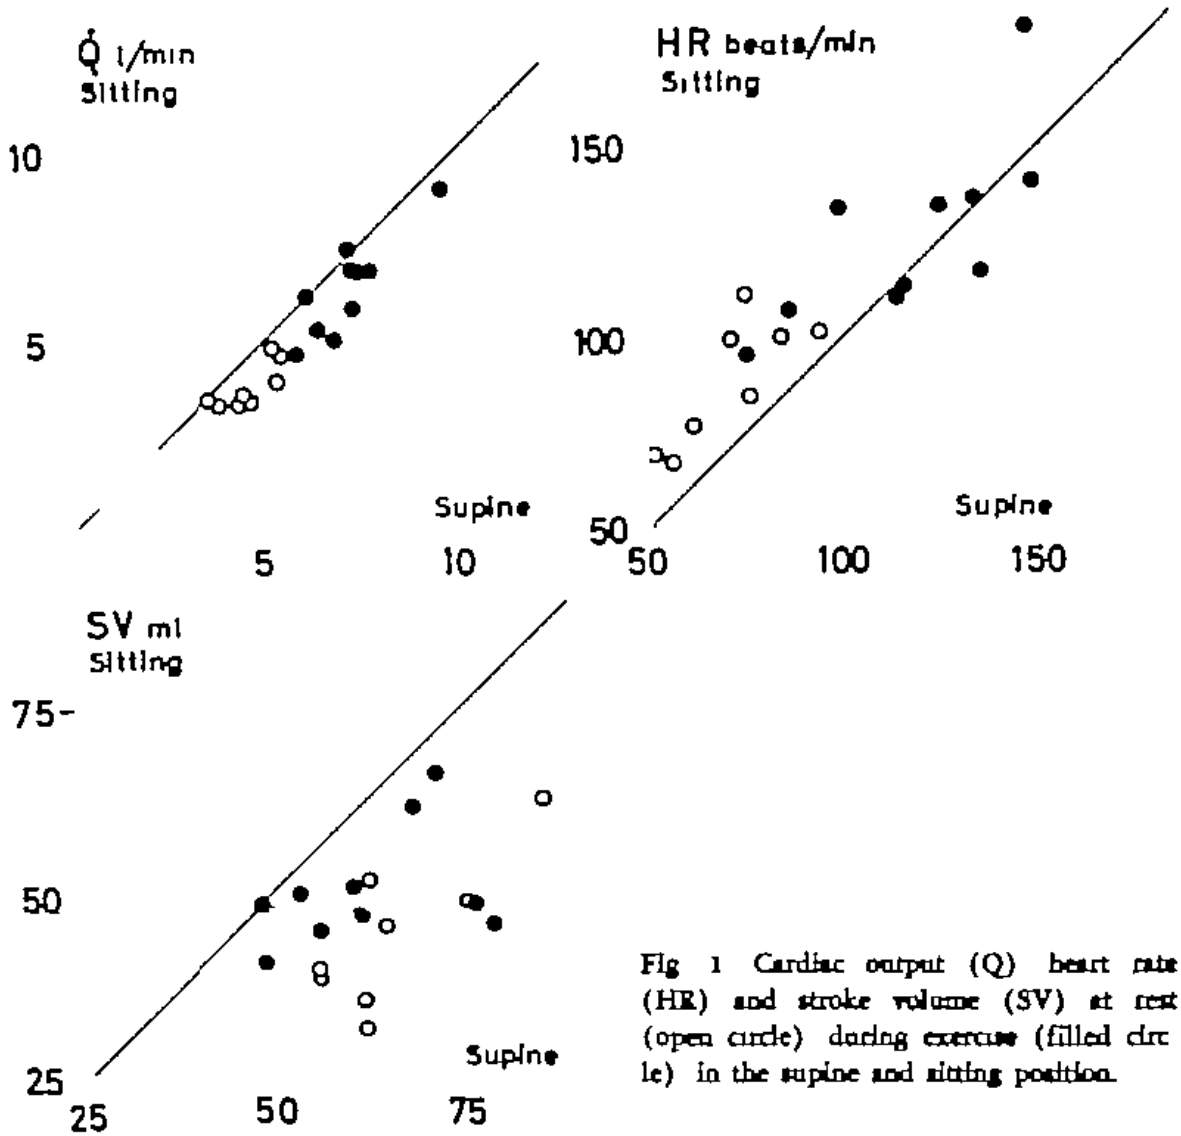
Oxygen uptake ($\dot{V}_{O_2}$) in the supine position during the first determination was 23 % higher than that found during basal conditions prior to the investigation. The basal metabolic rate as an average was 6 % higher than the predicted normal value (Harris and Benedict 1919). High oxygen consumption during catheterization is a normal finding and this increase corresponds well with that found in other investigations (Bevegård et al. 1960). There was no difference between the first and second determination at rest in the supine position. In the sitting position the oxygen uptake at rest was significantly 10 % higher than in the supine position. During exercise the oxygen uptake averaged 3.5 times the resting value and there was no postural difference.

Mechanical efficiency averaged 20 % in both positions. This is within the normal variation for the work loads studied (Åstrand 1960).

Heart rate (HR) at rest in the supine position was 73 beats/min. (range 52—95) and there was no difference between duplicate determinations in the supine position. In the sitting position the heart rate was 17 beats/min. greater ($p<0.001$) than when supine. Patients with atrial fibrillation responded in the same way as patients in sinus rhythm. During work the heart rate averaged 120 beats/min. (range 76—150) in the supine position and there was no significant postural difference (Fig. 1).

Arterial oxygen saturation ($S_{a_{O_2}}$) was normal at rest averaging 97.0 % (range 94—100) *and 97.2 % (range 95—100) in the supine and sitting positions* respectively. $S_{a_{O_2}}$ was mainly unchanged during exercise, although it decreased to 90 % in one patient. The mean $S_{a_{O_2}}$ was 1.9 % higher in the sitting than in the supine position although the difference was not significant.

Mixed venous oxygen saturation ($S\bar{v}_{O_2}$) averaged 69.3 % (range 66—75) at rest in the supine position and decreased in the upright position to 59.3 % (range



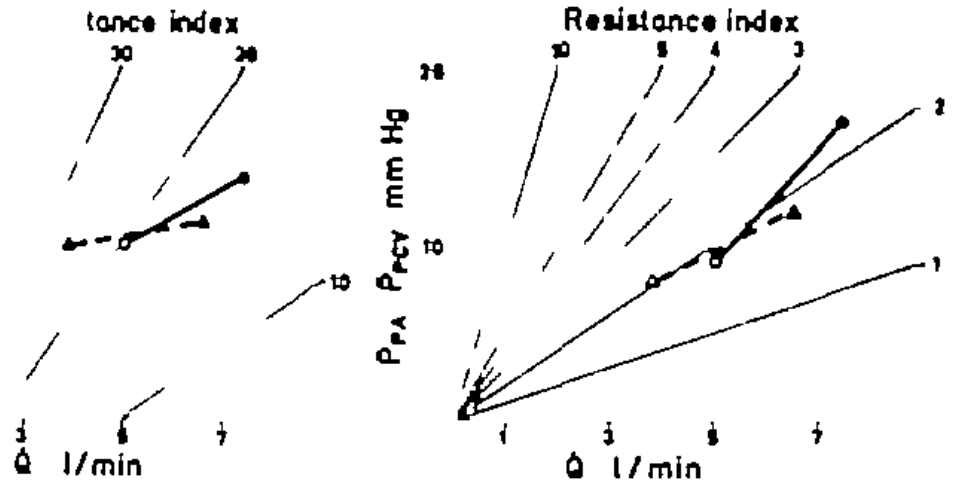


Fig 1 Cardiac output (Q) heart rate (HR) and stroke volume (SV) at rest (open circle) during exercise (filled circle) in the supine and sitting position.

52—65) During exercise the $S\bar{v}_{O_2}$ decreased markedly in both positions. The mean values were 33 3 % (range 24—46) and 29 1 % (range 19—42) in the supine and sitting positions respectively This difference of 4.2 % was not significant.

The oxygen capacity of the blood from the aorta and the pulmonary artery increased from rest to exercise in both body positions. There was also a significantly higher value in the sitting position than in the supine position both at rest and during exercise. The largest difference in capacity was thus between supine rest (mean 178 ml/l) and sitting exercise (mean 194 ml/l)

Arterio venous oxygen difference (AVD) at rest, supine, averaged 51 5 ml/l (range 43—61) and was unchanged at the second determination at rest. All patients in atrial fibrillation were two standard deviations above the mean normal AVD when plotted against $\dot{V}_{O_2}$ All except one of the patients with sinus rhythm were within the normal range (Fig. 2) At rest in the sitting position the AVD was significantly higher than in the supine position in all cases and averaged 73 4 ml/l (range 61—89) During work there were significantly higher values in the

ean pressure (P_{Ao}) in relation to cardiac output (Q) The mean pressure the pulmonary ascular bed (P_{PA}—P_{PCV}) in relation to cardiac output (Q) es are isoresistance lines. Symbols as in fig. 2

old individuals (Bevegård et al 1960 Strandell 1964) The regression rdiac output on oxygen uptake in this material was $Q = 3.70 + 0.0041$ ie supine position and $\dot{Q} = 2.50 + 0.0045\ \dot{V}_{O_2}$ in the sitting position ** and 0.96*** respectively)

volume (SV) at rest in the supine position was 67 ml (range 52—92) reased, not significantly to 63 ml (range 49—86) during exercise. When ition was changed at rest to sitting the stroke volume decreased to 44 ml 32—63) and this fall of 34 % from the supine resting value was highly icant. On exercise in the sitting position the stroke volume increased to 51 ange 41—66) The difference in stroke volume between supine and sitting ions was still significant and averaged 19 % less in the sitting position 1)

mean pressure (P_{Ao}) was within the normal range at rest and during n the supine position. Pressures averaged 101 mm Hg and 121 mm Hg changing to the sitting position did not alter the mean pressure at cise in the sitting position the aortic pressure did not increase to the during exercise when supine. The postural difference of 14 mm Hg ificant ($p < 0.05$)

resistance (SVR) at rest, increased significantly on transition sitting position. During exercise there was no positional l quite di jing from rest to exercise in supine is the same at rest as during y during exercise ($p < 0.001$)

levated in most of the patients mm Hg (range 13—30) This

1.2 l/min (24 %) is highly significant ($p<0.001$). During work the cardiac output increased to 7.4 l/min. (range 5.9—9.7) in the supine position and to 6.6 l/min. (range 4.7—9.0) in the sitting position. The postural difference during exercise between the cardiac outputs averaged 0.8 l/min. (11 %, $p<0.001$) (Fig. 1).

There was no significant difference between the slope of the two regression lines for cardiac output on oxygen uptake (Fig. 3). In both body positions, however, the slope was significantly less steep and the level lower than compared to normal

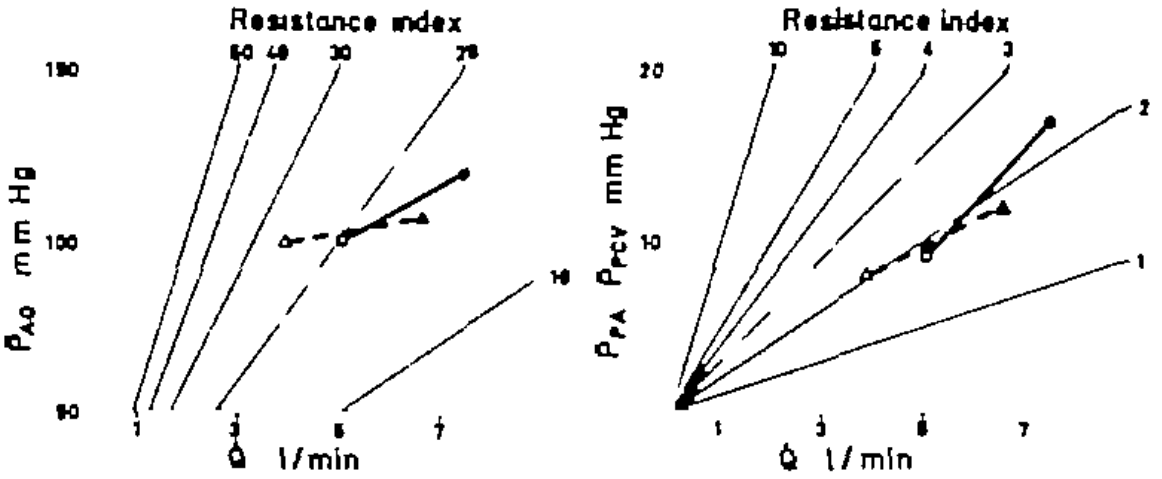

Fig. 4. Aortic mean pressure (P_{Ao}) in relation to cardiac output (Q). The mean pressure difference across the pulmonary vascular bed (P_A—P_{PCV}) in relation to cardiac output ($\dot{Q}$). The oblique lines are isoresistance lines. Symbols as in fig. 2.

young and old individuals (Bevegård et al. 1960, Strandell 1964). The regression line for cardiac output on oxygen uptake in this material was $Q = 3.70 + 0.0041\ \dot{V}_{O_2}$ in the supine position and $\dot{Q} = 2.50 + 0.0045\ \dot{V}_{O_2}$ in the sitting position ($r = 0.94^{***}$ and 0.96^{***} respectively).

Stroke volume (SV) at rest in the supine position was 67 ml (range 52—92) and decreased, not significantly to 63 ml (range 49—86) during exercise. When the position was changed at rest to sitting the stroke volume decreased to 44 ml (range 32—63) and this fall of 34 % from the supine resting value was highly significant. On exercise in the sitting position the stroke volume increased to 51 ml (range 41—66). The difference in stroke volume between supine and sitting positions was still significant and averaged 19 % less in the sitting position (Fig. 1).

Aortic mean pressure ($\bar{P}_{Ao}$) was within the normal range at rest and during exercise in the supine position. Pressures averaged 101 mm Hg and 121 mm Hg respectively; changing to the sitting position did not alter the mean pressure at rest. On exercise in the sitting position the aortic pressure did not increase to the same extent as during exercise when supine. The postural difference of 14 mm Hg was probably significant ($p < 0.05$).

Peripheral vascular resistance (SVR) at rest, increased significantly on transition from the supine to the sitting position. During exercise there was no positional difference. SVR responded quite differently on changing from rest to exercise in the two body positions. In the supine position SVR was the same at rest as during work but, when sitting, the resistance fell significantly during exercise ($p < 0.001$) (Fig. 4).

Pulmonary capillary venous pressure ($\bar{P}_{PCV}$) was elevated in most of the patients at rest in the supine position to a mean value of 20 mm Hg (range 13—30). This

1.2 l/min (24) is highly significant ($p<0.001$) During work the cardiac output increased to 7 4 l/min. (range 5 9—9 7) in the supine position and to 6.6 l/min. (range 4 7—9 0) in the sitting position. The postural difference during exercise between the cardiac outputs averaged 0.8 l/min. (11 % $p<0.001$) (Fig. 1)

There was no significant difference between the slope of the two regression lines for cardiac output on oxygen uptake (Fig. 3) In both body positions, however the slope was significantly *less steep and the level lower than compared to normal*

exercise in the supine position and was 20 mm Hg lower during work with the same intensity in the sitting position (Fig. 5)

Pulmonary vascular resistance (PVR) was almost normal in all cases at rest and averaged 1.8 units (0.7—3.1). It did not change significantly during exercise. The PVR was not different in the upright compared to the supine position either at rest or during exercise (Fig. 4)

The pressure in the right atrium increased from 5.7 mm Hg (range 4—8) at rest to 11.0 mm Hg (range 8—15) during exercise in the supine position. In the sitting position the pressure also increased during exercise but to a less degree, from 0.5 mm Hg (range —2—6) at rest to 2.3 mm Hg (range —2—9) during exercise.

Effect of previous exercise on the central circulation at rest

All patients were studied twice at rest in the recumbent position, before and after the first exercise study. There were no significant differences in the hemodynamic variables between the two determinations at rest. The oxygen capacity was slightly smaller (2.3 ml/l SD±2.8, $p<0.05$) during the second resting period. Strandell (1964) also found this when studying old normal subjects. He also found a decrease in stroke volume and slightly lower filling pressures for both ventricles during the second period. The effect of previous exercise on the circulation during repeated exercise has been reported by Widimsky et al. (1963) and they found a small decrease in the pulmonary artery pressure during the second period. Burkart et al. (1967) found a significant difference between repeated exercise determinations in the same body posture. In order to diminish this effect when comparing the behaviour of the patients in different positions, four of the patients were studied first in the sitting and then in the recumbent position, in the other five the order was reversed.

Respiratory data obtained during the circulatory study

Mean values during exercise are given in Table VII

Total ventilation ($\dot{V}$) increased at rest on changing from the supine to the upright position by 1.0 l/min. ($p<0.01$) and this was due to a higher metabolic rate when sitting as the ventilatory equivalent for oxygen did not change. Also during exercise the ventilation increased linearly with increasing oxygen uptake, and there was no difference between the two body positions. The mean values in the supine position were 27.8 and 28.4 l/l oxygen uptake at rest and during exercise respectively and in the sitting position 28.8 and 29.0 l/l respectively. The regression line ($\dot{V}_E = 0.031\ \dot{V}_{O_2} - 0.87$) was slightly steeper than in normal subjects (Fig. 25 in General discussion). The higher ventilation at rest in the sitting position was achieved with a higher respiratory rate but no change of the tidal volume. During exercise the ventilation increased both by a higher respiratory rate and a

difference lower in the sitting position than in supine, as was found during catheterization.

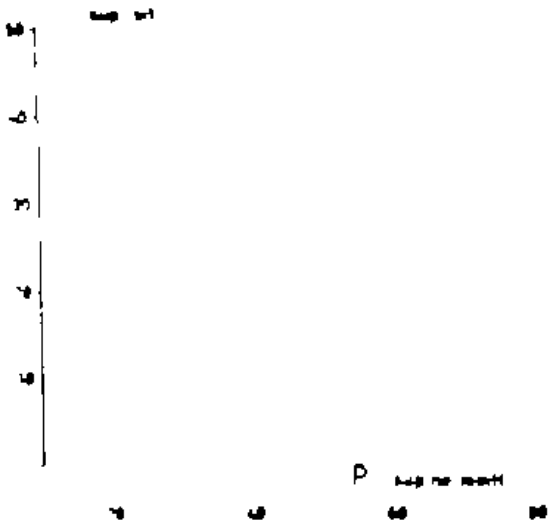
Pulmonary diffusing capacity (D_{LCO}) was measured during exercise at the same level of $\dot{V}_{O_2}$ in both body positions. In the supine position D_{LCO} averaged 20.1 ml min.$^{-1}$ mm Hg^{-1} (range 15.2—25.1) and in the sitting position the mean value for D_{LCO} was 22.0 ml min.$^{-1}$ mm Hg^{-1} (range 12.9—28.6). The difference of 1.9 ml min.$^{-1}$ mm Hg^{-1} between the two body positions was not significant (Fig. 6). In both body positions, however, the D_{LCO} was significantly lower than the predicted normal value for the patient. The mean observed D_{LCO} of the group was 24 % lower than the predicted value (Holmgren 1965). Only 2 patients, however, fell below two standard deviations of the normal regression line. In two patients D_{LCO} was determined on two work loads in both body positions (nos. 1 and 3). The difference of D_{LCO} between the two loads ranged between 1.4 to 2.8 ml min.$^{-1}$ mm Hg^{-1} which is within the reproducibility of the method (Holmgren 1965).

COMMENTS

The aim was to determine and analyse postural effects on circulation, ventilation and gas exchange in patients with increased pressures in all parts of the pulmonary vascular bed and low pulmonary blood flow. Patients with mitral stenosis without significant increase in the resistance of the pulmonary vascular bed were selected for the study. The material, although small, corresponds rather well with that in the pre- and postoperative study by Granath (1965) concerning the severity of stenosis, without highly increased pulmonary vascular resistance or signs of right heart failure.

Patients with right heart failure tolerate the upright position well and usually do not show any drop in cardiac output and stroke volume on postural change at rest (Taquini et al. 1961, Rapaport et al. 1966 and Lorentsen et al. 1967). This increased tolerance to the effect of gravitation contrasts to the reaction in normals. The difference probably depends on several factors secondary to the abnormal circulation. Increased plasma volume in combination with increased venous tone (Follow and Mellander 1964, Wood 1965) both counteract the blood shift, and thus *the filling energy for the ventricles is maintained. Peripheral oedema seen* in patients with heart failure increases tissue pressure around the vessels and this mechanism may also decrease the venous distensibility.

In patients with heart disease without failure the reaction to gravitational stress is reported to be similar to that found in normal subjects. This has, however, only been studied at rest and usually on tilting from recumbent to 45° feet down. Cardus et al. (1958) found in patients with mitral valve disease, on tilting to an angle of 40° from the horizontal, a fall of the pressures in the pulmonary vessels, but small changes in cardiac output. Most of their cases had moderate to markedly *increase in pulmonary vascular resistance (>4 units) and thus they were at a*



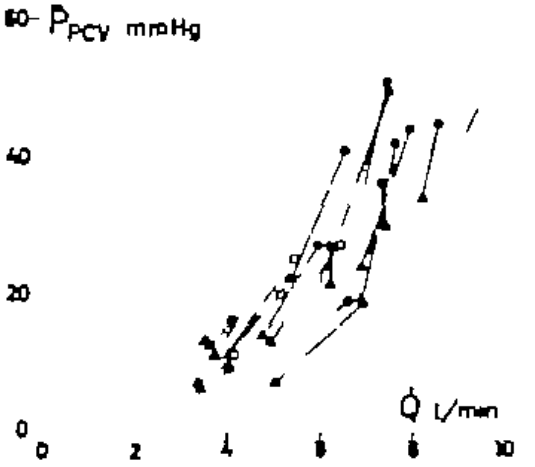


Fig. 7 Relative postural diff rence in stroke olume (ΔSV) calculated as difference be tween stroke volume in the supine and stroke volume in the sitting position in per cent f stroke olume in the supine position, in relation to the supine pulmonary artery mean pressure (P_{PA}) at rest (open circle) and during exercise (filled circle) in pa tients with mitral stenosis (r=0.85 *)

more advanced stage of the disease than the patients in this study Two patients with normal hemodynamics showed a considerable drop in pulmonary artery and PCV pressure as well as in cardiac output. Eliasch et al (1961) who compared recumbent and feet down tilted (45 —60°) patients with mitral disease found a small decrease in pulmonary vascular pressures but a more marked fall in stroke volume except in 2 patients with signs of right heart failure who did not change the pressure and flow on tilting.

The postural difference in blood flow was also demonstrated in this study On transition from supine to sitting position cardiac output fell 1 2 l/min., although the oxygen uptake was higher in the sitting position. The oxygen transport was thus maintained by an increased oxygen extraction In the sitting position the arteriovenous oxygen difference was on an average 73 ml/l corresponding to an oxygen saturation in the pulmonary artery of 59 % The stroke volume fell 34 % on an average, a value which agrees with the decrease found in normal individuals (Bevegård et al 1960) To compensate for this fall in stroke volume in an attempt to maintain cardiac output, the heart rate increases, which has special significance in patients with mitral valve obstruction Shortening of the diastolic filling time is probably one reason for the decreasing stroke volume during supine exercise seen in patients with tight mitral stenosis. If the increased heart rate alone in sitting were the main factor causing an impaired diastolic filling and the fall in stroke volume one would not expect the left atrial mean pressure (measured as PCV pressure) to drop markedly In the present study it decreased at rest from a mean of 20 mm Hg in the supine to a mean of 9 mm Hg in the sitting position.

On transition from rest to work in the sitting position the stroke volume in reased an average of 16 but was, however still significantly lower than that during exercise in the supine position. The postural difference in stroke volume during xercise varied widely between the patients. There was a correlation between the relative decrease in stroke volume on changing posture, and the left atrial and the pulmonary artery pressure levels in the supine position (Fig 7) The higher

Fig. 8. Relationship between PCV pressure ($\bar{P}_{PCV}$) and cardiac output (Q). Symbols are as in fig. 2. Lines connect values i the supine and sitting positions of indi idual patients.

the pulmonary artery and PCV pressure, the smaller was the difference in stroke volume between the sitting and supine positions. This could partly be explained on hydrodynamic grounds. The mitral valve obstruction forms a resistance to flow where the driving pressure is related to the second power of flow (Gorlin and Gorlin 1951). If it is assumed that the intra-thoracic pressure is approximately unchanged by body position, the PCV pressure may be used as an indicator of the driving pressure for the flow through the mitral valve. From the second power pressure-flow relationship it is obvious that tight and moderately tight obstructions result in large changes in driving pressure for a given change in flow (Fig. 8, 9).

When intravascular pressures are measured, and especially when comparing observations in different body positions, the zero reference level is critical, as long as absolute values are discussed, but not so when pressure differences are compared. The distending or transmural pressure also depends on the surrounding

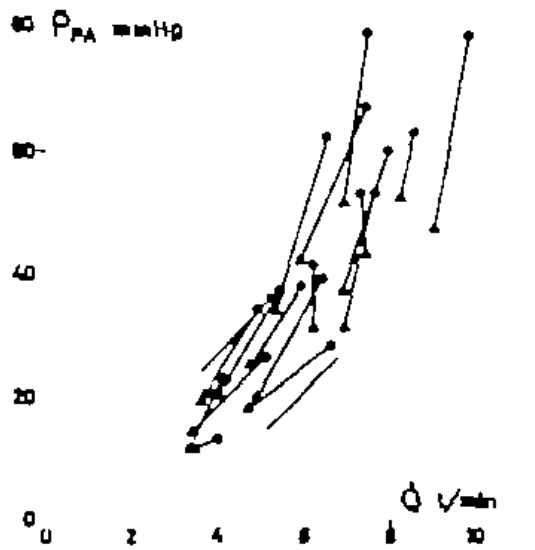

Fig. 9. Pulmonary artery mean pressure ($\bar{P}_{PA}$) in relation to cardiac output ($\dot{Q}$). Symbols as in fig. 2.

tissue pressure. In the normal lungs this latter pressure is negative when referred to atmospheric pressure and might also be changed when changing body position Such a change might introduce a bias in the pressure recordings in the sitting position but will probably only amount to a few millimeters of Hg (Cardus et al. 1958 Mead and Gaensler 1959) As such a systematic error would be relatively less at higher pressure levels it is improbable that this would explain the lower pressure when sitting observed here. Fig 5 (bottom, left) shows on the contrary that the difference between the pulmonary arterial pressure in the supine and sitting positions increases the greater the arterial pressure in the former position.

If there are no marked vessel changes in the pulmonary vascular bed the lung blood volume is to some extent correlated to the pulmonary venous pressure (Sar noff and Berglund 1952, Lindsey and Guyton 1959 Yu et al. 1967 Wilhelmsen 1968) and although the central blood volume was not measured, it could thus be presumed to be increased in the stage of the disease that all of the patients belonged to The importance of the lung blood volume and the displacement of blood from the lungs to the periphery for the filling of the left ventricle has been shown in normal subjects (Sjöstrand 1953) A change in lung blood volume also affects the vascular pressure. But if all lung vessels are perfused in the sitting position, then increasing vascular pressure will make the vessels less and less distensible and give small volume changes for given pressure changes (Borst et al. 1956) This partly explains the observation that the patients with high pulmonary artery and PCV pressures had great falls in pressure and showed less decrease in stroke volume, and thus had relatively smaller lung blood volume displacement and could keep up enough potential filling energy for the left ventricle.

Abelmann et al. (1969) who studied the tolerance to orthostatic stress at rest in normals and patients with cardio-vascular disease, found that elevation of ventri cular filling pressure was the prime determinant to increased tolerance to upright position, as they called the "heart failure response They also found that the toler ance increased with age. In this study the relative decrease in stroke volume was negatively correlated with the right atrial pressure in recumbent position (Fig. 10) Decreased distensibility of the capacitance vessels with increasing filling pressure of the right ventricle would explain this resistance to hydrostatic blood shifts.

In normal subjects and in patients with mitral stenosis with almost normal hemo-dynamics the pulmonary vascular resistance increases on tilting body position at rest (Lagerlöf et al. 1951) The patients in this study all had normal or almost normal pulmonary vascular resistance and thus had probably not developed marked structural changes in the pulmonary vessels. In the sitting position when the pul monary arteri mean pressure is above the hydrostatic pressure from top of the lung to the reference level (about 15 mm Hg) all vessels are supposed to be perfused and then pressure and flow are nearly linearly related to each other and changes in pulmonary vascular resistance are small (West 1965) This would fit well with the findings in this study where the pulmonary vascular resistance was unaltered by

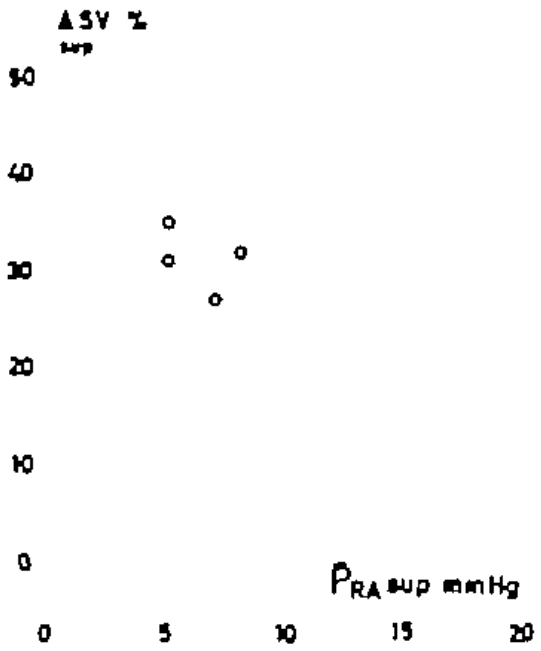

Fig. 10 Relative postural difference in stroke volume (ΔSV) in relation to supine right atrial mean pressure ($\bar{P}_{RA}$) Symbols as in fig. 1 (r=0.68)

changes in body position and the mean pressure in the pulmonary artery at rest in sitting averaged 17 mm Hg.

Topographical inequalities in the relationship between perfusion and ventilation in sitting normal individuals alter the physiological dead space (Riley et al. 1959) as a result of an increase in alveolar dead space in the sitting position because of underperfusion of pulmonary capillaries in the upper zones of the lung. Further support for this was given by observations from Mattson and Carlens (1955) and Malmberg (1966) Larson and Severinghaus (1962) however, could not confirm this The patients with mitral stenosis did not change the dead space when the position was altered either at rest or during work. This would further support the idea that the whole lung was evenly perfused also in the sitting position (Dollery and West 1960 Daly et al. 1964)

The alveolar arterial oxygen tension difference was mainly within the normal range when the age was taken into account (Vale 1967 Scherrer and Büchler 1967) and was not altered significantly by change of posture at rest. During exercise it increased significantly only in the supine position. In normal individuals $P_{(A-a)O_2}$ does not change significantly from rest to low intensity work (Hesser and Matell 1965 Vale 1967) some increase is seen at high oxygen uptakes (Holmgren and Linderholm 1958) but it increases greatly with the magnitude of the G-vector in the long axis of the body (Barr 1963) An increase in $P_{(A-a)O_2}$ could be due to three different mechanisms, either separately or in combination. These are the true right to-left shunts, the shunt component due to an unequal distribution of blood flow and ventilation within the lung and thirdly the diffusion components in the lungs. The two first components constitute about half each of the $P_{(A-a)O_2}$ in normal subjects (Mellemgaard 1966) It is not possible to separate these two factors in this study because the patients were breathing room air only Driscoll et al (1963)

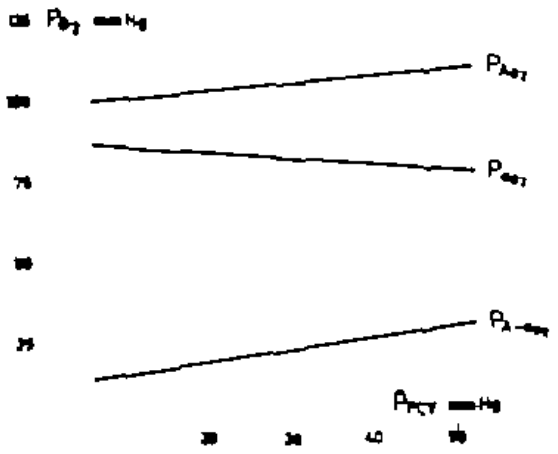

Fig. 11 Alveolar oxygen tension ($P_{A_{O_2}}$) arterial oxygen tension ($P_{a_{O_2}}$) and the alveolar-arterial oxygen tension difference ($P_{A-a_{O_2}}$) in relation to the PCV pressure (P_{PCV}) $P_{A_{O_2}}$ $r=0.46$ $P_{a_{O_2}}$ $r=0.24$, $P_{A-a_{O_2}}$ $r=0.52$ * $n=46$)

noted that the arterial oxygen desaturation at rest in mitral stenosis improved more significantly with mild exercise than with the breathing of 100 per cent oxygen *This was best explained by an improvement in ventilation perfusion balance in the* lung during mild exercise.

The mean value for the arterial oxygen pressure was the same at rest and during exercise in the supine position in this material but was greater in the sitting position. No significant correlation was found between the arterial oxygen tension and the PCV pressure in both body positions at rest and during work. The $P_{(A-a)_{O_2}}$ was, however highly correlated with the PCV pressure ($r=0.52$ $p<0.001$) (Fig. 11) This would probably best be explained by regional transudation of fluid, creating disturbances in the ventilation-perfusion balance. Guyton and Lindsey (1959) found in dogs that the ratio of wet to dry weight of the lung was propor *tional to the increase of left atrial pressure above 24 mm Hg.*

The D_{LCO} during exercise was somewhat low but mainly within the normal variation. As for normal lungs this would only give a negligible gradient for oxygen both at rest and during work (Linderholm 1959 Turino et al. 1959 Driscoll et al. 1963) Increased pulmonary capillary blood volume tends to counteract the effect of reduction in the membrane component of the D_{LCO}, so that D_{LCO} is often normal in patients with mitral valve disease (Hamer 1965) There was no positional difference in D_{LCO}, suggesting that the pulmonary capillary blood volume was unaffected by position in these patients.

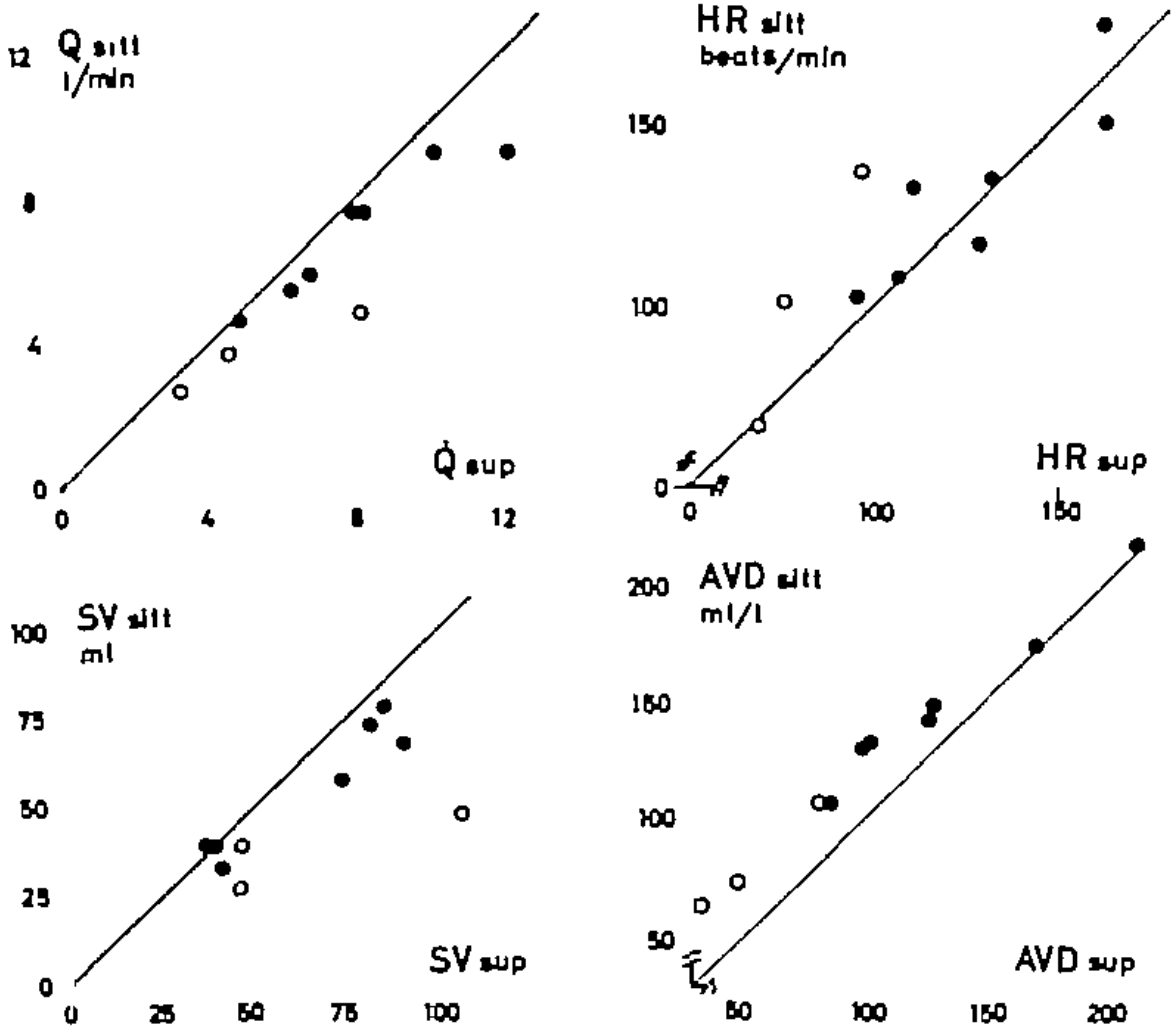
VIII

Postural effects on the central circulation and respiration at rest and during exercise in patients with PULMONARY STENOSIS

This patient group was selected to represent low blood flow and low pressure levels in the pulmonary circulation. Observations were made in five subjects of whom four fulfilled these criteria and had a tight valvular stenosis with a valve area calculated according to Gorlin and Gorlin (1951) of 0.35 cm^2 (range 0.20—0.50). In one patient (no. 3) the degree of stenosis was moderate (area 1.20 cm^2).

RESULTS

Hemodynamic data



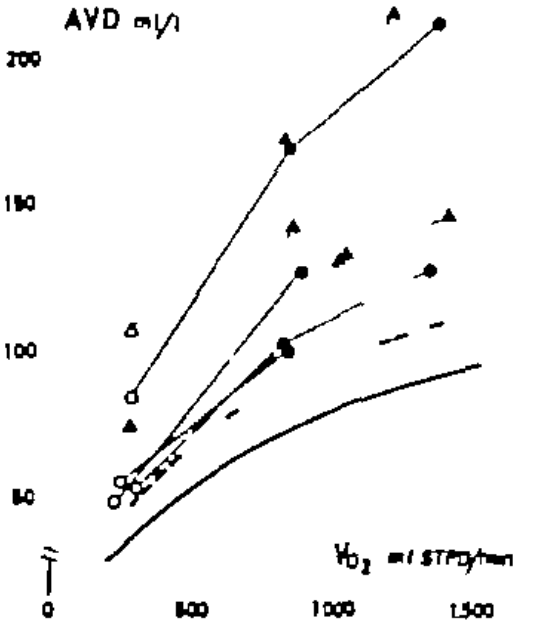
Oxygen uptake (V_{O_2}) averaged 253 ml/min. in the supine position at rest (range 218—301) and in the sitting position it was on the average 40 ml/min. higher (16 %) in the three patients studied also at rest in the sitting position. During exercise the oxygen uptake averaged 3.8 times the resting value. As a mean there was no positional difference in oxygen uptake during exercise. During supine exercise the V_{O_2} averaged 952 ml/min. (range 814—1385).

Heart rate (HR) at rest in the supine position averaged 78 beats/min. (range 69—97). At rest in the sitting position HR was in two patients (no. 1 and 3) 40 beats/min. and 25 beats/min. respectively higher than in the supine position in one patient (no. 5) there was no change.

During exercise there were no positional differences on the same load and the heart rate in the supine position averaged 130 beats/min. (range 96—162) and in sitting 133 beats/min. (range 102—177) (Fig. 12). The heart rate during the catheterization was as on average 85 per cent of the highest heart rate reached during the exercise test performed some days earlier.

Arterial oxygen saturation ($S_{a_{O_2}}$) was normal in all patients and averaged 96.8 % (range 95—99) and 98.0 % (range 97—99) respectively at rest in supine and sitting. In both body positions it increased somewhat during exercise.

Mixed venous oxygen saturation ($S\bar{v}_{O_2}$) at rest averaged 71.4 % (range 63—77) and 59.3 % (range 51—65) in the supine and sitting position respectively. During exercise it decreased markedly in both positions. In the supine position it averaged 38.6 % (range 11—56) and in the sitting position 33.7 % (range 13—43). This difference was significant ($p<0.02$). In one patient (no. 5) $S_{v_{O_2}}$ was almost equal in both positions. At the highest work load it was 11 % and 13 % in the supine and sitting positions respectively.



F g. 12. Cardiac output ($\dot{Q}$) heart rate (HR) stroke volume (SV) and arterio-venous oxygen difference (AVD) in the supine and sitting positions. Five patients with pulmonary stenosis studied at rest (open circle) and during exercise (filled circle)

The oxygen capacity of the blood averaged at supine rest for the three women 185 ml/l (range 177—197) and was 232 ml/l for the two men. It increased during exercise in both body positions and was as an average 8 % higher during sitting exercise than at supine rest.

Arterio-venous oxygen difference (AVD) at rest, in the supine position, averaged 54 6 ml/l blood One patient (no 3) had a normokinetic circulation with an AVD of 33 ml/l. This patient was considered to have a rather mild pulmonary stenosis with a systolic pressure in the right ventricle at rest of 72 mm Hg and a peak systolic pressure difference over the pulmonary valve of 42 mm Hg. The other four patients with tight stenosis had an increased AVD at rest compared to normals and thus displayed a hypokinetic circulation (range 48—84) (Fig. 13) The three patients studied at rest sitting all had a greater AVD compared to that when supine The AVD when sitting averaged 82.4 ml/l (range 65—108) During exercise in the supine position the AVD averaged 132.9 ml/l (range 86—

Fig. 13. Arterio-venous oxygen difference (AVD) in relation to oxygen uptake (V_{O_2}) in 4 patients with tight pulmonary stenosis. Thin full and broken lines represent the supine and sitting positions respectively. Thick lines represent corresponding regressions in normal subjects.

214). The individual maximal value for the patients with tight stenosis ranged 100—214 ml/l. In the sitting exercise the AVD was significantly ($p<0.001$) higher than in supine position. The mean value was 150 6 ml/l (range 109—217).

Cardiac output ($\dot{Q}$) at rest averaged 5 3 l/min. and 3.8 l/min. respectively in the two body positions. The patient with a normokinetic circulation (no. 3) demonstrated the most marked fall, 3 3 l/min. or 40 % of the cardiac output in the supine position. In the other two patients cardiac output fell 0 8 and 0 6 l/min. (17—18 % respectively when changing position from supine to sitting (Fig. 12). During supine exercise the cardiac output increased to 8.1 l/min. (range 4.9—12.2) and during sitting to 7.2 l/min. (range 4.7—9 3). The postural difference in cardiac output for the patients with tight pulmonary stenosis averaged 0 6 l/min. The patient with mild stenosis (no 3) had a normal cardiac output in relation to the oxygen uptake in both body positions (Fig. 14). The patients with tight stenosis

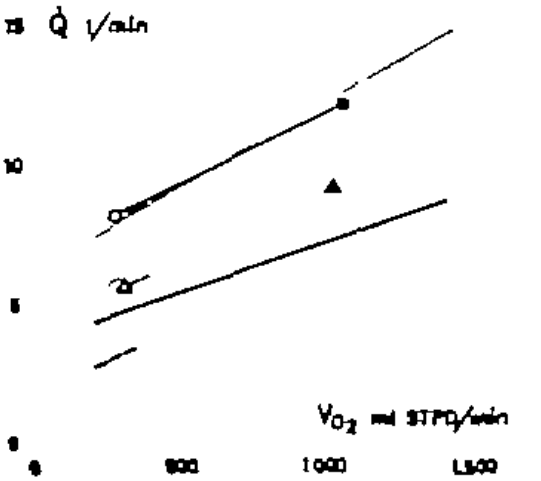


Fig. 14. Cardiac output ($\dot{Q}$) in relation to oxygen uptake (V_{O_2}). Thick full and broken lines represent 4 patients with tight pulmonary stenosis in the supine and sitting positions respectively. Patient no. 3 is indicated separately with symbols as in fig. 2. Thin lines represent normal subjects (Bevegård et al. 1960).

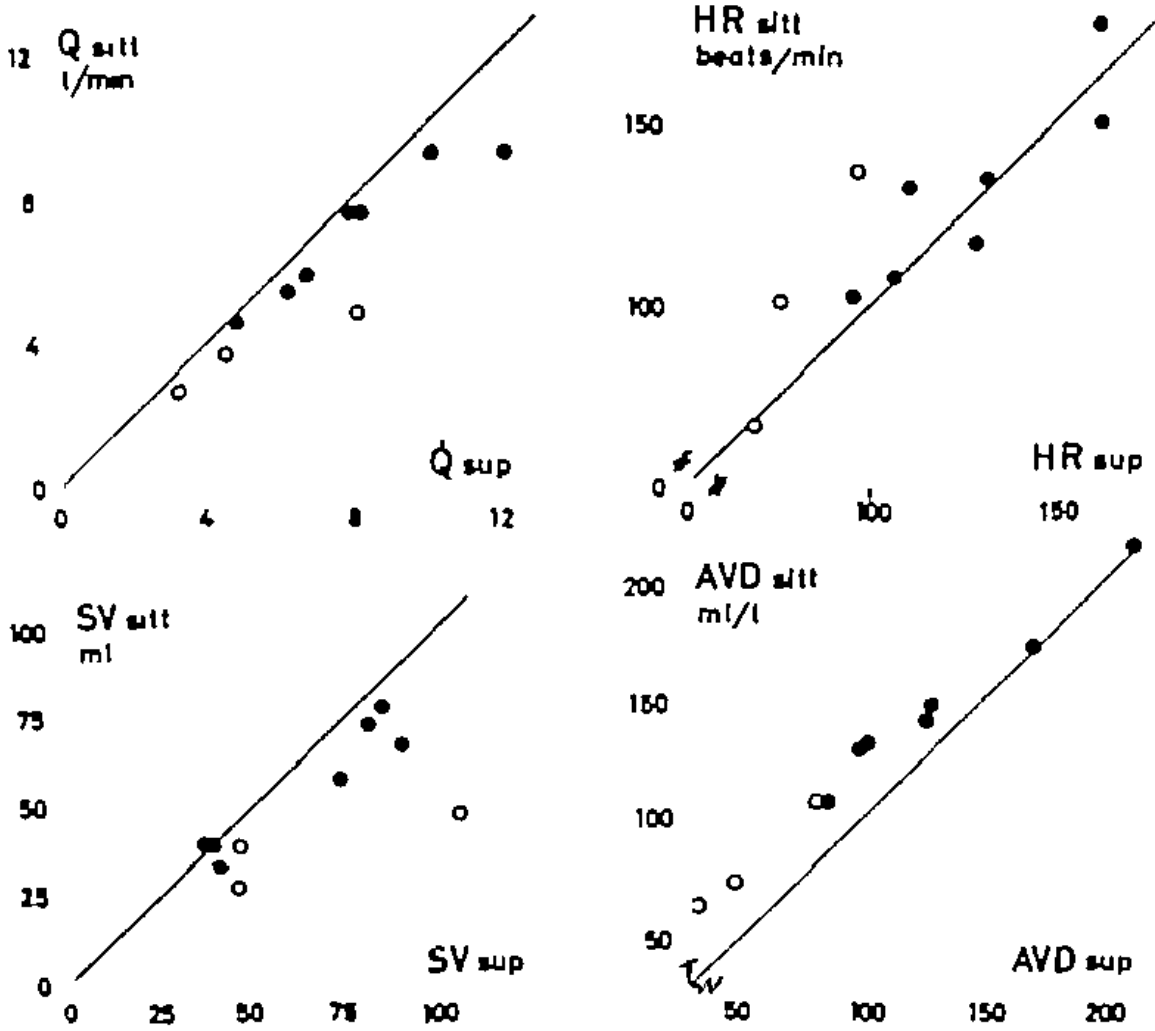

Fig. 12 Cardiac output (Q) heart rate (HR) stroke volume (SV) and arterio-venous oxygen difference (AVD) in the supine and sitting positions. Five patients with pulmonary stenosis studied at rest (open circle) and during exercise (filled circle)

The oxygen capacity of the blood averaged at supine rest for the three women 185 ml/l (range 177—197) and was 232 ml/l for the two men. It increased during exercise in both body positions and was as an average 8 % higher during sitting exercise than at supine rest.

A terio-venous oxygen difference (AVD) at rest, in the supine position, averaged 54.6 ml/l blood. One patient (no. 3) had a normokinetic circulation with an AVD of 33 ml/l This patient was considered to have a rather mild pulmonary stenosis with a systolic pressure in the right ventricle at rest of 72 mm Hg and a peak systolic pressure difference over the pulmonary valve of 42 mm Hg. The other four patients with tight stenosis had an increased AVD at rest compared to normals and thus displayed a hypokinetic circulation (range 48—84) (Fig. 13) The three patients studied at rest sitting all had a greater AVD compared to that when supine. The AVD when sitting averaged 82.4 ml/l (range 65—108) During exercise in the supine position the AVD averaged 132.9 ml/l (range 86—

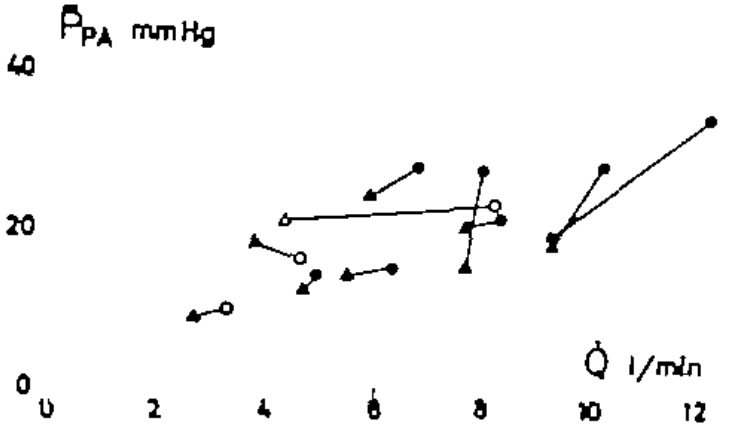

Fig. 13 Pulmonary artery mean pressure (P_{PA}) in relation to cardiac output ($\dot{Q}$) in 5 patients with pulmonary stenosis. Symbols as in fig. 2

on positional change (4—15 mm Hg) The other two patients with a lower pulmonary artery mean pressure had almost identical pressures in the sitting and supine positions (Fig. 13)

Pulmonary vascular resistance (PVR) was normal in all patients and did not change either from rest to exercise or by position. The mean value was 1.0 unit.

The end-diastolic pressure in the right ventricle averaged at rest 15 mm Hg (range 11—18) and during work 23 mm Hg (range 18—30) in the supine position. In the sitting position it could only be calculated in tree patients and averaged during work 12 mm Hg (range 7—20)

Respiratory data

The measured and calculated data are presented in Table IX as mean values for the four patients with tight pulmonary stenosis. The patient with a normokinetic circulation and moderately tight stenosis is presented separately

Total ventilation ($\dot{V}$) at rest was 0 5—3 3 l/min. higher in the sitting position than in the supine position (n=3) During work (250 kpm/min.) the total ventilation in the patients with tight stenosis increased to 28.8 l/min. in the supine and 29 6 l/min. in the sitting positions. The two patients also studied at 500 kpm/min. displayed a marked increase in ventilation and in patient no 5 it was 10 l/min. higher in the supine than in the sitting position. During exercise there was no significant difference in ventilatory equivalent between the two body positions. The total ventilation correlated linearly with oxygen uptake, but the regression line was steeper than in normal subjects (Fig. 25 in General discussion) The high $\dot{V}$ in patients with tight pulmonary stenosis was due to alveolar hyperventilation as is seen from $P_{a}CO_2$ during work. In the supine position at 250 kpm/min. $P_{a}CO_2$ was 34.5 mm Hg (range 32—37) and 34 3 mm Hg (range 32—36) in the sitting position in the patients with the tight stenosis. The patient with moderately tight stenosis had a normal $P_{a}CO_2$ and this was essentially the same on the transition from rest to work in both positions. At the highest work load the alveolar hyperventilation was further accentuated, particularly in patient no. 5 in whom $P_{a}CO_2$

TABLE IX. Mean value of some respiratory data in 4 patients with right pulmonary stenosis at rest and during work. One patient with moderately tight pulmonary stenosis (no. 5) is indicated separately. See list of symbols and abbreviations.

venous pressure in patients with heart failure. During mild exercise their venomotor tone is further augmented (Wood 1965) Although the patients with tight pulmonary stenosis were not in *failure*, the *filling* pressure for the *right* ventricle during supine exercise was within the same range as that found in patients with heart failure. This could to some extent explain the inverse correlation between right ventricular diastolic pressure and the orthostatic change in the stroke volume, as a decrease in the distensibility of the capacitance vessels would result in less blood volume displacement.

Hyperventilation during exercise in patients with pulmonary stenosis has been reported by others (Lewis et al. 1964, Gazetopoulos et al. 1966) Gazetopoulos et al. was unable to show any relationship between cardiac output and hyperventilation during supine exercise but suggested that mechanisms connected with tissue hypoxia contributed to the hyperventilation. In this study hyperventilation during exercise was also found in the patients with tight pulmonary stenosis, with no marked influence of body position. The patient (no 5) with the most hypokinetic circulation, independent of position, displayed a more pronounced hyperventilation in the supine than in the sitting position. When the maximum oxygen transport capacity is reached (mixed venous saturation in both body positions was around 12 %) the lower perfusion pressure in the exercising muscle in the supine position could be critical and support the idea of the mechanism for inducing hyperventilation to be connected with the increased anaerobic metabolism observed (St.b $= 16.0$ mEq/l)

In the four patients with a hypokinetic circulation the $P_{(A-a)O_2}$ was normal or small during exercise in both body positions, indicating small alterations in ventilation—perfusion ratios with changes in posture. Pulmonary diffusing capacity

measured during exercise, was normal and no significant difference was found after changing body position.

Hemoglobin concentration increases on changing from the supine to the upright position both at rest and during work (Beregård 1962, Strandell 1964, Ekelund 1967 Smeenk 1969) and this will increase the oxygen transport capacity per litre cardiac output. In two patients (no 4 and 5) the oxygen capacity of the blood was higher than in normal subjects (232 ml/l) at supine rest. This could be interpreted as an adaptation to increase oxygen transport capacity in a patient with a long-standing hypokinetic circulation.

IX

Postural effects on the central circulation in patients with ATRIAL SEPTAL DEFECT

Observations were made on seven patients, all of whom had an ASD of secundum type (1 6 7 18, 22, 23 24) These patients, belonging to the larger group described in Chapter V were studied separately with additional measurements of respiratory function There were 4 women and 3 men with an average age of 35 years (range 16—57) All patients were studied at rest in the supine position and then during exercise in the supine and sitting position.

RESULTS

Hemodynamic data

Mean values during exercise are given in Table X.

Heart rate (HR) at rest in the supine position was 74 beats/min. (range 66—82) It increased during exercise to 124 beats/min. (range 113—152) in the supine position and was significantly higher in the sitting position, 137 beats/min. (range 110—178) ($p<0.01$)

Oxygen uptake (V_{O_2}) at supine rest averaged 245 ml/min. and increased during work in the same position to 1105 ml/min (range 653—1600) It increased to 1219 ml (range 839—1940) at the same load in the sitting position. The difference in oxygen uptake was significant ($p<0.01$) This could partly explain the higher heart rate during work in the sitting position.

Arterial oxygen saturation ($S_{a_{O_2}}$) averaged 98.8 % (range 96 7—100) at rest and 97.8 % (range 96 0—100) during exercise in the supine position. During exercise in the sitting position the saturation decreased to an average of 96 6 % (range 94 4—97 9) This difference of 1 2 % was almost significant ($p<0.05$) The arterial oxygen tension, measured at the same time, was similar however in the two body positions. It was 89 mm Hg (range 79—97) in the supine and 86 mm Hg (range 74—97) in the sitting position

Oxygen saturation of pulmonary artery blood was on average 90.0 % (range 85 0—92 5) at rest and decreased during work in all patients to an average 74.6 % (range 61 5—82 8) During exercise in the sitting position it was significantly lower 69 2 (range 60 5—82 1) ($p<0.01$) Three patients (nos. 1 7 and 18) however had almost the same or higher saturation when sitting.

Arterio-venous oxygen difference (AVD_P) for the pulmonary circulation was 16 9 ml/l at rest and increased to 46 1 ml/l during exercise in the supine and to 55 9 ml/l in the sitting position Small variations in the determination of the high pulmonary artery oxygen saturation at rest will largely affect the accuracy of the

determination of the pulmonary blood flow. No conclusion will therefore be drawn from postural differences at rest.

Pulmonary flow ($\dot{Q}_P$) at rest in the supine position was 15.6 l/min. (range 8.3—24.6). This was on average 3.2 times the aortic flow (range 1.7—5.0). During exercise in the supine position the pulmonary flow increased to 24.4 l/min. (range 16.3—33.0) and in the sitting position to 22.6 l/min. (range 16.8—35.8). This difference between values in the two body positions was not significant. The individual variation was, however, large. In three patients (nos. 1, 7 and 18) the pulmonary blood flow was higher in the sitting position (Fig. 17 a, bottom) and in the others it was lower in the sitting than in the supine position (Fig. 17 a, top).

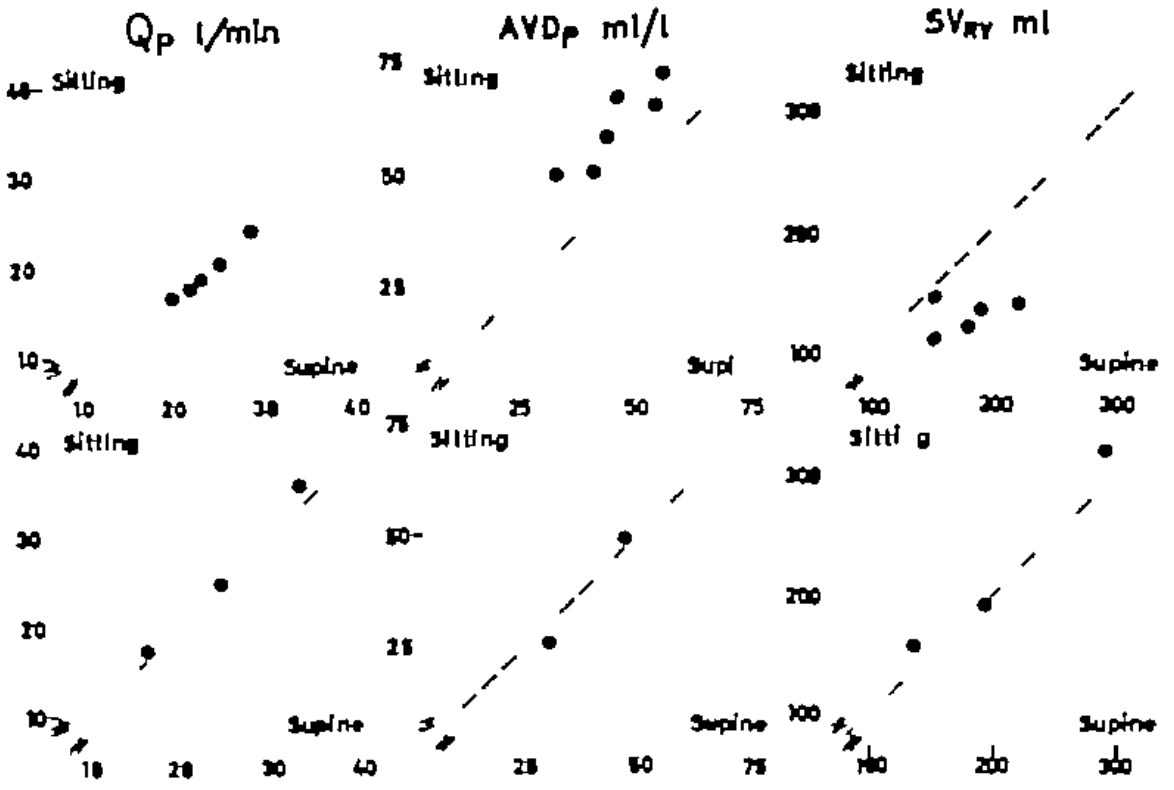

Fig. a.

Fig. 17 a and b. Pulmonary blood flow (Q_P) arterio-venous oxygen difference for the pulmonary circulation (AVD_P) stroke volume of the right ventricle (SV_{RV}) heart rate (HR) and aortic mean pressure (P_{Ao}) in the supine and sitting position Six patients with ASD studied during exercise For further explanation see text

Left ventricular stroke volume at rest in the supine position was 67 ml (range 53—91) *The right ventricular* stroke volume averaged 210 ml (range 123—312) at rest and 198 ml (range 137—292) during exercise in the supine position. This difference was not significant. In the sitting position during work it averaged 169 ml (range 113—319) The positional difference (range 4—81 ml) during exercise was probably significant ($p<0.05$) (Fig. 17 a)

Aortic pressure ($\bar{P}_{Ao}$) was within the normal range both at rest and during exercise in the supine position. The mean pressure averaged 93 mm Hg (range 90—108) at rest and increased to 110 mm Hg during exercise in the supine position In the two patients studied at rest in the sitting position the aortic mean pressure was almost unchanged. During work in the sitting position the mean pressure increased to a slightly lower level than in the supine, although the positional difference (7 mm Hg) was not significant. The individual variation was, however, large The patients could be separated into two groups according to the positional response. In three patients (nos 1 7 and 18) the aortic mean pressure during exercise was 17 to 32 mm Hg lower in the sitting than in the supine position. This was mainly due to a fall of 3—33 mm Hg in the diastolic pressure, the pulse pressure being almost unchanged. These patients all had a larger pul

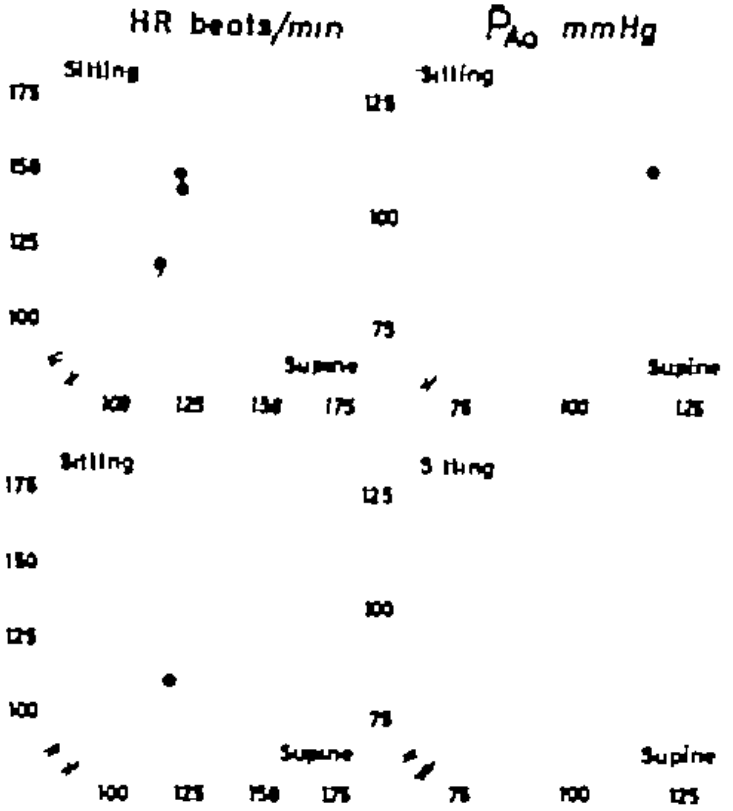

Fig. b.

monary blood flow in the sitting compared with the supine position. The heart rate was almost the same in the two body positions in this group (Fig. 17 b, lower part) In the other group (nos. 22, 23, 24) the aortic mean pressure was mainly unchanged by position during work, with small differences in diastolic and pulse pressures. The *pulmonary blood flow in all these patients was lower and the heart* rate higher (mean 16 %) in the sitting than in the supine position (Fig. 17 a, b, upper part) (No. 6 is excluded in this comparison, as the aortic pressure was not measured in the sitting position)

Pulmonary capillary venous pressure ($\bar{P}_{PCV}$) was normal at rest in the supine position. It increased normally during work in all except in two patients (nos. 1 and 7) who had slightly elevated pressures (21 and 24 mm Hg) In the sitting position $\bar{P}_{PCV}$ was not measured in all patients and so no conclusions could be drawn.

Pulmonary artery mean pressure ($\bar{P}_{A}$) increased from 21 mm Hg (range 17—31) at rest to 34 mm Hg (range 23—59) during supine exercise. In the sitting exercise the pressure was 7 mm lower ($p<0.05$) (Fig. 18)

Right ventricular end-diastolic pressure and *right atrial pressure* were elevated in the two patients (nos. 1 and 7) who also had increased values for $\bar{P}_{PCV}$ The other patients had values which were within the normal range in the supine position both at rest and during exercise. The atrial pressure was lower in the sitting position in all patients. The postural difference during exercise was 8 mm Hg

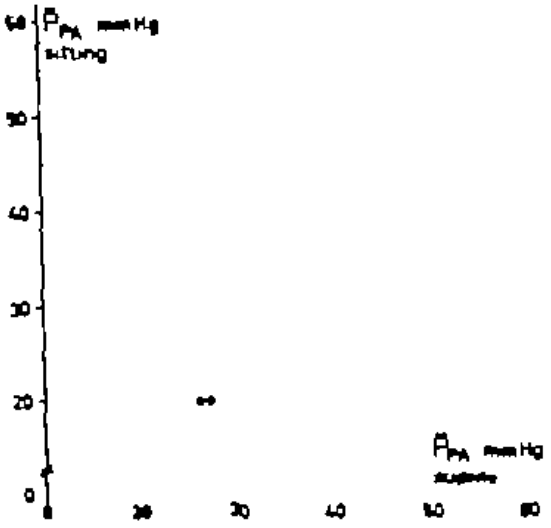

Fig. 18. Pulmonary artery mean pressure ($\bar{P}_{PA}$) in the supine and sitting positions in patients with ASD. Figures refer to case no. 1 and 7. Symbols as in fig. 1.

Pulmonary vascular resistance (PVR) was less than 1 unit in all except in one patient (no. 7) in whom it was 2.3 units. This patient had the smallest left-to-right shunt (pulmonary systemic flow ratio = 1.7) and the most elevated $\bar{P}_{Pcv}$ and $\bar{P}_{PA}$. These pressures increased much less during work in the sitting than in the supine position. Her pulmonary artery mean pressure was 59 mm Hg and 34 mm Hg respectively in the two positions (Fig. 18). The PCV pressure dropped from 24 mm Hg to 11 mm Hg. PVR was unaltered by change in body position.

COMMENTS

In patients with ASD the size of the defect is less important in determining the magnitude of the left-to-right shunt than the difference between wall compliances of the stiffer left ventricle and the more compliant right ventricle when subjected to equal filling pressures (Rowe et al. 1961). The systemic blood flow and left ventricular stroke volume have been found to be normal or slightly low in ASD at rest, a result supported by the common finding of a narrow aortic root. During exercise the systemic blood flow increases normally so that patients with low resting values have correspondingly low values on exercise (Davies and Gazetopoulos 1966). The explanation for a low working capacity in a patient with left-to-right shunt is probably a low left ventricular output, there being no correlation between left to-right shunt and physical working capacity (Jonsson et al. 1957). Physical working capacity is of the same order in the supine and sitting positions (Jonsson et al. 1957) but with a great variation in the working capacity and a marked discrepancy between this and the degree of disability described by the patient at the work test. This fits well with the findings in the 24 patients studied here in whom there was no significant change in working capacity on altering position.

Most studies concerning the hemodynamics in ASD during exercise have been done in the supine position, when the left-to-right shunt either remains unchanged or decreases (Jonsson et al. 1957, Swan et al. 1958, Davies and Gazetopoulos 1966,

Peterssen 1967 Siltanen 1968) Bruce and John (1957) described in 4 patients with ASD an increase of 21 % in pulmonary blood flow at rest on changing from the supine to the upright position This increase was proportional to the extent the oxygen consumption was greater in the upright position No comparison was made during exercise in the two body positions.

No patient in the present group had signs of right-to-left shunt in either the supine or sitting position. Davies and Gazetopoulos (1966) described, in patients with ASD with low pulmonary vascular resistance, a parallel increase in systemic and pulmonary flow during supine exercise, with little change in the magnitude of the left-to-right shunt

In patients with a large atrial septal defect, the atria can be looked upon as one chamber with a common filling potential for both ventricles, and stroke volume for each is determined mostly by the difference in diastolic filling resistance. On changing body position to the sitting position there is some change in intrathoracic pressure and a hydrostatic shift of blood, but this would act equally on both ventricles. If the systemic and pulmonary pressures are not markedly changed the outputs of both ventricles would not be affected by altering body position.

There were inter individual variations in the two types of response. Three patients had lower systemic pressures during exercise in the sitting position. Probably they all had lower peripheral resistances in this position, revealed by a dominant fall in diastolic pressure. Contrary to the normal response the heart rate was not increased. These patients all maintained the same stroke volume and cardiac output for the right ventricle during exercise in both positions. Two of these patients

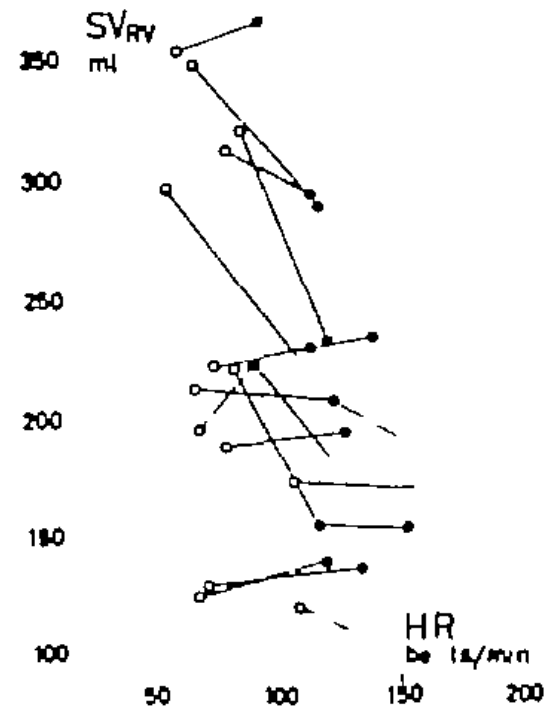

Fig 19 Stroke volume of the right ventricle (SV_{RV}) in relation to heart rate (HR) at rest (open circle) and during exercise (filled circle) in the supine position, in 14 patients with ASD

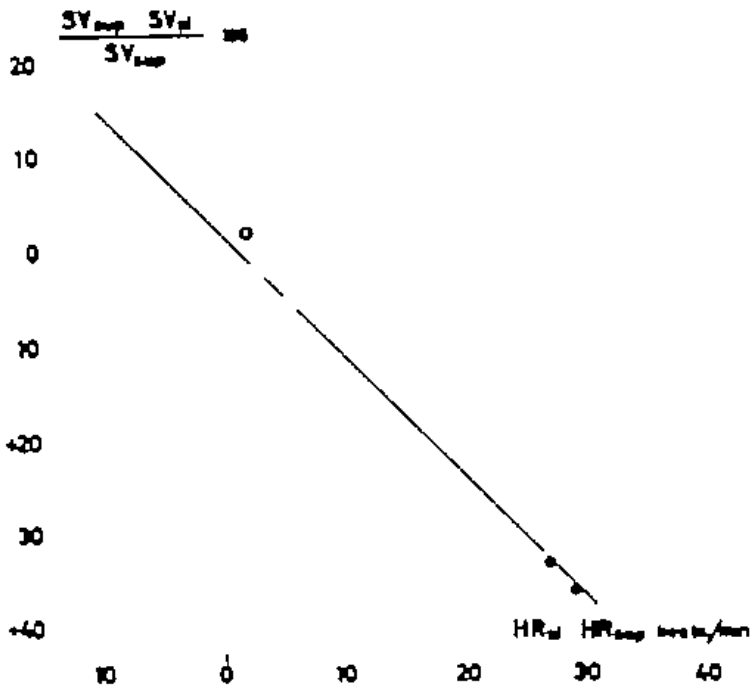

Fig. 20. Relative postural difference in stroke volume of the right ventricle (ΔSV) related to the difference in heart rate between the sitting and supine positions (r= —0 95)

(1 and 7) had in supine abnormally increased atrial and pulmonary artery pressures that were lower in the sitting position (Fig. 18) The other three patients had mainly unchanged aortic pressures on changing position and heart rate was higher in the sitting position. All in this group displayed a lower pulmonary blood flow and even lower right ventricular stroke volume when sitting The response of the latter group was, concerning the regulation of the systemic circulation, more normal.

Jonsson et al. (1957) pointed out that in ASD with a large diastolic flow through the tricuspid valve a significant filling of the right ventricle also takes place during the last part of diastole, contrary to the situation in normals in whom most filling probably takes place in the early part of diastole. The lower right ventricular stroke volume during supine exercise, seen particularly in those with a large stroke volume at rest, could be explained by the shortening of diastole at high rates This would decrease the filling of the right ventricle while filling of the left ventricle could be unchanged (Fig. 19) The difference in heart rate between the sitting and supine positions was correlated with the relative change in stroke volume of the right ventricle (Fig. 20) which may indicate that the difference in pulmonary blood flow on changing position could be secondary to the different reactions in heart rate Why some patients showed a decrease in systemic pressure without a rise in heart rate (in this response being similar to patients with postural hypotension) could not be explained. The lower aortic pressure during sitting exercise did not cause any symptoms. A sustained vaso-vagal reaction which was not counteracted by exercise cannot be excluded as one possible explanation of the absence of increasing heart rate on changing posture.

X

Ventilation alveolar gas exchange and D_{LCO} during exercise in patients with ATRIAL SEPTAL DEFECT with special reference to body posture

All patients described earlier were studied during exercise in the supine position. In three patients (nos. 22, 23 24) the D_{LCO} was not measured. In sixteen patients observations were also made during sitting exercise at the same load as that studied in the supine position. At rest the patients were only investigated in the supine position. Seven patients had been diagnosed preoperatively by heart catheterization in other hospitals.

RESULTS

Hemodynamic data

The pulmonary blood flow ($\dot{Q}_P$) at rest varied between 8 3 and 46.5 l/mm. and this was 1 7—9 3 times the systemic flow In most patients the pulmonary blood flow increased during exercise (Fig 21)

The pulmonary vascular resistance (PVR) was within the normal range in most patients and in only 2 patients was it above 2 units

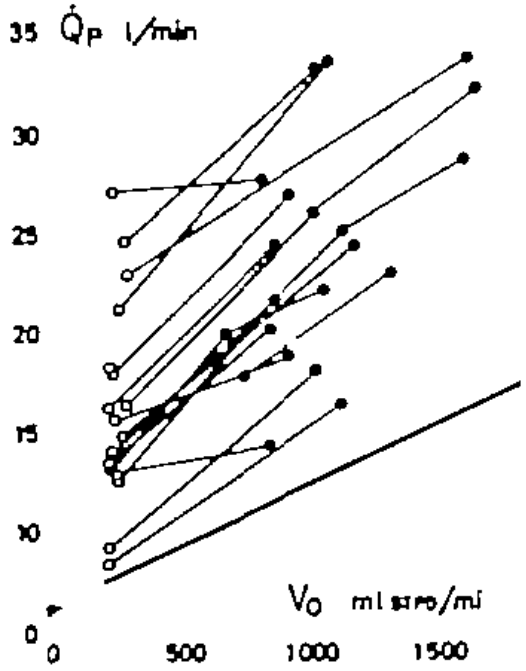

Fig. 21 Pulmonary blood flow (Q_P) in relation to oxygen uptake (V_{O_2}) in the supine position. Thick line represents the normal regression ($Q = 0\,0063\ V_{O_2} + 6.17$)

The pulmonary artery mean pressure ($\bar{P}_A$) varied between 13 and 33 mm Hg at rest and 18 and 64 mm Hg during exercise. In eleven patients the pressure was above 30 mm Hg during exercise

Comments All patients had increased pulmonary blood flow without marked vessel changes in the lungs The hyperkinetic blood flow was accompained by a slight pulmonary hypertension in about half the patients.

Respiratory data

Mean values during exercise are given in Table XI

Oxygen uptake (V_{O_2}) averaged 243 ml/min at rest in the supine position. During exercise in the same position the average increase was about 3 times the resting value to 960 ml/min. In the sitting position it was still higher than in the supine position and the difference of 55 ml/min. was significant ($p<0.01$)

Minute ventilation (V_E) in the supine position increased from 7 8 l/min at rest to 31 l/min (range 16—40) during work. In the sitting position the ventilation was 2 6 l/min higher and this was probably due to the increased oxygen uptake in the sitting position, the ventilatory equivalent being the same in the two positions There was a linear increase of minute ventilation in relation to oxygen uptake $V_E = 0.032\ V_{O_2} + 0\ 62$ ($r = 0\ 92^{***}$) (see Fig. 25 in General discussion)

The ventilatory equivalent during exercise was 5 0 units higher in this group with ASD than in normal subjects. The increase in ventilation during work was achieved by both an increase in respiratory rate and tidal volume but there was a significant difference between the findings in the two body positions. During work in the supine the respiratory rate was higher and the tidal volume smaller than in the sitting position

Physiological dead space (V_D) was higher in the sitting than in the supine position but when related to the tidal volume (V_D/V_T) there was no positional difference during work (0.21 in the supine and 0 22 in the sitting positions respectively)

Arterial carbon dioxide tension ($P_{a_{CO_2}}$) in the supine position averaged 32.2 mm Hg (range 25—42) at rest and 35 7 (range 28—42) during exercise and was unchanged by body position.

Arterial oxygen tension ($P_{a_{O_2}}$) averaged 85.0 mm Hg (range 72—100) at rest. In six patients it was below 80 mm Hg at rest but in five of these it increased during work to over 80 mm Hg. These patients were considered not to have any right-to-left shunt through the atrial septal defect. One patient (no. 11) having the largest left-to-right shunt, with a pulmonary blood flow over 9 times the systemic flow had a $P_{a_{O_2}}$ of 75 mm Hg at rest and it decreased to 61 mm Hg and 59 mm Hg during work in the supine and sitting positions respectively In this patient it seemed probable that some desaturated blood from the right atrium could have been mixed with blood leaving the pulmonary veins. (At operation a large central secundum defect 3×4 cm was found) During exercise $P_{a_{O_2}}$ averaged 88.2 mm Hg (range 80—102) In the supine position and it was unchanged during exercise in the sitting position.

Alveolar oxygen tension ($P_{A_{O_2}}$) increased from 105 0 mm Hg at rest to 112.2 mm Hg (range 103—120) during exercise and was unaffected by body position.

Alveolar-arterial oxygen tension difference ($P_{(A-a)_{O_2}}$) averaged 20 4 mm Hg at rest (range 4—32) and 24.0 mm Hg during exercise (range 10—35) There was no significant positional difference. *pH* was on a erage 7 44 (range 7 40—7 51) at rest and 7 40 (range 7 32—7 45) during exercise in the supine position. In the sitting position it decreased to 7 38 (range 7 30—7 45) This difference of 0.02 was highly significant ($p<0.001$) The *standard bicarbonate* was slightly lower (0 4 mEq/l) in the sitting than in the supine position during exercise ($p<0.05$)

Respiratory exchange ratio (R) averaged 0 78 at rest and increased to 0 96 during exercise in both positions.

Pulmonary diffusing capacity (D_{LCO}) was measured at rest in 5 patients and averaged 28.2 ml min.$^{-1}$ mm Hg^{-1} The variation was large. In 3 patients in whom the resting value was measured both before and after exercise the difference ranged between 4.8 and 25 1 ml min^{-1} mm Hg^{-1} During supine exercise in

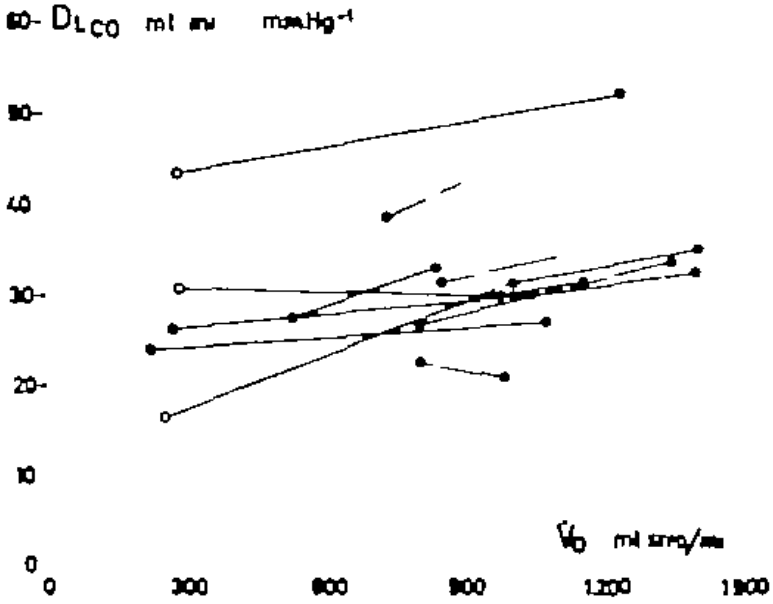

Fig. 22. Pulmonary diffusing capacity (D_{LCO}) in relation to oxygen uptake ($V_{O_2}^{l}$) at rest (open circle) and during exercise (filled circle) in 10 patients with ASD

this group D_{LCO} increased to an average of 34.2 ml min.$^{-1}$ mm Hg^{-1} This increase from the resting value was however not significant. For the whole group there was no significant positional difference during exercise. Thus D_{LCO} averaged 34 9 ml min.$^{-1}$ mm Hg^{-1} (range 26—52) in the supine and 36.8 ml min.$^{-1}$ mm Hg^{-1} (range 24—58) in the sitting position. In about half the group of patients D_{LCO} was measured at two work loads and there was a small increase ($p<0.05$) from 33 2 ml min.$^{-1}$ mm Hg^{-1} on the first load to 36.9 ml min.$^{-1}$ mm Hg^{-1} on the second load (Fig. 22) Maximal measured values for D_{LCO} were compared with those in normal subjects studied by Holmgren (1965) All cases were within the normal range, except two cases who were above (Fig. 23) For the whole group there was a significantly elevated D_{LCO} of 11 % from the predicted normal mean value.

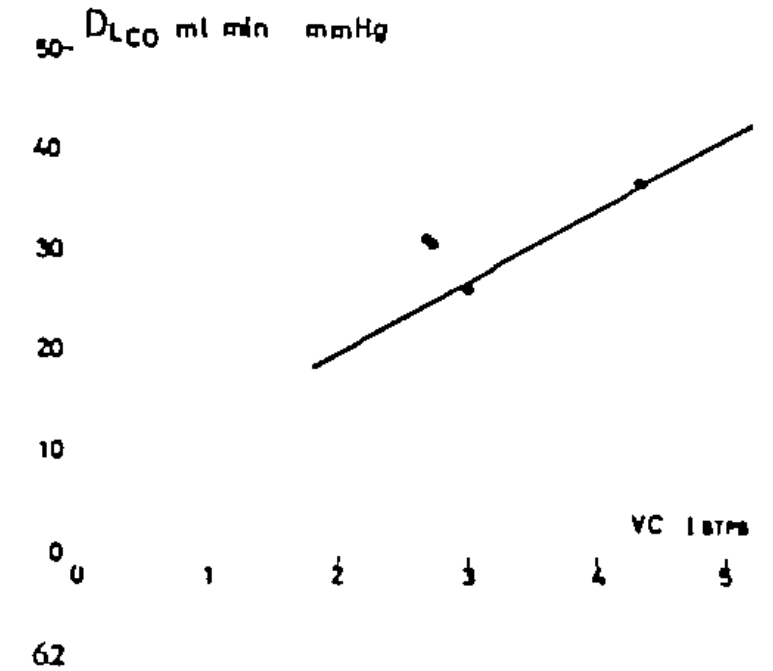

Fig. 23 Pulmonary diffusing capacity (D_{LCO}) in relation to vital capacity (VC) The maximal individual value during exercise is plotted. Lines represent the normal regression line ±2 SD. D_{LCO} =7 13 VC+5 4, SD ±4.6 (Holmgren 1965)

Effect of age on some respiratory data

The data were divided in two groups according to the age of the patient at the time for the investigation. Eleven patients belonged to the group younger than 40 years of age with a mean age of 30 5 years (range 16—39) and thirteen patients were older than 40 years with a mean age of 48 9 years (range 41—57) There was no significant difference between the groups concerning the oxygen uptake, ventilatory equivalent, V_D/V_T alveolar oxygen tension, carbon dioxide tension, pH or diffusing capacity in either position during work.

In the supine position arterial oxygen tension was lower however both at rest and during work in the older patients. The average oxygen tension in the older group was 81 mm Hg at rest and 83 mm Hg during supine exercise and this averaged 9 mm Hg and 8 mm Hg lower respectively ($p<0.01$) than in the younger group During sitting exercise there was no significant difference between the values in the two groups.

COMMENTS

All patients had a pure left-to-right shunt, except one, in whom there was suspicion of a slight right-to-left shunt due to a large secundum defect. The pulmonary blood flow was higher than normal in all patients but there was a large variation in the absolute values both at rest and during exercise. The pulmonary artery mean pressure was normal or slightly elevated due to the hyperkinetic lung circulation.

Total ventilation was found to be increased in relation to oxygen uptake due to alveolar hyperventilation (Fig. 25) This was not affected by body position although the ventilation in the supine position was achieved with a higher respiratory rate than that in the sitting position. The arterial gas tensions were mainly changed as a consequence of hyperventilation.

The arterial oxygen tension was normal in most cases during work in both body positions, suggesting that no right to-left shunt developed during exercise as a consequence of the change from the supine to the sitting position. In one patient $P_{a_{O_2}}$ decreased to the same extent during exercise in both positions. The relationship between the different ventricular wall compliances that mainly governs the amount and direction of the shunt does not seem to be markedly altered by body position.

Hyperventilation in patients with increased pulmonary blood flow has been reported earlier (Shephard 1955) Ressl et al. (1969) described in adults with atrial septal defect a correlation of resting hyperventilation to pulmonary hypertension but not to the left-to-right shunt. Gazetopoulos and Davies (1966) also demonstrated an excessive ventilatory response to exercise, but this was apparently not related directly to the level of he pulmonary arterial pressure or the magnitude of the pulmonary flow Such a relationship could not be demonstrated in this study either

The slightly lower pH, StB and base excess in the sitting position could be explained by increased anaerobic metabolism in this position.

Pulmonary diffusing capacity (D_{LCO}) measured with a steady state technique has been found to vary hyperbolically with oxygen uptake in normal subjects (Freyschuss and Holmgren 1965) The increase in D_{LCO} above an oxygen uptake of 40 % of the maximum uptake or a heart rate during exercise above 120 beats/min. was found to be small.

D_{LCO} at rest in patients with increased pulmonary flow has been found to be elevated, due to an increase in the pulmonary capillary blood volume (McCredie et al 1964) and the increase during work is less than normal (MacNamara et al 1960) or normal (Rotman and Wolf 1963)

The reproducibility of D_{LCO} at rest with the steady state technique is poor in normal subjects as has been pointed out (Bjure 1965 Holmgren 1965) and this is also verified in the patients studied During work it increases and is estimated to be 7.2 % The coefficients of variation of the D_{LCO} differences during exercise between the supine and sitting positions and between two work loads in the supine position in this material were 8.1 % and 6.2 % respectively Smaller changes than about 10 % would thus not be significant with this technique. Although there was a significant increase in D_{LCO} with increasing oxygen uptake during exercise it is of a small amount and including the resting values it seems to be an approximately unchanged D_{LCO} from rest to exercise (Fig. 22) The explanation of this may be that the pulmonary capillary blood volume is large at rest and a further increase is small The absolute value of D_{LCO} was not directly correlated with the amount of pulmonary blood flow

In patients with ASD all pulmonary vessels are probably perfused at rest with no new recruitment during work and this is not influenced by body position as was also found by Giammona and Daly (1968)

Alveolar gas change and pulmonary diffusing capacity have not been found to be restricted in patients with ASD and these cannot account for the hyperventilation usually seen. It might be due to altered lung mechanics.

XI

Ventilation alveolar gas exchange and D_{CO} in patients after corrective surgery of ATRIAL SEPTAL DEFECT

Dyspnea is the most common symptom restricting physical activity in patients with atrial septal defect The relief of this symptom postoperatively is also a most striking clinical finding Most studies of the pulmonary function in this type of patients have been under resting conditions, when hyperventilation has been found, both in children (Gamalero 1957) and adults (Ressl et al. 1969) with left-to-right shunts.

In the previous Chapter it was shown that high total ventilation due to alveolar hyperventilation is common during exercise in these patients and no differences were found in the ventilatory equivalent with change in body position. The arterial blood gases changed mainly as consequence of hyperventilation.

This chapter deals mainly with the postoperative measurements of lung ventilation, alveolar gas exchange and diffusing capacity of the lungs in 11 patients, belonging to the larger group of ASD studied earlier preoperatively

PATIENTS AND PROCEDURES

Eleven patients with atrial septal defect, operated on at the Thoracic Clinics, were selected for the postoperative study There were 6 females and 5 men with a mean age of 45 years (range 21—57) One patient (no 3) had a defect of primum type and all the others had secundum defects. Six patients were operated on with the use of hypothermia and five with an extracorporeal circulation. Two patients had atrial fibrillation both at the pre and postoperative study and one had a first degree AV-block preoperatively and atrial flutter at the postoperative investigation. All the others were in sinus rhythm at both investigations.

The heart catheterizations and all methods used were as described earlier The circulatory and ventilatory investigations were done at the same time and the same work loads were chosen for the pre and postoperative studies The patients were investigated 7 to 20 months (mean 13 months) after operation.

The catheterization studies were performed only in the supine position. In five patients who were also studied in the sitting position preoperatively the double-lumen venous catheter was withdrawn and alveolar gas exchange and diffusing capacity were studied also during exercise in the sitting position. One patient (no.

8) was not subject to heart catheterization but only examined with determination of the diffusing capacity She had radiological and clinical evidence of a closed defect postoperatively

RESULTS

Mean values for some anthropometric data are given in Table XII

Heart volume was on average 15 % smaller postoperatively ($p<0.05$) In two patients the heart volume was almost unchanged, one of these was the patient with atrial fibrillation.

Total hemoglobin and *blood volume* were 10 % and 9 % respectively smaller after operation ($p<0.01$ and $p<0.05$)

Maximal work intensity in the two body positions was on average not significantly changed after operation.

Spirometry There was no significant difference pre and postoperatively in the total lung capacity and its subdivisions The dynamic spirometry displayed an increase of 12 l/min. in the MVV_{12s} from the preoperative 103 4 l/min. ($p<0.05$) the other variables being unchanged

Hemodynamic data

Mean values for 10 patients studied with heart catheterization pre and postoperatively are given in Table XIII.

Heart rate (HR) and *oxygen uptake* (V_{O_2}) were the same before and after operation both at rest and during work. None of the patients had any residual left to-right shunt postoperatively The difference between the oxygen saturation in superior vena cava (S_{svc}) and that in pulmonary artery (S^-) ranged between —5.8 and 4.1 %. There was a significantly higher S_{svc} postoperatively compared to that preoperatively

Pulmonary blood flow ($\dot{Q}_T$) decreased from 16.8 l/min. to 5 7 l/min. after operation at rest and from 23 9 l/min. to 9.8 l/min. during exercise. After operation there was a significantly higher systemic blood flow at rest, corresponding to an average stroke volume of 65 ml preoperatively and 85 ml postoperatively The stroke volume did not increase significantly from rest to exercise after operation.

Intracardiac and intravascular pressures averaged about the same level pre- and postoperatively The *right ventricular end-diastolic pressure* decreased in 2 patients, increased in one and was unchanged in the rest. The *pulmonary artery mean pressure* ($\bar{P}$) at rest and during work was slightly above normal in one patient preoperatively (no 3 33 and 56 mm Hg) and postoperatively all were within the normal range. The *PCV pressure* ranged from 5—19 mm Hg at rest preoperatively and from 6—17 mm Hg postoperatively and were in most patients unchanged. During exercise the findings were similar although the pressure levels were higher The range before operation was 4—28 mm Hg and after 11—29 mm Hg. The *aortic mean pressure* ($\bar{P}_{Ao}$) at rest and during exercise was unchanged by operation both at rest and during work. The *pulmonary vascular resistance* (PVR) was normal both before and after operation in all patients

Respiratory data

Mean values of ventilation, alveolar gas exchange, blood gases and diffusing capacity during exercise are given in Table XIV

At rest there was no significant difference between pre- and postoperative values of total ventilation, tidal volume, alveolar or dead space ventilation. The same was found for arterial oxygen and carbon dioxide tensions and pH. During *exercise* with an average oxygen uptake of 1.0 l/min. there was a highly significant difference in *total ventilation* which was on an average 3 l/min lower after operation for the same oxygen uptake (Fig. 24 a). This was achieved with a lower *respiratory rate*, *tidal volume* being unchanged. The *dead space ventilation* was unchanged and therefore the lower total ventilation after operation was due to a significantly smaller alveolar ventilation. P_{aCO_2} increased from an average of 34.8 mm Hg preoperatively to 38.6 mm Hg postoperatively (Fig. 24 b). The *pH* was lower postoperatively although the standard bicarbonate and base excess were unchanged.

Arterial oxygen tension (P_{aO_2}) was not changed by operation (Fig. 24 c). There was a significant decrease of the $P_{(A-a)O_2}$ postoperatively and this was due to a lower $P_{\bar{v}O_2}$.

Diffusing capacity for the lungs (D_{LCO}) during supine work, decreased from 32.2 to 24.7 ml min^{-1} mm Hg^{-1} ($p<0.01$) (Fig. 24 d). This value after

operation did not significantly deviate from the predicted normal mean value. In five patients studied during work in both body positions pre and postoperatively the fall in D_{LCO} after operation was even more marked in the sitting position, although the d fference between the two positions was not significant either before or after operation.

COMMENTS

The natural history for patients with ASD is usually uncomplicated, a normal physical act ty being maintained into middle age, when they often develop dyspoea on effort. The patients studied, except for one, were over 35 yea

of age. All patients had a pure left to-right shunt at atrial level preoperatively with a hyperkinetic pulmonary circulation without increased pulmonary vascular resistance. The hemodynamic disturbance is usually corrected by the operation even in older patients (Peterson 1967 Siltanen 1968) This also fits well with the findings in the present study where no residual left-to-right shunt was found postoperatively The pressures in the pulmonary circulation were in most cases within the normal range preoperatively and remained unchanged or were lower after operation. The PCV pressure during exercise increased postoperatively in some patients and this has been found earlier among older patients (Siltanen 1968 Jonsson 1969)

The systemic cardiac output at rest was greater after operation due to a significantly larger left ventricular stroke volume as was also found by Peterson (1967) Probably this is acting also during work, although it cannot be proved.

Increased ventilatory equivalent at rest and during work in patients with heart disease has been reported by many authors (Campbell et al. 1923 Gazetopoulos et al. 1966) Shephard (1955) found resting hyperventilation in patients with increased pulmonary blood flow and it was mainly due to high respiratory rate. Krantwald et al. (1962) found in patients with left-to-right shunt a good correlation between the resting hyperventilation and pulmonary artery pressure but no correlation with the magnitude of the shunt. Resal et al. (1969) reported the same and found no correlation with pulmonary blood flow or femoral venous oxygen saturation.

Increased pulmonary blood flow and pulmonary hypertension in atrial septal defect may alter the lung mechanics Davies and Gazetopoulos (1967) found a significant inverse relation between the product of pulmonary pressure and flow and the compliance of the lungs They also observed an increase in compliance after closure of the atrial septal defect. Woolf (1963) found no relation between total ventilation and compliance during exercise. However he pointed out that in patients with moderate or severe dyspnea, the abnormally high ventilation during mild exertion was associated with a high work of breathing and this dual abnormality distinguished them from patients with only slight dyspnea on exertion. Hyperkinetic pulmonary hypertension could thus be of importance for the hyperventilation in these patients A significant correlation was also found in the present study between the decrease in ventilation and the change in the product of pulmonary flow and pressure pre- and postoperatively ($r=0.60$ $p<0.05$)

In the present study no changes were found in ventilation or alveolar gas exchange at rest after the defect had been closed. During exercise, however there was a significantly lower total ventilation with a lower respiratory rate postoperatively

As the $P_{a_{O_2}}$ was unchanged $P_{a_{CO_2}}$ increased, and the pH decreased after operation, these variables do not seem to be important determinants for the hyperventilation in these patients. Impairment of systemic output has been proposed as a stimulus to ventilation (McIlroy 1959) but was not proved by others (Sloman and Gandevia 1964 Gazetopoulos et al 1966) Although the systemic output was

higher at rest after operation in this group of patients, there was no difference in standard bicarbonate during exercise, indicating any marked changes in the aneorobic metabolism pre and postoperatively

Diffusing capacity of the lungs in patients with ASD has been reported to be increased at rest (Rankin and Callies 1958) and this is mainly due to an increase in the pulmonary capillary blood volume (McCredie et al. 1964) The increase of D_{LCO} during exercise in patients with ASD has been reported to be both lower (MacNamara et al. 1960) and the same as in normal subjects (Rotman and Woolf 1963) Reversibility of the elevated D_{LCO} and pulmonary capillary blood volume after surgical repair has been observed at rest (Murao et al 1963) Tala et al (1968) reported a postoperative decrease of 25 % in D_{LCO} at rest 9—16 weeks after surgery

The present study demonstrates a postoperative decrease in D_{LCO} also during exercise on an average of 23 % This probably suggests that the pulmonary capillary bed during exercise is also reduced after surgical correction In two patients, however there was a small increase in D_{LCO} after operation, although the pulmonary flow in these patients decreased by 23.1 l/min. and 8.7 l/min. respectively

stroke volume at rest in the supine position. Shortening of diastole with increasing heart rate would interfere with the filling of the right ventricle because of its large stroke volume, while the filling time for the left ventricle would not be critical. In the present study most patients with a stroke volume larger than 200 ml at rest displayed a decrease during supine exercise, while in the others it was essentially unchanged (Fig. 19). If the relationship between the left and right ventricular filling resistances, which is the main determinant of the size of the shunt, remains essentially unchanged by exercise and posture, the stroke volume of the right ventricle and probably also the shunt would decrease at high heart rates. A highly significant negative correlation was found between the relative change in stroke volume of the right ventricle and the change in heart rate when body position was altered (Fig. 20). When the heart rate during exercise was approximately the same when supine and sitting, pulmonary blood flow was also equal in the two positions. Changes in right ventricular stroke volume in ASD after shifting body position is likely to be secondary to changes in heart rate, which are mainly controlled by the systemic circulation.

Vital capacity and total lung capacity were lower in patients with MS and ASD than in normal subjects. Both groups of patients had a significant decrease in vital capacity of 15 % from the predicted normal mean values and contrary to the findings of Siltanen (1968) the vital capacity in ASD was not changed after operation. In patients with pulmonary stenosis the lung volumes were within the normal range. Lung volumes are thus affected by increased pressure levels and/or an increased pulmonary blood flow. This is usually accompanied by a low lung compliance (McIlroy and Apthorp 1958, White et al. 1958, Woolf 1963).

Total ventilation in normal subjects is linearly correlated with oxygen uptake during submaximal work loads. At higher work loads, when the lactate concentration starts to increase rapidly, the ventilation increases more steeply with increasing oxygen uptake (Asmussen 1965). In this study the oxygen uptake was increased up to about 1.5 l/min, and within this range the ventilation in normal subjects is linearly related with oxygen uptake. This was also found in the present three patients groups (Fig. 25). The ventilation was, however, larger for any given oxygen uptake during exercise compared with that in normal subjects, particularly in patients with PS and ASD. After surgical correction of the ASD the ventilation during exercise was normal and the ventilatory equivalent was significantly decreased from 33.0 to 27.3. This decrease in ventilation for the same oxygen uptake in combination with an increase in compliance after operation, reported by Davies and Gazetopoulos (1967), correlates with the relief of exercise dyspnea, which is the principal improvement in symptoms after surgery.

The mechanism of the increased ventilation cannot be fully explained and it is probably multifactorial and not necessarily the same in the different patient groups. As the pulmonary artery pressure and flow were so different in the three groups of patients and as ventilation did not alter with change in posture, the vascular

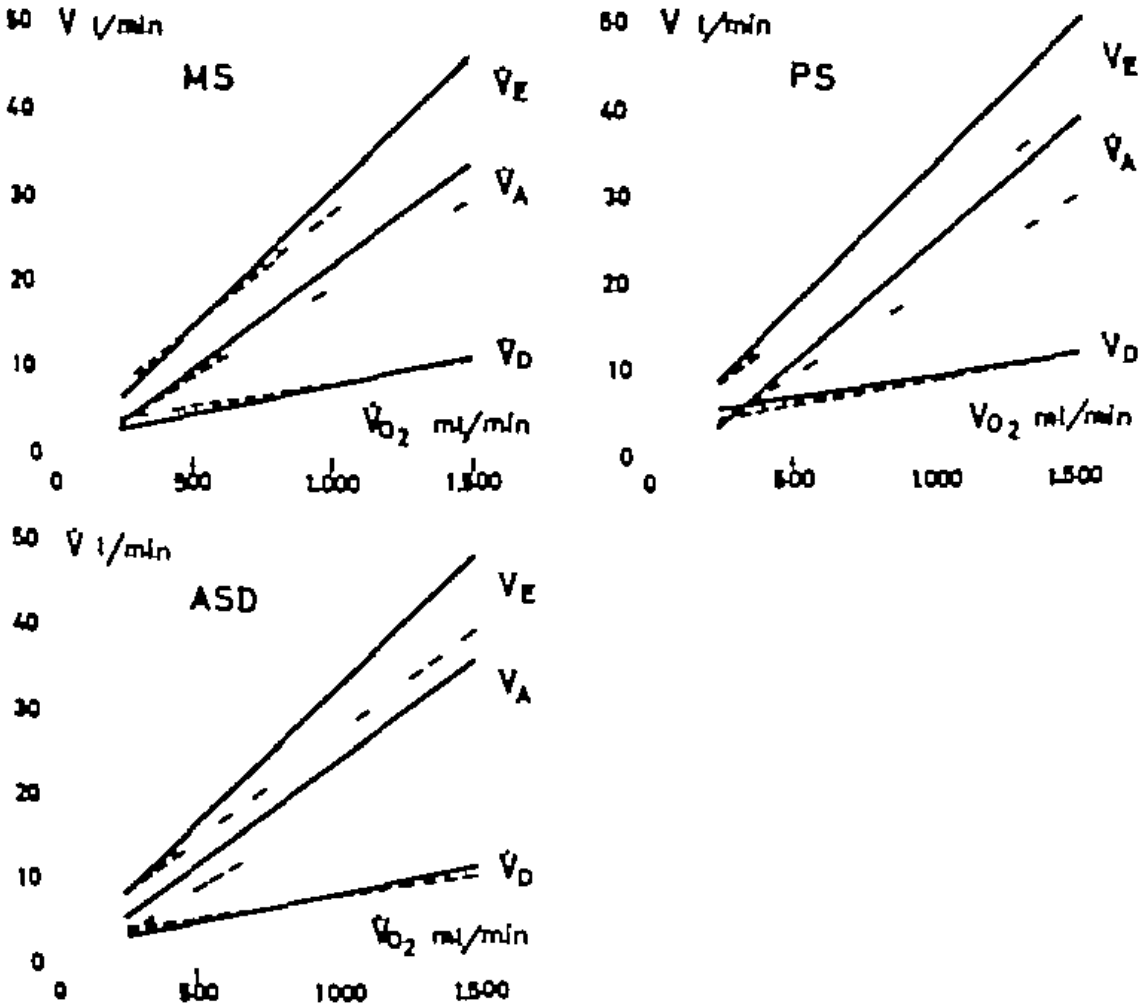

Fig. 25 Lung ventilation (V_E) alveolar ventilation (V_A) and dead space ventilation (V_D) in relation to oxygen uptake (V_{O_2}) in patients with mitral stenosis (MS) pulmonary stenosis (PS) and atrial septal defect (ASD). Broken lines represent the normal regression $V_E = 0.026\ V_{O_2} + 1.53$ (Holmgren 1967). Regression equation in MS $V_E = 0.037\ \dot{V}_{O_2} - 0.87$ ($r = 0.95$) in PS $\dot{V}_E = 0.033\ V_{O_2} + 0.19$ ($r = 0.88^{**}$) and in ASD $V_E = 0.032\ V_{O_2} + 0.62$ ($r = 0.92^{*}$)

pressures and flow in the lung do not appear to be important causes of hyperventilation. Gazetopoulos and Davies (1966) suggested a mechanism connected with tissue hypoxia. In one patient with the tightest pulmonary stenosis and the most markedly hypokinetic circulation the ventilatory equivalent was high but did not change from rest to the first load ($S_{vo_2} = 26\ \%$) but then increased markedly on the second load in both body positions ($S_{vo_2} = 12\ \%$) which may support such a mechanism. Holmgren and Strömberg (1959) found higher blood lactate concentrations in relation to absolute work load in patients with MS and ASD than in normal untrained individuals. In the patients with ASD after corrective operation the pH was lower and the standard bicarbonate unchanged at a given work l

The decrease in ventilation therefore could not be fully explained by any marked difference in anaerobic metabolism.

Variation in the alveolar arterial oxygen tension difference ($P_{(A-a)O_2}$) is dependent on three factors the diffusing properties of the lung, the distribution of alveolar ventilation perfusion ratios in the lung and the right to-left shunt. The D_{L-CO} was not markedly changed in the three groups of patients and would therefore not affect the $P_{(A-a)O_2}$ to any important extent. The other two components could not be separated in this study but constitute about half each of the gradient in normals at rest (Mellemgaard 1966) In this study the $P_{(A-a)O_2}$ was unchanged by body position in patients with PS and ASD during exercise, although at a slightly higher level in the latter group In patients with MS the $P_{(A-a)O_2}$ was lower during sitting than supine exercise. This suggests changes in the ventilation perfusion ratios in the lungs related to high capillary venous pressure (Blount et al. 1955) $P_{(A-a)O_2}$ was related to PCV pressure in the present study (Fig. 11) After closure of the ASD the $P_{(A-a)O_2}$decreased due to a lower alveolar oxygen tension as the arterial oxygen tension was unchanged and the decrease in $P_{(A-a)O_2}$ thus depends on the absence of alveolar hyperventilation.

The $P_{a_{O_2}}$ at rest decreases with increasing age (Raine and Bishop 1963) The only respiratory variable in the group with ASD that differed between patients above and below the age of 40 was the arterial oxygen tension in the supine position. This was lower in the older group, both at rest and during exercise. It decreased, however within the normal range quoted by Raine and Bishop (1963) when age was taken in account. This probably indicates that long standing high pulmonary blood flow in patients with ASD does not accelerate any structural lung changes

Pulmonary diffusing capacity during exercise was mainly within the normal range in all three patient groups, although the mean values for MS were lower and for ASD higher than the predicted normal values. This is suggested to indicate differences in the pulmonary capillary blood volume (Bates et al. 1960 Yu 1969) Bjure (1965) found a correlation between stroke volume and D_{L-CO} in normal subjects and suggested that the stroke volume approximates the volume of the functioning pulmonary capillary bed. The D_{L-CO} during exercise was, however not affected by change in body position in any of the three groups of patients studied During exercise D_{L-CO} is thus little affected by postural changes in pulmonary blood flow and pulmonary vascular pressures. In the patients with ASD there was a small difference in D_{L-CO} from rest to exercise with increasing work loads. The exercise D_{L-CO} decreased markedly after surgical closure of the defect, suggesting a smaller pulmonary capillary blood volume.

Summary

1 The present investigation was undertaken to study how changes in body posture affect central hemodynamics, lung ventilation, alveolar gas exchange and pulmonary diffusing capacity in patients with heart disease. The patients were selected to have a large range of pressures and flows in the pulmonary circulation with an almost normal vascular resistance to flow None was in heart failure.

2. High pressures and low blood flow in the pulmonary circulation were studied in 9 patients with mitral stenosis Low pressures and low blood flow were studied in 5 patients with pulmonary valve stenosis. High pulmonary blood flow was studied in 24 patients with atrial septal defect (ASD) and 11 of these were also studied after successful surgical correction.

3 To study the influence of body posture, patients were studied in the supine and sitting positions at rest and during exercise on a bicycle ergometer

4. The central hemodynamics were studied by catheterization of the pulmonary artery and the aorta, and blood flow was measured using the direct Fick technique. The pulmonary diffusing capacity (D_{L-CO}) was measured during exercise as the diffusing capacity for carbon monoxide, using the steady state technique of Filley

5 *High pressure—low blood flow (Mitral stenosis)* The 9 patients with mitral stenosis (valve area 1.2—2.3 cm^2) and a mean pulmonary vascular resistance of 1.8 units at rest had a low cardiac output in relation to oxygen uptake both at rest and during exercise in the *supine position* (i.e. hypokinetic circulation) compared to normal subjects. The mean pulmonary capillary venous pressure (PCV) averaged 20 mm Hg and the pulmonary artery mean pressure 29 mm Hg at rest in the supine position and increased during exercise to 40 mm Hg and 57 mm Hg, respectively In the *sitting position* the circulation became even more hypokinetic. The postural difference in cardiac output was 1 2 l/min. at rest and 0.8 l/min. during exercise at a mean oxygen uptake of 0 90 l/min. The pressure level in the lung vessels decreased markedly at rest and increased less during exercise in the sitting position. The pulmonary vascular resistance was unchanged by body position. The low cardiac output in the sitting position was accompanied by a reduction in stroke volume. The relative decrease in stroke volume, after changing position, was inversely related to the right atrial and PCV pressures High pressure levels in the pulmonary circulation were accompanied by large postural pressure changes and small variations in blood flow

Total lung ventilation as well as its components *alveolar* and *dead space ventilation* increased linearly with oxygen uptake during exercise in both body positions, with no postural difference. $\dot{V}/\dot{V}$ remained unchanged after shifting position *Arterial oxygen tension* was mainly within the normal range and did not

change from rest to exercise in the supine position, but was significantly higher during exercise in the sitting compared to the supine position. The *alveolar-arterial oxygen tension difference* was positively correlated with the PCV pressure and was highest during exercise in the supine position (26 mm Hg) D_{L-CO} during exercise was mainly within the normal range, although on average significantly lower than the predicted normal value. No postural difference was found.

6. *Low pressure—low blood flow (Pulmonary stenosis)* 4 patients with tight pulmonary stenosis (valve area 0.20—0 50 cm^2) had a low cardiac output in relation to oxygen uptake at rest and during exercise in the *supine position* One patient with a moderately tight pulmonary stenosis (valve area 1.20 cm^2) and a normokinetic circulation is discussed separately The mean pressure in the pulmonary artery was 15 mm Hg at rest and 23 mm Hg during exercise (the peak systolic pressure difference, at rest, between the right ventricle and the pulmonary artery averaged 126 mm Hg) In the *sitting position* the circulation became even more hypokinetic. The postural difference in cardiac output during exercise was 0 6 l/min. at a mean oxygen uptake of 0 95 l/min. At rest the difference was 0 7 l/min (2 patients) The *pulmonary artery mean pressure* was only slightly affected by changes in position. The patient with a normokinetic circulation had a decrease in cardiac output of a similar magnitude to that found in normal subjects. The pulmonary artery mean pressure also dropped more in this patient than in the others. The relative change in stroke volume after changing body position was negatively correlated with the end-diastolic pressure of the right ventricle in the supine position.

Total lung ventilation was high in both body positions in relation to oxygen uptake due to *alveolar hyperventilation* The *dead space ventilation* was normal. The *alveolar-arterial oxygen tension difference* was normal or small and was not influenced by changes in body position. The D_{L-CO} was normal and was not affected by changes in position.

7 *High blood flow (Atrial septal defect)* The twenty four patients with great pulmonary blood flow at rest, the pulmonary blood flow increased further during exercise in the supine position. In 7/24 patients the central hemodynamic was studied in both body positions during exercise. The pulmonary blood flow in the *supine position* averaged 15 6 l/min. at rest and 26.4 l/min. during exercise at an average oxygen uptake of 1 11 l/min. and the pulmonary artery mean pressure increased from 21 mm Hg to 34 mm Hg. Pulmonary blood flow during exercise was not significantly altered by changes in position, but the interindividual variation was large Changes in the right ventricular stroke volume from rest in the supine position to exercise in both patients was considered to be mainly secondary to changes in heart rate. Pulmonary artery mean pressure during exercise averaged 7 mm Hg lower in the sitting than in the supine position. In 11/24 patients, studied 13 months after surgical closure of the ASD the left ventricular output at rest was increased in relation to oxygen uptake compared with preoperative

Total lung ventilation rose linearly with increasing oxygen uptake (up to 1.5 l/min.) at a higher level than in normal subjects, due to *alveolar hyperventilation* and thus was unaffected by changes in position. *Dead space ventilation* was normal. The ventilation during exercise was lower after surgery and alveolar ventilation became normal. *Arterial oxygen tension* was normal, except in one patient, and was not influenced by body position during exercise, either before or after closure of the ASD *Alveolar-arterial oxygen tension difference* during exercise was unchanged by posture but decreased after operation due to a decrease in the alveolar oxygen tension. The D_{LCO} was high preoperatively at rest and increased by a small amount during exercise, irrespective of body position Exercise D_{LCO} decreased markedly after operation in both positions. This probably indicates that pulmonary capillary blood volume during exercise is increased in patients with ASD but is reduced after surgery

8. The investigation has shown that in patients with low blood flow and high or low pressure levels in all lung vessels, the hemodynamics are characterized by a smaller cardiac output in the sitting both at rest and during exercise than in the supine position. The postural difference, however being smaller than in normal young and old subjects. The postural difference in pulmonary artery mean pressure increases with increasing pressure level in the supine position, particularly when pulmonary artery mean pressure exceeds 25 mm Hg. The relative change in stroke volume after shifting from the supine to sitting position varies inversely with the filling pressure of the right ventricle. This is interpreted as indicating a stabilization of the capacitance vessels. In patients with high pulmonary blood flow (ASD) there is no postural change in pulmonary blood flow and only small variations in the pulmonary pressures.

Total ventilation, alveolar gas exchange, alveolar-arterial oxygen tension difference and pulmonary diffusing capacity are little influenced by changes in body position. Thus variations in pulmonary blood flow and pressure levels influence these variables only slightly The pulmonary diffusing capacity during exercise is affected by large changes in pulmonary blood flow e.g. after surgical correction of ASD

I INTRODUCTION

1 Preface

The growth characteristics of the sympathetic nervous system are much less well-known than the growth of *e g* sensory and skeleto-motor nerves. Yet, growth of the postganglionic sympathetic adrenergic nerves can be assumed to be an important process also in the adult individual. Regeneration of adrenergic nerves after lesions of the axons as well as ingrowth of new adrenergic nerves into regenerating and transplanted tissues and organs constitutes one of the necessities for reestablishment of proper function in denervated tissues.

The relatively limited knowledge concerning growing adrenergic nerves in the organism has been due to the lack of specific histochemical methods. Earlier investigators have evaded this problem *e g* by isolating the sympathetic ganglia in tissue cultures or by using more indirect evidence for growth and regeneration such as the reappearance of the transmitter or other compounds of the axons in different organs as determined by biochemical methods. Also, non-specific nerve staining techniques have been used although it has sometimes been difficult to interprete results from such investigations.

The introduction in 1962 of the Falck Hillarp fluorescence technique for histochemical visualization of the transmitter distribution in the adrenergic nerves opened new possibilities for specific studies of these nerves in the organism. The normal extension and appearance of the adrenergic innervation apparatus could be determined with high precision at the light microscopical level. This knowledge constitutes the necessary background when growth of the adrenergic nerves is to be studied.

The present investigation is based upon transplantation of tissues to the anterior chamber of the eye in the rat (Textfig 1). When organs or tissues are transplanted, new adrenergic nerves will grow over from the host iris to the transplant. When sympathetic ganglion cell bodies are transplanted, regenerating axons will instead grow out into the iris of the host eye. This model system is investigated with the histochemical fluorescence techni-

que in combination with isotope uptake measurements and pharmacological and physiological methods.

The morphology pharmacology and function of the newly formed nerv es is described. Qualitative and quantitative information concerning rege- neration and reinnervation by adrenergic nerves in the adult animal is obtained. The specificity of the growing nerves vis-a-vi the effector organs as well as problems concerning the regulation of growth and factors that influence growth will be elucidated.

2. Founders of the present concepts of neuronal ontogeny and growth

In 1839 Schwann put forward a theory of nerve fibre formation, the s.c. "cell-chain hypothesis" stating that one nerve fibre originated by fusion of several aligned cells. This idea survived for several decades but was successively replaced by the "outgrowth theory according to which all peripheral nerves originate from the central nervous system from which the fibres (not cells) grow out into the periphery Bidder and Kupffer (1857) realized that the fibres of the white matter of the spinal cord derived from the cells of the grey matter Kölliker (1879) concluded that Schwann cells and nerve fibres were of different origin and His (1887) postulated that each nerve fibre derives from a single cell, the neuroblast. Later on Cajal definitely settled the question by giving strong evidence to the now generally accepted "neuron doctrine" formulated by Waldeyer (1891) Cajal also introduced the concept of "neurotropism — Chiefly through the monumental work of Cajal (1928) using the Golgi (1873) tech nique, the classical histological features of nerve degeneration and regene ration were established. Cajal was able to demonstrate not only axons but also dendrites and the principle organization of these elements in relation to the cell bodies in his embryological studies on the chick embryo spinal cord

generates. New nerves grow over from the host iris to the transplant.

c. Standard ganglion transplantation. The superior cervical ganglion is extirpated and transplanted to the anterior chamber of the ipsilateral eye. The original plexus of adrenergic nerves in the host iris degenerates. New nerves grow out from the transplanted ganglion and reinnerv te the host iris.

d. Ganglion transplantation to an intact eye. The superior cervical ganglion is extirpated and transplanted to the anterior chamber of the contralateral eye. The normal plexus of adrenergic nerves in the host iris is thus left intact. New nerves will grow out from the transplanted ganglion but to a much smaller extent than in model 3

(1890). Experimental neuroembryology was further developed by Harrison using amphibians and transplantation techniques. Harrison also developed the technique of tissue culture and was able to show that nerve fibres can grow out without Schwann cells or any other cellular support (Harrison 1910). Spiedel (1932, 1933) in his "studies on living nerves" fully confirmed the findings of Harrison and vividly described the ameboid movements of the advancing axon tips. Weiss introduced the concept of "contact guidance" (1941) as a complement to the theory of "neurotropism" put forward by Cajal. Weiss and Hiscoe (1948) convincingly demonstrated the axonal flow which was shown to occur continuously also in mature nerve fibres.

3 Early studies on regeneration of sympathetic postganglionic neurons

As late as 1960 Hillarp, in his comprehensive review on peripheral autonomic mechanisms, had to state: "The data hitherto reported concerning the various aspects of regeneration in the autonomic nervous system are incomplete, unsystematic and often highly contradictory". This is especially true of postganglionic sympathetic nerves because most earlier studies have dealt with regeneration of preganglionic fibres and the reestablishment of ganglionic transmission (Langley 1895, see also *e.g.* Lee 1930, Brücke 1931).

Regeneration of the postganglionic sympathetic nerves after axotomy above the superior cervical ganglion has been studied functionally by following the disappearance of Horner's syndrome (Horner 1869), the temperature changes of the ear and the response to stimulation of the preganglionic trunk in cats and rabbits (Tucket 1895—96, Langley 1897, Mashida 1929, Simeone 1938, see also review by Guth 1956). It can be concluded from these investigations that although a number of neurons succumb to the close axotomy, regeneration does occur. It takes, however, much longer time than preganglionic regeneration and is often incomplete. Histological examinations have been few. Mashida (1929) described regenerating fibres at the site of lesion above the superior cervical ganglion at the 14th day postoperatively. Ingrowth of regenerating sympathetic fibres into scar tissue was likewise observed by de Castro (1931).

Observations of growing sympathetic nerves in the living state were described by Matsumoto (1920) using vitally stained tissue cultures. Remarkably this investigator observed movements of mitochondria and vitally stained granules within the nerve fibres and stated that the granules

"exhibited considerable movement, especially in a longitudinal direction along the fibre and at the periphery" — perhaps an early description of axonal flow in growing sympathetic neurons.

Marinesco and Minea (1907) and Marinesco (1907) have described homologous transplantations of sympathetic ganglia subcutaneously or into the liver. The ganglion cells were reported to survive for a few days after which neurofibrillar degeneration began. Newly formed sprouts were not described. Similar experiments were subsequently performed by Cajal and Cardenal (Cajal 1928). To quote Cajal: "Since the experiments of Marinesco, Cardenal and ourselves have made some attempts at grafting sympathetic ganglia with not very brilliant results. In general if the ganglion comes from a young animal, the cells retain their condition well until eight or ten days after the operation. As in the spinal ganglia, the central neurons become necrobiosed; on the other hand, two or three rows of the marginal cells maintain their normal stainability and structure, and fine and pale neurofibrils are visible. The method of Nissl shows in the protoplasm delicate chromatin granules. It is difficult to establish whether among the expansions seen some are newly formed. Cajal, however concludes: "the sympathetic ganglia survive grafting, like the sensory cells of spinal ganglia. Like them also they are capable of producing, though less abundantly, sprouts, balls, and other structures and phenomena that reveal an attempt on the part of the neuronal protoplasm to accomodate itself to the abnormal environment and to turn it to the best account. Perhaps it is the satellite cells that take the initiative in this compensatory reaction; their number is much increased in the cells in which supcapsular expansions are formed."

4 Transplantation technique

The technique of tissue transplantation suggests itself as a tool for experimental *in vivo* studies when investigating the growth characteristics of adrenergic nerves.

Various transplantation techniques were tried on rats in an explorative survey of different possibilities. The purpose was to find simple, reproducible models where results could be quantitated in terms of amount of reinnervation. It should also be possible to study the influence of various experimental procedures on the nerve growth as well as the pharmacology and function of these nerves.

The anterior chamber of the eye has been widely used as a site of transplantation both in lower and higher animals. It offers a series of

advantages when compared to other areas used for transplantation such as the spleen, renal capsule, omentum rectus muscle or subcutis. The anterior chamber provides a suitable space which does not become obliterated by proliferating connective tissue. The condition of the transplants can be continuously followed in the living animal through the cornea. The aqueous humor constitutes a relatively good nutritive milieu and local injections can be performed. Furthermore, it is known since long that the eye is an immunologically privileged site (see Woodruff and Woodruff 1949 Raju and Grogan 1969 Waltman Burde and Faulkner 1969) and transplantations to the anterior chamber have therefore been used for a number of purposes such as endocrinological (e g Schochet 1920 Goodman 1934 Falck 1959) or to study heterologous tumor growth (see Krementz and Greene 1953).

It was soon found that an autologous transplantation of the left iris to the right eye in the rat performed as described in IL2 constituted a reproducible model for reinnervation studies and that the graft as well as the host iris could be easily studied with the fluorescence technique by means of stretch preparations. As described in a preliminary report (Malmfors and Olson 1967) a new adrenergic ground plexus was formed in the transplant under these circumstances. Transplantation of sympathetic ganglia were also tried initially In spite of the close axotomy the ganglion cells were found to respond with a vigourous regeneration when transplanted to the ipsilateral, and hence sympathetically denervated, iris of the host eye.

The promising results from the initial iris and ganglion transplantations prompted experiments with a large variety of other tissues (see VIII) Out of the different transplantation experiments tried it was decided to use the iris and the superior cervical ganglion transplantations to the anterior chamber for a closer investigation of some qualitative and quantitative aspects of the nerve growth.

5 Aim of the present study

Summarizing the introductory paragraphs above the following fields of interest of the present study can be listed:

1 The possibilities for growth of sympathetic adrenergic nerves into transplanted tissues or from transplanted ganglia to its local surroundings in the adult animal.

2. A qualitative morphological description of the growing adrenergic nerves reinnervating different tissues.

3 A quantitative determination of the rate of growth of the adrenergic nerves.

4 The transmitter pharmacology of the newly formed nerves with regard to the uptake, storage and release of NA.

5 The possible influence on the nervous growth rate of different experimental and pharmacological procedures.

6 The reestablishment of functional neurotransmission between the newly formed nerves and the reinnervated tissues.

II MATERIAL AND METHODS

1 Animals[1]

About 1700 adult albino rats of the Sprague-Dawley stem were used. Females weighing mostly 200 g were used except when the experiments required the use of males. In comparative experiments a few mice (NMRI) hamsters and newborn rats were used. These animals were also albinos.

2. Transplantation techniques

Autologous transplantation of the iris to the anterior chamber of the contralateral eye.

This method will be described in detail. Other methods will be described only to the extent that they differ from the following scheme. The animal was anaesthetized with ether and the vibrissae cut off. The right eye was atropinized (1 drop of atropine, 10 mg/ml, applied to the cornea). The left eye was removed and a haemostatic gelatin pad was placed in the orbit and the eyelids clipped together. The eyeball was carefully washed with cold sterile Ringer solution and the iris[2] dissected free (Malmfors 1965a) on an ice-chilled glass plate, covered with Krebs-Ringer solution.

The right eye and its surroundings were carefully washed with sterile Ringer solution. A small incision, 2—3 mm long, was made obliquely to the surface of the cornea of the right eye with a small piece of a razor blade in a peang. The incision was made slightly anterior to the corneo-scleral junction. Cutting of the iris was avoided since the atropine treatment now caused maximal dilatation of the iris.

The isolated left iris was cut radially once and carefully sucked up together with Ringer solution as a string into a thin specially grounded

1 The term *normal* will be used in the following only to define the situation in unoperated and otherwise untreated animals when compared to operated or otherwise treated while the term *control* has different meanings in different experimental set-ups.

2. In the following, "iris" refers to the iris proper and the ciliary body which were always handled as one piece.

Pasteur pipette. The oblique, blunt tip of the pipette was inserted into the corneal slit and the transplant was injected into the anterior chamber of the recipient eye by means of a rubber stall attached to the pipette. The injection of a transplant in Ringer solution approximately restored the intraocular fluid volume after the loss caused by the corneal incision. When sometimes too large a volume was injected, the excess drained away when the pipette was slowly withdrawn. As the pipette was removed, the corneal slit closed immediately and the transplant could be manipulated into the desired position along the lateral margin of the anterior chamber by application of slight pressure to the cornea.

All operative procedures were performed under dissection microscopes, using sterile instruments, preparative plates and solutions. Homologous iris transplantations (from one rat to another) were performed in a similar way

Transplantations of sympathetic ganglia to the anterior chamber

The superior cervical ganglion was transplanted either auto- or homologously and either into an intact or into a sympathetically denervated eye. The ganglion was carefully exturpated, its capsule opened and carefully peeled off and the preganglionic and the two postganglionic nerve trunks cut close to the ganglion. It was then divided longitudinally with a razor blade. The two halves were sucked up into the transplantation pipette and injected into the anterior chamber of the recipient eye as described above. They were manipulated to diametrically opposite positions over the iris and away from the corneal slit.

Other sympathetic ganglia which were transplanted in a similar way included the lumbar sympathetic chain ganglia, th coeliac ganglion and some of the small hypogastric ganglia innervating the vas deferens. Smaller ganglia were neither decapsulated nor divided before being transferred to the anterior chamber When ganglia were transplanted to intact eyes (*cf* Textfig 1) the eyes were sometimes sympathetically denervated 24—48 hrs before preparation by exturpation of the ipsilateral superior cervical ganglion. In this way only the adrenergic nerves belonging to the transplants were seen in the fluorescence microscope.

Transplantations of other tissues to the anterior chamber

Small pieces of several other tissues were prepared for transplantation and injected as described above. Adrenal medulla: After decapsulation the adrenal medulla was prepared free from the cortex. Transplants were trimmed to a size of about $^1/_1 \times {}^1/_3 \times 2$ mm. Salivary gland: Small pieces from decap-

sulated apical lobules of the submaxillary and sublingual glands were trimmed to the same size as the adrenal medulla. Smooth muscle strips: Thin strips, about 3 mm in length, were prepared from the following tissues: Small intestine: The outer longitudinal and inner circular muscle layers with the plexus of Auerbach in between was peeled off from the mucosa and used for the strips. Vas deferens: After removal of the serosa and mucosa, strips were prepared by two longitudinal radial cuts so that each strip contained a thin part of the whole width of the muscle layer. Portal vein: 5 mm longitudinal strips were taken from the vein. They included the external longitudinal muscle layer which is present in this vessel. Uterus: After removal of the endometrium, longitudinal strips were prepared from one horn of the organ.

Transplantation of the anterior half of the eye.

The eyeball was removed and divided just behind the corneo-scleral junction. The lens and lens capsule was removed from the anterior half. The remaining anterior part of the eye, including the iris, was then placed in the required position and glued to the underlying tissues by applying a small amount of plastic adhesive (isobutylcyanocrylate I. Ethicon Inc., U.S.A.) around the cut edge of the sclera, thereby connecting it to the underlying tissues. The anterior part of the eye was transplanted in this manner to 1) the decapsulated surface of the submaxillary gland, 2) the cut end of the vas deferens, and 3) the proximal stump of the cut sciatic nerve.

Transplantation of the superior cervical ganglion to other locations.

By means of the described glass pipette decapsulated ganglia were transplanted to 1) the subconjuctival tissue of the eye, 2) the sciatic nerve through a small whole in the epineurium to the inner part of the nerve.

3 Postoperative in vivo observations

By using a dissection microscope, the anterior chamber of the eye can be easily examined in the living animal keeping the animal slightly anaesthesized with ether. Thus, the condition of the aqueous humour, sclera, cornea, lens and the iris of the recipient eye as well as the transplant could be followed. The typical changes following a transplantation and the various complications which sometimes occurred were the following.

Twenty four hours after the operation most transplants had a dark blue-red colour. At the same time the plexus of blood vessels in the

host iris became more prominent while the cornea was somewhat blurred and whitish. No vascular connection between the transplant and host iris could be observed.

The pattern was similar after 48 hrs. The vascular reaction in the host iris persisted. The colour of the transplant was, however often much weaker

Four days after the transplantation, most eyes were clear and without signs of irritation. The transplants were vascularized by vessels running in thin tissue strands between the host and the transplant. The circulation of individual red blood corpuscles could be directly observed. The vascularization of the transplant became more prominent during the following days. This pattern then remained even during the longest periods studied (10 months)

Aberrations from the described scheme sometimes occurred. The complications were of varying seriousness but a few eyes (1 to 3) from each experiment (*e g* 20 eyes) were often excluded. Aberrations included

a. Faulty localization of transplant: The transplant was sometimes distorted or fastened at the pupil edge or even below the host iris, instead of being located at the ideal site above the host iris, at its peripheral border Rarely no connections at all were established with the host iris, and the transplant then became vascularized via the cornea, which in turn had become vascularized itself

b. Lens damage: This probably occurred when the edge of the razor blade injured the lens or after an infection. The lens became white and opaque and was later partially resorbed.

c. Intraocular bleeding: Bleeding was encountered if the host iris was injured with the edge of the razor blade. A small haemorrhage was soon resorbed. Heavy bleeding, apart from making the injection of the transplant difficult, caused fibrotizations and impaired nutrition of the transplant. Such eyes were always discarded.

d Infections: Sometimes the blurred cornea never cleared up after the transplantation and the content of the anterior chamber became opaque and deep red blue as a sign of an infection. The transplant remained discoloured and the cornea became vascularized. The fate of the infections varied but sometimes caused prolapses, micro-ophtalmy or macro-ophtalmy fibrous and changes of all components of the eye. Such eyes were always discarded.

4 Dissection procedures

At the time of sacrifice the eye was rapidly exturpated without compressing the eyebulb since this might reopen the corneal scar and cause the eye to collapse, especially after short post-operative periods. All dissection procedures were performed on ice-chilled plates covered with Krebs-Ringer solution. The eye was divided and the host iris and ciliary body with its attached transplant(s) freed from the anterior half of the eye in the same way as used for the routine preparations of irides (Malmfors 1965a) The host iris and the transplant were separated by tearing the two pieces apart using fine tipped watch makers tweezers. Usually this did not damage the tissues since the connective tissue bridges between the host iris and the transplant were fragile and thus broke up first. Sometimes, however a slight damage of the host iris was unvoidable especially after long postoperative intervals. When irides had been transplanted, the iris transplants had to be unfolded. This was done on a glass slide under a *high magnification stereoscopic microscope and using the fine tweezers.* By letting an identified part of the transplanted iris dry and thus fasten to the slide, the rest could usually be unfolded and stretched so that the transplant resembled a stretch prepared iris from a control animal. However a certain reduction in size of the dried and stretched specimen was always noted. If an *in vitro* incubation was to be done, the unfolding was performed after the incubation.

5 In vivo treatment with drugs

The number of animals doses and times before killing are given in the respective chapters. The following drugs were administered *in vivo* either acutely in single doses or chronically in repeated doses during several days.

(—)—NA bitartrate monohydrate (Sigma): i v

Nialamide (Niamid® Pifzer) i.p.

Reserpine (Serpasil® Ciba) i p.

H44/68 the methylester of (±)-α-methyl p-tyrosine (doc. H. Corrodi AB Hässle) i.p

H59/64 the methylester of 3,α-dimethyl tyrosine (doc. H Corrodi AB Hässle) i p.

H56/28 1-(0-allylphenoxy) 3 isopropylamino-2 propanol (doc H. Corrodi, AB Hässle) i.p

Desipramine hydrochloride (Petrofran® Geigy)

Phenoxybenzamine hydrochloride (Dibenzyline® S K F)

Phentolamin methansulfon (Regitin® Ciba)
Isoproterenol sulphate.

All drugs except nialamide and reserpine were dissolved in 0.9 per cent sodium chloride and calculated as the salts. NA was calculated as the free base.

6. In vitro incubations

In most transplantation experiments the irides of the host eyes and the transplants when these consisted of ganglia or irides and the control irides were incubated in a medium containing ^{3}H NA. The tissues were transferred to an ice-chilled medium which consisted of a Krebs-Ringer bicarbonate buffer (in g/liter: NaCl 6.92, KCl 0.35, $CaCl_2$ $6H_2O$ 0.28, KH_2PO_4 0.16, $MgSO_4$ $7H_2O$ 0.29, $NaHCO_3$ 2.10; ascorbic acid 0.2, glucose 1.8). Incubations were performed for 30 min at 37° C in a metabolic shaker using 1 ml of the medium, pH 7.4, saturated with 93,5 per cent and 6.5 per cent CO_2 and in an atmosphere of the same composition. Unlabelled medium contained 10^{-6}—10^{-7} *l* NA. Labelled medium contained 10^{-6}—10^{-7}M *d,l* NA with added *d,l* 7-^{3}H NA (New England Nuclear Corp. Boston, Mass. specific activity 1—2 and 5—10 C/mM respective). The tissues were rinsed for 10 min in isotope-free buffer. In some experiments the tissues were preincubated in 10^{-4}M DMI for 15 min before the addition of NA. For further details of the *in vitro* technique, see Hamberger 1967 and Jonsson, Hamberger, Malmfors and Sachs 1969. Following the incubation irides were prepared as whole mounts for fluorescence microscopy as described below. The ganglia incubated were directly combusted or solubilized for radioactivity determination (see below).

7. Histochemistry

The fluorescence method of Falck and Hillarp (development of the present method: Ehringer 1955; Falck, Hillarp, Thieme and Torp 1962; Falck 1962; Carlsson, Falck and Hillarp 1962; Falck and Owman 1965; Hillarp, Fuxe and Dahlström 1966; Hamberger 1967; Corrodi and Jonsson 1967) was used on two types of preparations. 1. Stretch preparations. All irides, including the transplants were treated as stretch preparations according to Malmfors (1965a). 2. Freeze-drying. All tissues except irides were freeze dried in a simple high capacity freeze-drier (Olson and Ungerstedt 1970) which gives good preservation of morphology with short drying times. Specimens were then reacted with formaldehyde of optimum humidity (Hamberger 1967) and embedded in paraffin *in vacuo* before manipulation.

of the individual tissue pieces took place The specimens were then further embedded, sectioned (8μ) and mounted for fluorescence microscopy

8 Isotope measurements

More than 95 per cent of radioactivity recovered in the rat iris after incubation in ^{3}H NA as described above is due to ^{3}H NA (Jonsson, Hamberger Malmfors and Sachs 1969) The corresponding value for ^{3}H NA incubated ganglia has been estimated to be about 80 per cent (unpublished results) The total radioactivity in the incubated specimens was therefore used as a measurement of the ^{3}H NA-content in most cases.

After fluorescence microscopy the irides were scraped off the slides with a razor blade and the radioactivity determined (Olson Hamberger Jonsson and Malmfors 1968) In most cases, specimens were combusted to water and CO_2 in an oxygen atmosphere and the radioactivity determined (Gupta 1966, Maurer 1968) in a liquid scintillation spectrometer (Packard Tri-Carb 3002) Two others means of determining the total radioactivity were also used In the early experiments, irides were homogenized in butanol/hydrochloric acid and an aliquot of the extract counted in a toluene-ethanol scintillation solution (see Jonsson, Hamberger Malmfors and Sachs 1969) This method showed the same good recovery as the combustion technique. Recently a new simple technique with high efficiency was introduced. The specimens were dissolved in 0.5 ml of a special sample solubilizer containing a strong organic base (Soluene™ 100 Packard Instr Co) directly in the counting vial. The technique was applied to the latter part of the present study It was found that dried specimens treated with paraformaldehyde gas required a longer solubilization time than fresh tissues and they were thus left over night at 50°C in the solubilizer whereafter they were usually completely dissolved. Ten ml toluene scintillation solution was then added.

9 Evaluation of fluorescence microscopical judgements

For quantitative estimations of the amount of nerves on the irides the fluorescence method was combined with ^{3}H NA incubations (see II.8 and Olson Hamberger Jonsson and Malmfors 1968) The stretch preparations were always coded often looked upon by both authors independently and always compared to irides from normal animals. The accuracy of the fluorescence histochemical estimations of amounts of nerves was tested by th following experiment

Partial denervations of irides were performed by bilateral excision of smaller or larger parts of the superior cervical ganglion in 15 rats 1 7 or 14 days before killing. The irides were incubated in ^{3}H NA and then prepared for fluorescence microscopy The amount of nerves remaining in the partially denervated irides was estimated and expressed as a percentage of the normal content (*cf* Fig 1) Finally the irides were scraped off and the radioactivity determined. Correlation coefficients were calculated for the judgements of the two authors, and for the mean percentage of nerves in each individual iris compared to the amount of radioactivity found. All these coefficients were found to be high, the latter *e g* 0.91 and the former even higher

When the three postoperative times were compared to each other the percentage estimations of remaining nerves were approximately 50 per cent after 1 day 30 per cent after 7 days and 55 per cent after 14 days. This pattern is suggestive of an initial degeneration of damaged neurons during the first week and a compensatory hypertrophy of the remaining nerves during the second week ("collateral sprouting see Murray and Thompson 1957a) Since all three groups were equally well correlated to their respective ^{3}H NA uptake values, the experiment indicates that also the growing nerves have an essentially unchanged ^{3}H NA uptake.

It thus seems that in the partially denervated irides the number of nerves can reliably be subjectively estimated by a trained observer The uptake of ^{3}H NA was also very well correlated to the estimated amount of nerves in these partially denervated irides within the whole range from 0 to 100 per cent, which further support the accuracy of the quantitative estimations of the number of fluorescent nerves. It cannot *a priori* be assumed that the uptake of NA in the growing nerves of *e g* the iris transplants and the reinnervated irides is the same as that of the fully developed nerves but the partial denervation experiments make such an assumption likely Thus, if there is a high correlation between the two parameters also in the transplantation experiments, the uptake of ^{3}H NA can be used as a measurement of the amount of nerves. The isotope-parameter is easily obtained from irides, and is the only one easily obtainable in other organs than those which can be stretched as whole mounts.

In the host irides of th iris transplants it was early observed that the plexus of fluorescent fibres was denser than in a normal iris. This hyperinnervation had to be estimated and correlated to the uptake of ^{3}H NA. These estimations were more difficult to perform than those performed after partial denervation. The hyperinnervation was, however

of the individual tissue pieces took place. The specimens were then further embedded, sectioned (8μ) and mounted for fluorescence microscopy

8 Isotope measurements

More than 95 per cent of radioactivity recovered in the rat iris after incubation in ^{3}H NA as described above is due to ^{3}H NA (Jonsson Hamberger Malmfors and Sachs 1969) The corresponding value for ^{3}H NA incubated ganglia has been estimated to be about 80 per cent (unpublished results) The total radioactivity in the incubated specimens was therefore used as a measurement of the ^{3}H NA-content in most cases.

After fluorescence microscopy the irides were scraped off the slides with a razor blade and the radioactivity determined (Olson Hamberger Jonsson and Malmfors 1968). In most cases, specimens were combusted to water and CO_2 in an oxygen atmosphere and the radioactivity determined (Gupta 1966 Maurer 1968) in a liquid scintillation spectrometer (Packard Tri-Carb 3002). Two others means of determining the total radioactivity were also used: In the early experiments, irides were homogenized in butanol/hydrochloric acid and an aliquot of the extract counted in a toluene-ethanol scintillation solution (see Jonsson, Hamberger Malmfors and Sachs 1969) This method showed the same good recovery as the combustion technique. Recently a new simple technique with high efficiency was introduced. The specimens were dissolved in 0.5 ml of a special sample solubilizer containing a strong organic base (Soluene™ 100, Packard Instr Co) directly in the counting vial. The technique was applied to the latter part of the present study It was found that dried specimens treated with paraformaldehyde gas required a longer solubilization time than fresh tissues and they were thus left over night at 50°C in the solubilizer whereafter they were usually completely dissolved. Ten ml toluene scintillation solution was then added.

9 Evaluation of fluorescence microscopical judgements

For quantitative estimations of the amount of nerves on the irides the fluorescence method was combined with ^{3}H NA incubations (see II.8 and Olson Hamberger Jonsson and Malmfors 1968). The stretch preparations were always coded, often looked upon by both authors independently and always compared to irides from normal animals. The accuracy of the fluorescence histochemical estimations of amounts of nerves was tested by the following experiment

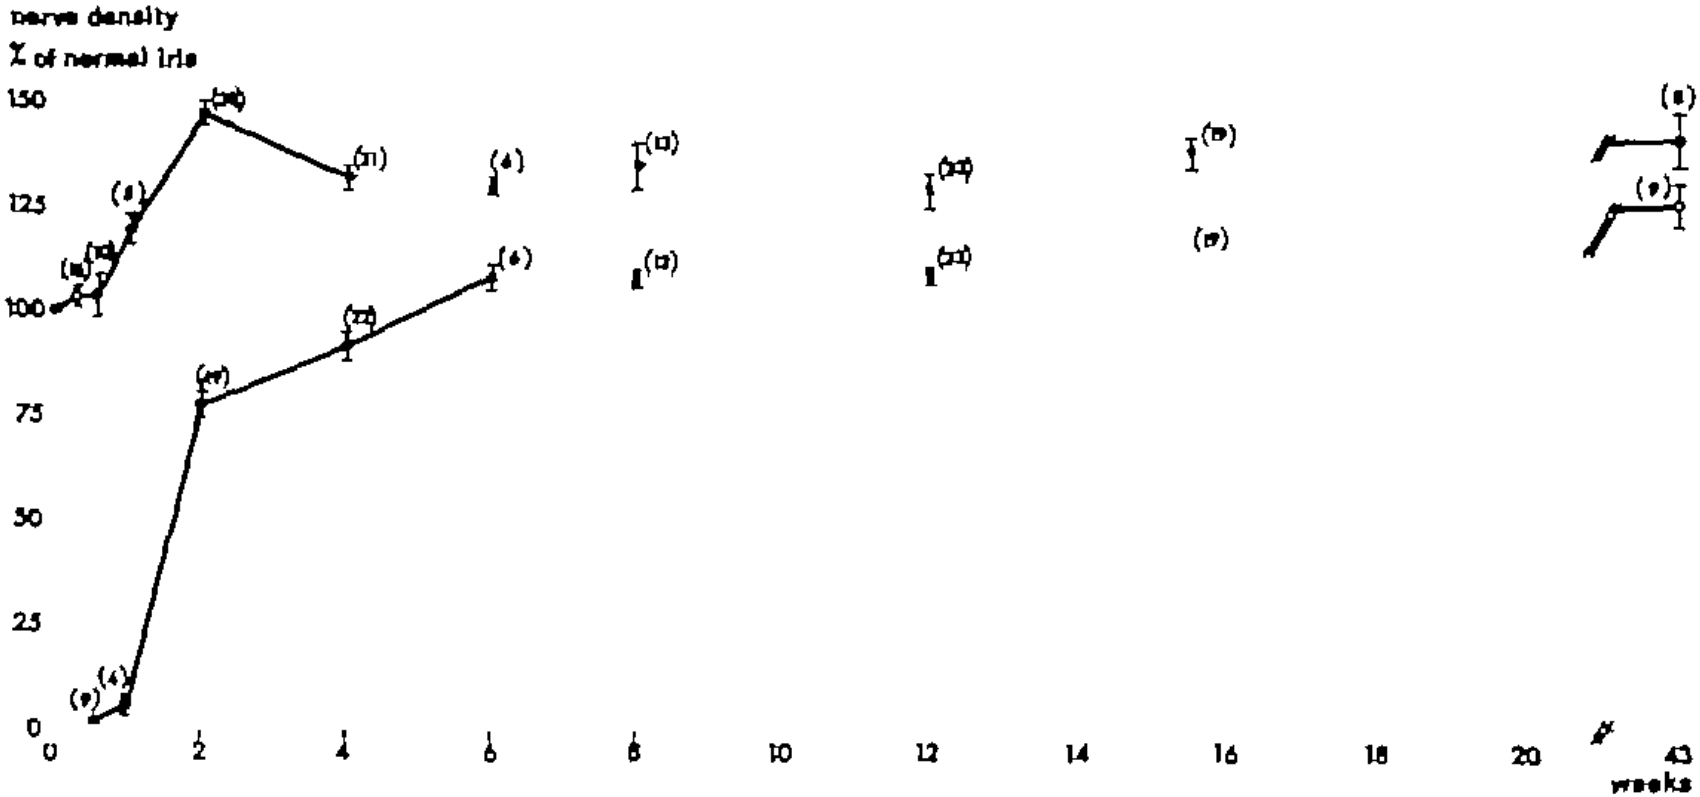
III REINNERVATION OF IRIDES TRANSPLANTED TO THE ANTERIOR CHAMBER OF THE EYE

Initial experiments showed that an iris grafted to the anterior chamber of the contralateral eye received a new plexus of adrenergic nerves which grew out from the adrenergic nerve plexus of the host iris (Malmfors and Olson 1967) It was decided to use this experimental model in a closer investigation of the fluorescence morphology of the outgrowing adrenergic nerves and to quantitate the rate of outgrowth both with the histochemical and the biochemical techniques described. Furthermore, the observed hyperinnervation of the host irides called for a closer examination. For *in vivo* observations of the eye after transplantation refer to II.3

1 Time course of reinnervation of iris transplants and the effects on the host irides

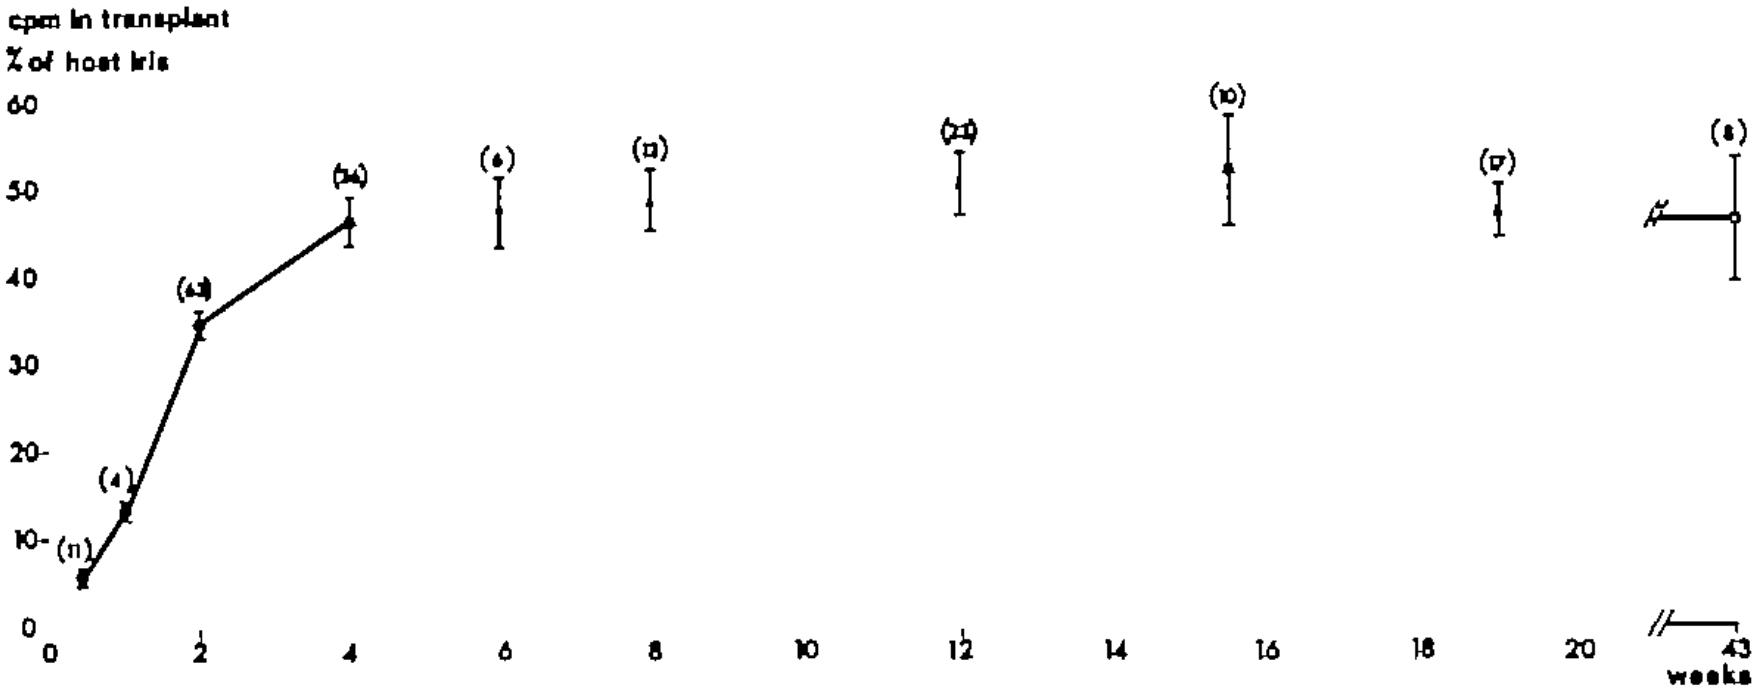
Fluorescence microscopy (see Textfig 2)

Two days after the transplantation no clear effect on the host iris was noted. It was thus seldom possible to differentiate between host and control irides in the coded slides (Fig 2, 3) No fluorescent nerve fibres could be found in the transplanted iris at this time.



At four days, a reactive change in the host iris could be seen. While some of the host irides already showed a tendency of hyperinnervation (see II 9) *i* a somewhat denser plexus of fluorescent fib es than normally found, others had instead areas where the plexus of fluorescent nerves was less pronounced. Moreover the fluorescence intensity of the host irides was often slightly lower than normally The first few arborizing fibres were constantly found in the 4 days old transplant. At this time, a new circulation was also reestablished as described in II.3 The ingrowing fibres looked thinner and had a weaker fluorescence intensity than the adrenergic nerve terminals of the host iris. They were rather smooth with irregularly spaced small ovoid enlargements and were sometimes found to terminate with small drop-like enlargements.

One week postoperatively a slight hyperinnervation was evident in host irides. In the transplants, small areas of plexus forming nerves were found at about 2—6 different sites, and were judged as representing roughly 5—10 per cent of the normal number of nerves (Fig 5) The nerves forming a plexus now looked more like the varicose nerve terminals found in irides from normal animals.



After two weeks the hyperinnervation of the host irides was judged as representing 150 per cent of the normal density (Fig 7 9) The network of nerve terminals was denser and in addition to this a second, wide-meshed plexus of fluorescent axon bundles and single axons was observed, especially towards the sphincter margin. The iris transplants had a well developed plexus of varicose adrenergic nerves. The plexus covered the whole iris in most specimens. The variation in density observed was due to the differing size of the meshes in the fibre network and to the number of fibres in each strand. The average density of the plexus was judged as about 80 per cent of the normal density with a range of 50 to 100 per cent (Fig 6 8) Axon bundles were found in the host irides. They could be followed through the connective tissue strands between the host and transplants when stretch preparations were made without separation of the two irides *cf* (Fig 4 5) These bundles were seen giving off branches over the transplant. The fluorescence morphology of the individual non terminal axons in the connections was characterized by bulgy and somewhat irregular ovoid enlargements with varying, but comparatively short, thinner parts in between The fluorescence intensity of the axons was almost as high as that found in the nerve terminals of normal irides.

At two weeks it was still relatively easy both to separate the transplant from the host iris and to unfold the transplant and make a stretch preparation. The sphincter margin the dilator area, the ciliary body and parts of the choroid were easily identifiable also in the transplant. The adrenergic innervation at the border between the ciliary body and the choroid is very specifically organized with short, radially running, almost parallel single fibres which end without any ramifications and all at the same distance from the ciliary body This pattern was exactly reestablished in the transplants (*cf* Fig 36)

In preparing and stretching the transplants it was invariably noted that the total areas of the transplants had decreased in spite of good stretching This decrease became more marked at longer times and was probably mainly due to the difficulties in unfolding and stretching older transplants. An actual loss of specific tissue mass might however also very well have occurred

2. Time course of reinnervation of irides autologously transplanted to the anterior chamber and the effect on the host irides as observed in the fluorescence microscope. The density of the nerve plexus after different times was estimated on coded slides as per cent of the density in normal irides (see II.9). At each point the mean ± s.e.m. is given. Number of observations within brackets. Upper curve: Host irides. Lower curve: Iris transplants. The first few fluorescent fibres were found in the transplants after four days (seven out of nine transplants)

4 Ratio between the radioactivity recovered in irides autologously transplanted to the anterior chamber and their respective host irides after incubation in ^{3}H NA (10^{-5}M 30 min plus 10 min rinsing). From each eye, the cpm found in the transplant is expressed as per cent of the cpm in the host iris. At each time point, the mean ± s.e.m. is given. Number of eyes within brackets. When the values are expressed in this way the small variation in the mean ^{3}H NA uptake of normal irides between different experiments does not influence the curve (*cf* Textfig 2, 3 5 and 6).

the relative growth rates of the nerves in the two irides. After a rapid increase this ratio levels off between 45 and 50 per cent from the fourth week on.

Homologous iris transplants were reinnervated in the same way as the autologous transplants described above. In a few experiments four irides were transplanted to one eye. All four transplants became reinnervated. After two weeks the total amount of nerves in the quadruple transplants clearly exceeded that of a single transplant.

2. Control experiments (see Table 1)

The hyperinnervation reaction of the host irides was first detected after iris transplantations. It was soon realized, however that the host irides reacted with a hyperinnervation following all types of transplantations, even when using non innervated tissues although these transplants remained non innervated (except for the vessel innervation). Furthermore, eyes showing signs of mild infection often revealed a more pronounced hyper innervation. However a serious and lasting infection led to a "less than normal" picture regarding all the three parameters, *i e* the number of nerves, their fluorescence intensity and the ^{3}H NA uptake.

Table 1

^{3}H NA uptake and density of the adrenergic nerve plexus in irides of control experiments.

Results are expressed as per cent of the corresponding values from irides from untreated animals in the same experiments ± s.e.m

Operation	Postoperative time (days)	number of irides	open	nerve density
Sham operations	14	8	100±14	114±8
Control side of unilateral homologous iris transplantation	28	6	104±9	100±0

It seemed feasible that at least a part of the increased number of nerves was due to the fibres growing over to the transplant. It could also be speculated that the same "factor" that caused nerves to grow into the transplant and make new terminal arborizations there also affected the nerves in the host iris. Finally as judged from the response to mild infections it seemed possible that even in the absence of any transplant the eye could react to a local irritation with an increase in the density of the adrenergic nerve plexus in the iris.

Two types of experiments were performed

1 Sham operations. These included all steps of the normal transplantation procedure except that the pipette contained only the Ringer solution when introduced into the eye.

2. Unilateral homologous iris transplantations where the irides of the unoperated eyes were compared to irides from normal animals.

The described operations did not cause any noticable mean change of the total uptake of ^{3}H NA in the irides (Table 1) A slightly increased variation between individual irides was however often encountered. This increased variation was reflected also in the fluorescence microscopical judgements. In the case of unilateral homologous iris transplantations the irides of the non-operated side were completely unaffected.

3 Discussion

The *in vivo* observations made it possible to follow the posttransplantation changes that occurred in the anterior chamber of the eye as well as in the transplant. Except for severe infections in a few cases, the tissue reactions were minor and fairly constant. During the first one to two days the transplant apparently had to rely upon nutrition from the aqueous humor while later a blood circulation was reestablished in the transplant. Any permanent changes in the transplanted tissue which might have occurred during the period of circulatory arrest was not examined in detail. It could however be expected that the thin iris would survive the transplantation well and there was no marked reduction in size of the transplant after longer times. The morphology of the transplant was always recognizable. Furthermore, also the thicker transplants used in this study clearly showed survival of e g smooth muscle cells (see VII) Not only autologous, but also homologous transplants survived well and showed no macroscopical signs of immunological responses.

The detachment of the iris to be transplanted from its normal site causes complete axotomy of all its nerves since no nerve cell bodies have been observed within the rat iris. Axotomy is known to be followed by a rapid disappearance of both adrenergic and cholinergic nerves (Malmfors and Sachs 1965a, Ehinger and Falck 1966, Roth and Richardson 1969) and probably also of other types of nerves possibly present. Consequently two days after transplantation, no fluorescent nerves could be found in the transplant.

Concomitantly to the reestablishment of circulation the first fluorescent nerves appeared in the transplant around the fourth day. These nerves could thus be safely regarded as *new* nerves. In fact, the new nerves could sometimes be followed all the way from the host iris through the connective tissue strands to the transplant.

Fluorescent growth cones (*cf* Blümcke and Niedorf 1965, Dahlström 1965, Malmfors and Olson 1967) were sometimes observed at the growing tips but the advancing fibres showed great morphological variations. It seems highly probable, that the fluorescence method reveals also the growing sympathetic nerves to their full extent (see Olson 1969).

From the attachments with the host iris the nerves grew to different parts of the transplanted iris. There seemed not to be any preferential direction or localization of the growing nerves. After the establishment of vascularization during the first week the growth rate increased to reach its highest level during the second postoperative week. After two weeks the iris transplants were well supplied with nerves and the growth slowed down as if the stimulus for growth had now decreased. It is less likely that a limited growth capacity caused the growth rate to slow down as judged from the experiment where four irides were transplanted to one eye. The total amount of nerves found in the four transplants of one eye clearly exceeded that found in the control with one transplant after the same time.

The exact origin of the new nerves could not be determined. It seems likely however that they were formed anywhere along the axon trees of the host iris, either as arborizations or as elongations of the very ends of the terminals (*cf* Fig 1).

At six weeks, the density of the nerve plexus in the transplant was similar to that of a normal iris while the uptake studies indicated only 70 per cent of the normal amount of nerves.

However the discrepancy between the fluorescence and isotope uptake parameters found can be explained if one considers th t the iris transplant had decreased somewhat in size. It therefo e contained a normal density

of fluorescent nerves but a smaller amount of fibres. After six weeks there was no further growth of the nerves. It thus seems as if steady state was reached around this time.

A conspicuous increase in the amount of nerves in the host irides was observed already in the preliminary experiments and it was therefore decided always to investigate the host irides together with the transplants in the present study. The density of the ground plexus varied from slightly less than normal to slightly more than normal during the first postoperative week. The fluorescence intensity and the NA uptake was somewhat decreased. These changes could be interpreted as reactions due to the operation which could cause disturbances in the homeostasis of the anterior chamber regardless of the transplant. After two weeks hyperinnervation (see II.9) was quite obvious, even if the exact number or amount of nerves could not be estimated. The NA uptake was also increased. The amount of nerves in the host irides seemed to reach a maximum after two weeks. The amount of nerves remained above the normal level during the whole period studied. The NA uptake was maximal after 4—8 weeks and then decreased somewhat. In both cases the level reached was about 25 per cent above that of a normal iris. — For a discussion of the correlation between the fluorescence findings and the radiometric results see General Discussion.

There are several possible explanations to the hyperinnervation. Some precautions and experiments were made in order to rule out certain of these alternatives. Normal irides were always taken from mates of the same sex, age and size as the operated animals. The increase in NA uptake which takes place during growth of the rats (unpublished results) could thus not be responsible for the difference in NA uptake between host irides and controls. Furthermore, sham operations did not reveal any hyperinnervation after two weeks which excludes the possibility of unspecific changes. The control irides from unoperated eyes of animals with unilateral homologous transplants were also essentially unchanged and it must therefore be concluded that the hyperinnervation is not somehow induced by a generally distributed humoral factor. The hyperinnervation was fairly uniformly distributed over the whole iris and it therefore seems unlikely that it is *only caused by the nerve fibres growing over to the transplant.*

The hyperinnervation of the host iris might be due either to a humoral factor reaching all the nerves in the host iris or to that the same factors that causes the nerves to grow in the transplant also stimulates the branches from the same neurons within the host iris to an overgrowth. It is known that the non terminal axons branch several times on the iris

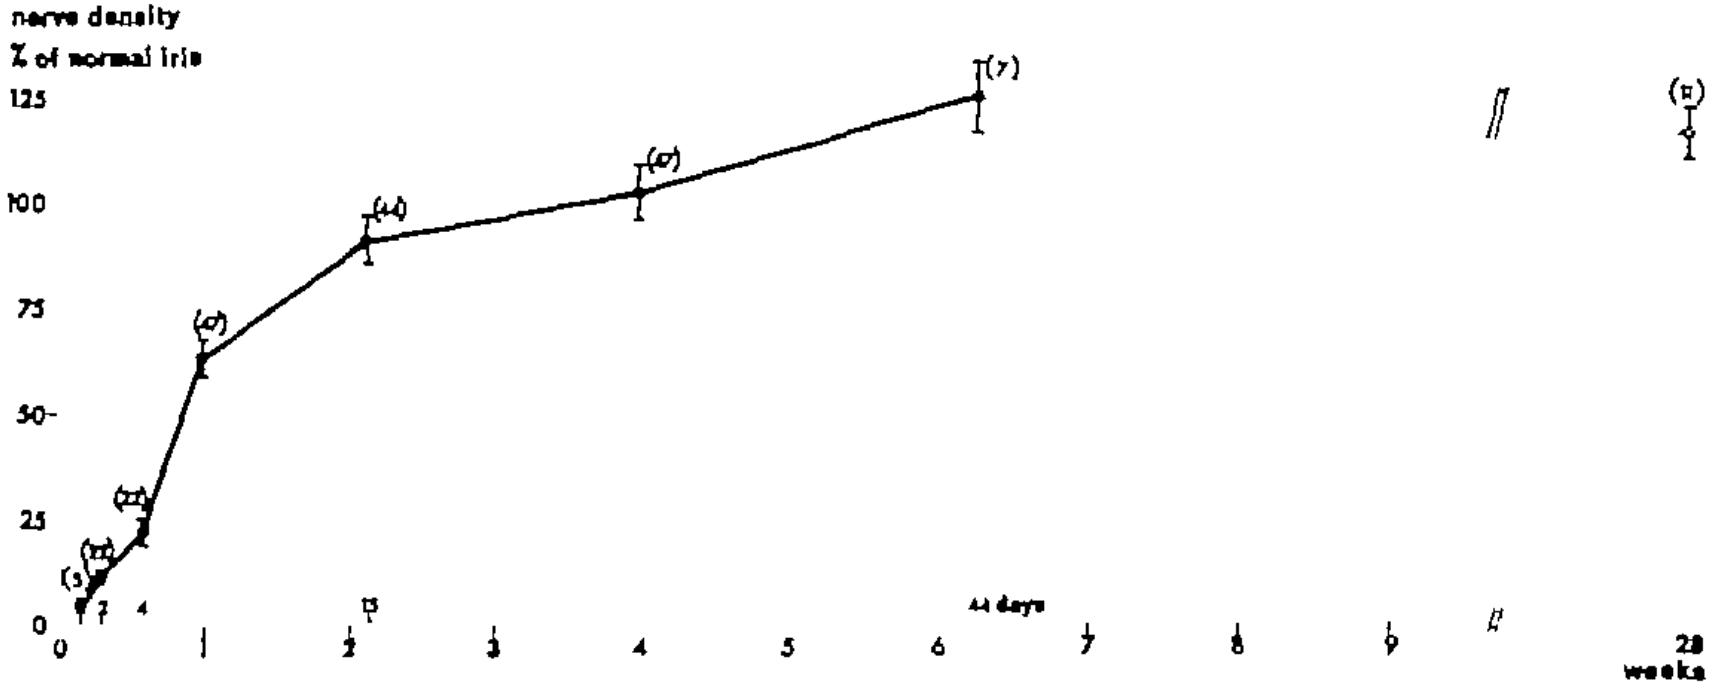
surface and that each branch gives rise to a terminal plexus innervating a smaller relatively circumscribed area (Malmfors and Sachs 1965b) Thus several smaller areas often at considerable distances from each other are innervated by one single neuron. It does not seem unlikely then to suggest that a certain proportion of the neurons just add some axonal branches innervating the transplant and that the same neuron then probably innervates both the host iris and the transplant. The hyperinnervation coincides with the most rapid growth into the transplant which indicates that it is due to the same mechanism. While the amount of nerves reach a constant level in the transplant it has a tendency to decrease in the host iris. It may be that those nerve fibres which have grown in vain within the host irides degenerate, when the stimulus for growth from the transplant decreases. However a slight hyperinnervation of the host iris is present also 12—15 weeks after the transplantation.

The nerves in the host iris extend their field of innervation to include also the transplant. Such an enlargement of the area covered by a neuron is a well known phenomen occurring after partial denervation when the remaining intact neurons sproot into the denervated areas and it is referred to as collateral sprouting (see Edds 1953 Murray and Thompson 1956, 1957a, 1957b, *cf* also II 9) Thus, reinnervation of a transplanted effector organ may be more similar to collarteral sprouting than to regeneration after axotomy where several neurons just refill their old territories.

When an iris is transplanted to the anterior chamber of the eye it becomes rapidly reinnervated by the nerves in the host iris. The appearance, distributions and amount of the new adrenergic nerves are the same as normally At the same time there is an increase in the number of nerves in the host iris.

IV REINNERVATION OF IRIDES FROM SYMPATHETIC GANGLIA TRANSPLANTED TO THE ANTERIOR CHAMBER

Since the initial experiments had proven that sympathetic ganglia survived well in the anterior chamber and showed a vigorous axonal outgrowth onto denervated host irides, it was decided to quantitate the rate of outgrowth from the superior cervical ganglion to the iris in the same way as in the iris transplantation experiments. When the basic parameters of outgrowth had been established in the standardized preparation, experiments could be undertaken in order to influence this outgrowth



Initially several different decapsulated preparations of the superior cervical ganglion were tried including whole ganglia, cranial halves, caudal halves, and longitudinally divided specimens. Also non decapsulated ganglia were tried. Although all these preparations were found to be able to reinnervate host irides, the most consistent results were obtained by using the two decapsulated longitudinal halves of one ganglion in each eye. This preparation was therefore used in the quantitative experiments.

The condition of the transplanted ganglia followed the general scheme given in II.3 The vascularization of the two halves of the ganglion was a rapid process, evident at four days but probably present to some extent earlier

1 Time course of reinnervation of the denervated iris and appearance of the ipsilaterally transplanted superior cervical ganglion

Fluorescence microscopy (see Textfig 5).

Host irides. A new plexus of adrenergic nerves was rapidly formed on the host iris. The first few arborizing fibres were observed already at the first postoperative day (Fig 18) The new nerves were found in small circumscribed areas at the sites of attachment of the transplants. The morphology on the newly formed nerves was extremely varying. Thinner and thicker fibres, commonly with irregular enlargements and varying

5 Time course of outgrowth of adrenergic nerves in host irides after unilateral transplantation of the superior cervical ganglion to the anterior chamber of the eye as observed in the fluorescence microscope. The density of the nerve plexus was estimated on coded slides as per cent of the density in normal irides (see II 9). At each point the mean ± s.e.m. is given. Number of observations within brackets.

fluorescence intensities, were intermingled with some very thick, distorted and heavily fluorescent fibres (Fig 18) The *one day* host irides contained about 5% of the normal amount of nerves. This amount increased in a regular manner during the subsequent days (second day 12 per cent fourth day 23 per cent) The morphology of the nerve fibres was still variable on the second and fourth day but the heavy accumulations of fluorescent material had disappeared (Fig 20 21 24) At *four days* the outgrowing adrenergic nerves were centered around the sites of attachment between transplants and host irides and the innervated areas extended all from the sphincter margin to the corpus ciliare. These areas were often well radially demarcated from the neighbouring non-innervated parts and contained fluorescent plexuses of medium fluorescence intensity but often higher density than found in normal animals. Between the *first and the second week* post operatively areas with a rather regular meshwork containing more than one fluorescent fibre in each strand of the plexus were formed (Fig 25 27) Some fibres now looked similar to normal adrenergic nerve terminals, *i.e* ovoid, highly fluorescent, regularly spaced varicosities were formed (Fig 13) After two weeks the amount of nerves on the reinnervated host irides was judged as being close to the normal amount. After four weeks the varicose appearance was more pronounced than after one week (*cf* Fig 25 32)

As the amount of nerves in the host iris increased, the site of attachment of the transplants became more and more prominent. Thick, compact bundles of fluorescent axons (Fig 28) spread on the iris around the transplant in a fan shaped arrangement (Fig 35) which did not resemble any preexisting pattern of innervation. Peripheral to this central region the fluorescent axons seemed to follow the old nerve trunks (*cf* Fig 37 38)

The high initial growth rate of the outgrowing nerves, as followed by fluorescence histochemistry gradually leveled off around the 100 per cent level after one month and then remained constant for at least several months. Apart from the fan-shaped site of origin of the fluorescent axons in the newly formed ground plexus, the general structure of the ground plexus after one month was similar to the normal picture (Fig 32, 33 34) Thus, the distributions of fluorescent nerves in the sphincter margin, the dilator area, the corpus ciliare and the choroid membrane including the ciliary choroid junction (Fig 38) all resembled those of normal irides. Certain dissimilarities, however made it possible always to distinguish a host iris from a normal one also without looking at the site of attachment of the transplant. The varicosities were often less marked and of a slightly lower fluorescence intensity in the host irides, and the ground plexus was less regular

Ganglion transplants. The most conspicuous difference between transplanted and normal ganglia was the great increase in the relative amount of fluorescent nerve fibres, as compared to the amount of nerve cell bodies in the transplants (cf Fig 16, 17 with 22, 23) This was obviously due to an actual increase in the number of fibres and probably also to a decrease in the number of nerve cell bodies. The change was first observed on the second postoperative day after which it became increasingly more prominent during the first week. After that there was very little change in the relative amount of fibres in the transplants.

The first signs of differences between normal and transplanted ganglia were observed already on the first postoperative day as an increased fluorescence intensity of most nerve fibres (Fig 19) Most nerve cell bodies displayed normal fluorescence intensities at this time, but cells with an increased fluorescence intensity and cells with a very low intensity were more common in the transplants. The increased fluorescence intensity of the nerve fibres persisted, while, from the second day on, most cell bodies showed a slightly less than normal fluorescence intensity The strong fluorescence of some cell bodies thus disappeared. Small areas containing non-fluorescent cell were found. These groups of non-fluorescent cells disappeared at later stages, although single non fluorescent cells were still found. Both in some fluorescent and some non-fluorescent cells exentric nuclei were found at all times, but after about 14 days most cells had centrally located nuclei. The so called SIF-cells ("small, intensely fluorescent cells" Norberg, Ritzén and Ungerstedt 1966, Eränkö and Härkönen 1963) were found in the transplants at all times and did not differ from those found in normal ganglia as viewed in the fluorescence microscope (*cf* Fig 16,30)

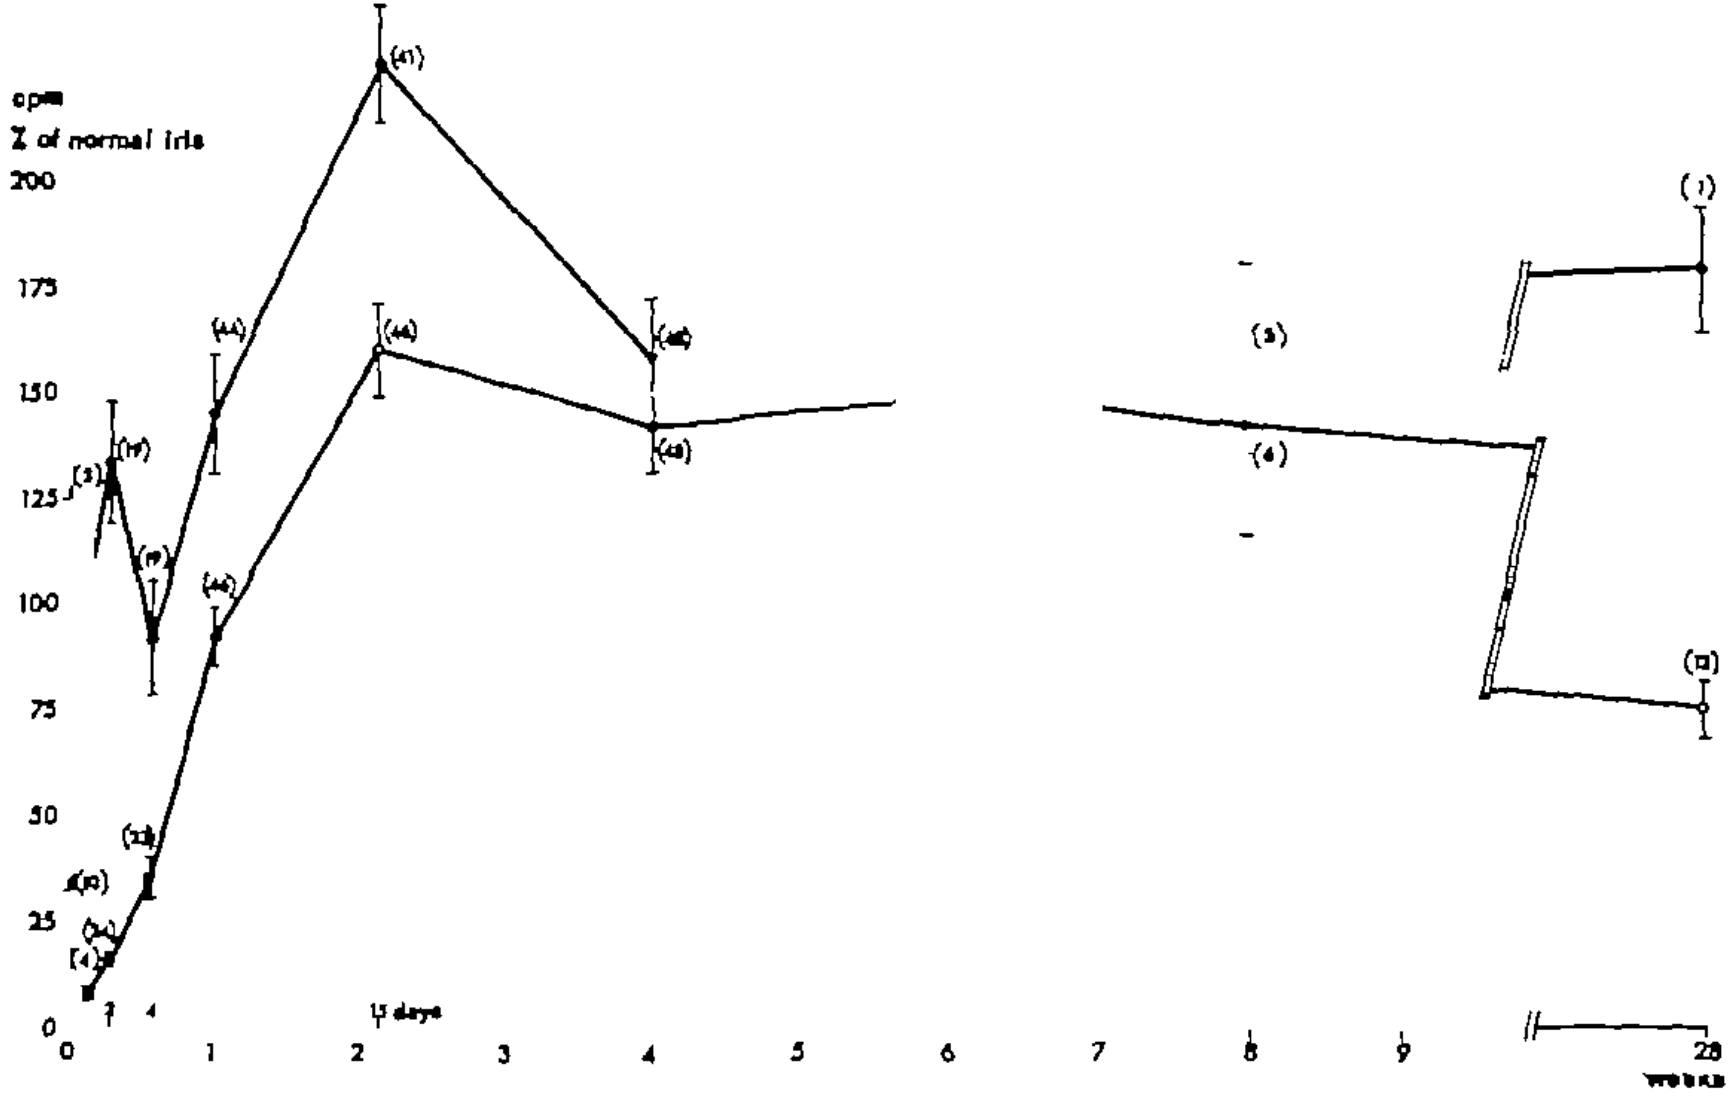
On the first postoperative day both highly fluorescent, swollen fibres and very thin weakly fluorescent ones were found (Fig 19) Soon, both these structures disappeared. Later large bundles of fibres were found traversing the ganglia in all directions. The fluorescence intensity of the bundles of fibres was higher than that of the cell bodies. Fibres showing both smooth and bulgy outlines were seen. At later stages, fluorescent fibres similar to normal nerve terminals were often found to surround individual cell bodies closely (Fig 22, 23 26, 29 30, 31 45)

^{3}H NA Incubations (see Textfig 6).

Reinnervated host irides. Incubations in ^{3}H NA were performed in the same way as described for the iris transplantation experiments. The radioactivity in the host irides increased with postoperative time in the same way as the amount of fluorescent nerves. Thus a rapid initial increase during the

first week was followed by a slower increase and a steady level was reached after about one month. When compared to normal irides the radioactivity found in reinnervated host irides was found to lie at a higher level then the estimated amount of nerves.

Ganglion transplants. When incubated in a decapsulated and bisected form, the superior cervical ganglia from normal animals were found to contain less than half the amount of total radioactivity of that found in the corresponding normal irides. After 1—2 days in the anterior chamber the radioactivity recovered from the ganglia, was about four times higher than the radioactivity in decapsulated bisected control ganglia. A clearcut drop from this level occurred at the fourth day after which the radioactivity increased again to reach a maximum of about six times the original uptake of about twice as much as that found in normal irides after two weeks. The latter peak was followed by a decrease which was most marked during the third and fourth week. The original low level was not reached within the time interval studied (6 1/2 months)



2. Transplantation of other sympathetic ganglia

The coeliac ganglion, lumbar sympathetic chain ganglia and small anterior chamber The superior cervical ganglia of these animals were extirpated in a second operation 1—2 days later The animals were sacrificed after 1,5—3 months.

A plexus of varicose adrenergic nerves, arising from the transplants, was formed on the host irides. However only the coeliac and the lumbar sympathetic chain ganglia were capable of reinnervating the whole host iris to an approximately normal amount (Fig 40) In these cases, also the blood vessels of the choroid membrane were fully reinnervated.

Typically a transplant of a small hypogastric ganglion gave rise to a small discrete area of fluorescent nerves around the site of attachment of the transplant. The rest of the iris and the choroid membrane were

first week was followed by a slower increase and a steady level was reached after about one month. When compared to normal irides the radioactivity found in reinnervated host irides was found to lie at a higher level then the estimated amount of nerves.

Ganglion transplants. When incubated in a decapsulated and bisected form the superior cervical ganglia from normal animals were found to contain less than half the amount of total radioactivity of that found in the corresponding normal irides. After 1—2 days in the anterior chamber the radioactivity recovered from the ganglia, was about four times higher than the radioactivity in decapsulated bisected control ganglia. A clearcut drop from this level occurred at the fourth day after which the radioactivity increased again to reach a maximum of about six times the original uptake of about twice as much as that found in normal irides after two weeks. The latter peak was followed by a decrease which was most marked during the third and fourth week. The original low level was not reached within the time interval studied (6 ½ months)

2. Transplantation of other sympathetic ganglia

The coeliac ganglion, lumbar sympathetic chain ganglia and small anterior chamber The superior cervical ganglia of these animals were exirpated in a second operation 1—2 days later The animals were sacrificed after 1,5—3 months.

A plexus of varicose adrenergic nerves, arising from the transplants, was formed on the host irides. However only the coeliac and the lumbar sympathetic chain ganglia were capable of reinnervating the whole host iris to an approximately normal amount (Fig 40). In these cases, also the blood vessels of the choroid membrane were fully reinnervated.

Typically a transplant of a small hypogastric ganglion gave rise to a small discrete area of fluorescent nerves around the site of attachment of the transplant. The rest of the iris and the choroid membrane were

6. Time course of outgrowth of adrenergic nerves in host irides after unilateral transplantation of the superior cervical ganglion as revealed by the ^{3}H NA uptake. Reinnervated host irides and ganglion transplants were incubated in ^{3}H NA, 10^{-7}M, 30 min plus 10 min rinsing. Values are expressed as cpm in per cent of the cpm found in normal irides of the same batches, incubated in the same way and at the same time. At each point the mean ± s.e.m. is given. Number of observations within brackets. Upper curve (left) Ganglion transplants. Lower curve (left) Reinnervated host irides.

Whether the very first bundles of fluorescent fibres emerging from the transplant were accompanied by supporting Schwann cells from the transplant itself was not determined. Such an arrangement is however highly probable, since Schwann cells (forming the bands of Büngner Büngner 1891) as well as fibroblasts and possibly other cellular elements are known to proliferate vigorously after nerve injury (see Thomas 1966, Thomas and Jones 1967 Haftek and Thomas 1968)

The varicosities of the fluorescent fibres were less pronounced during the first week. This might be interpreted as immaturity since developing adrenergic nerves also lack the typical varicose appearance (Enemar Falck and Håkanson 1965 Friedman, Pool, Jacobowitz, Seagren and Braunwald 1968 Ehinger Gennser Owman, Persson and Sjöberg 1968 Schiebler and Heene 1968 Winckler 1969 Olson, de Champlain, Malmfors and Sachs 1970) The lack of typical varicosities, from which the transmitter is supposed to be released, indicates a lower NA content and perhaps also a smaller amount of amine storage granules in the outgrowing nerves. It is not known at present how the absence of distinctly fluorescent varicosities is related to the distribution of the amine storage granules. It may be that the high growth rate of the nerve fibres makes the amount of granules insufficient for a proper accumulation in the varicosities. When the growth rate slowed down after 2—4 weeks the varicosities became more distinct, which would be consistent with the above idea

From the site of attachment of the transplant, the new nerves grew in all directions and all parts of the iris became well innervated. After somewhat longer times fluorescent nerve fibres could be observed also in the anterior part of the choroid. The very typical appearance and distribution of the innervation of the border between the ciliary body and the choroid was inseparable from the normal pattern This fact strongly indicates that outgrowing adrenergic nerves grow to the same positions as the original adrenergic nerves. If this is due to guidance from the remaining Schwann cells or to specific attraction from the effector tissue or to information within the adrenergic neuron remains to be disclosed. The last alternative seems unlikely as ganglion cells not normally innervating these areas easily repeat the same reinnervation pattern.

The resemblance between th reinnervation pattern and the normal distribution especially concerning the trunks of non terminal axons in the dilator muscle makes it likely that the outgrowing nerve fibres from the transplanted ganglion reached the remaining trunks of non-terminal cholinergic axons where they became enclosed in the old Schwann cells. Adrenergic nerves can be found much proximal to the attachment of the transplant

ed ganglion indicating that the new axons can grow in a direction opposite to that of the original fibres. This has also been shown when ganglia were transplanted to the sciatic nerve (Olson 1969 see also VIII.2)

Within four weeks the density of the ground plexus reached that of the *normal iris* However the areas close to the attachment of the transplant had a much denser plexus due to the fibres radiating from the site of attachment. This indicates that the retardation of the growth is at least not solely due to a limited capacity of the Schwann cells to harbour the nerves but probably to another regulating mechanism, possibly more directly coupled to the effector tissue.

The uptake of ^{3}H NA in the host iris was as high as in a normal iris already after one week when the amount of nerves was estimated to be only about 60 per cent. This discrepancy existed also at longer times and to the same extent. The most feasable explanation might be that the extra trunks of non terminal axons emerging from the ganglion transplant caused the increased NA uptake as they were not considered when estimating the density of the terminal ground plexus.

The growth rate of the nerves coming from a transplanted ganglion was similar to that of the nerves growing into a transplanted iris. Thus the transplanted ganglia showed a vigorous ability to reinnervate the denervated host iris in spite the fact that the axons were cut close to the nerve cell bodies. From the histological examination of the transplants it is clear that the ganglia underwent marked changes after transplantation Firstly the cut axons showed accumulations of NA (Dahlström and Fuxe 1964a, Owman 1964 Härkönen 1964) due to the continuous axonal flow (Weiss and Hiscoe 1948). During the first two days these accumulations obviously extended all the way to the cell bodies (Dahlström and Fuxe 1964a, Owman 1964 Jacobowitz and Woodward 1968) Secondly there was a progressive increase in the relative number of fluorescent fibres in the ganglion, obviously due to sprouting Thirdly several cell bodies showed the well-known sign of chromatolysis (see Bodian and Mellors 1945) and excentrically located nuclei. This observation and the somewhat decreased fluorescence intensity from the second day on might have been due to the initiation of regenerative cycle (*cf* Bodian and Mellors 1945), but possibly also to impaired nutrition before restitution of blood circulation. In some cases the changes must have been irreversible as there *seemed to be a marked reduction of the number* of cell bodies after longer times.

Several authors have studied the effect of postganglionic axotomy upon the superior cervical ganglion *in situ* The initial changes thus described

were found to be quite similar to the changes observed in the present investigation after transplantation of the ganglion to the anterior chamber of the eye.

Close postganglionic axotomy of the superior cervical ganglion is known to cause a marked decrease in the density and probably also number of nerve cells in the ganglion (*e g* Hillarp 1946, Shashurina 1963 Härkönen 1964 Nagata and Tsukada 1967). The superior cervical ganglion of the rat undergoes swelling and increases both its dry and wet weights about 50 per cent one week after cutting of its major postganglionic nerve as shown by Nagata and Tsukada (1967) The latter authors also described the apparant decrease in the number of nerve cells and ascribed the swelling to a marked proliferation of Schwann cells and other fibrous elements following the axotomy This shift in the ratio of nerve cell density to density of supportive tissue and fibrous elements is consistent with the fluorescence microscopical findings of the transplanted ganglia in the present investigation. The transplanted ganglia of course underwent an almost total axotomy leaving only the possibly existing intraganglionic axons and/or collaterals (Norberg and Sjöqvist 1966, Jacobowitz and Woodward 1968) intact. Surprisingly Nagata and Tsukada found the axotomized ganglia to have the same amino acid metabolism as normal ganglia, which is characterized by a dominance of aspartic and glutamic acids. This suggests that nevertheless a considerable number of neurons indeed remained in the ganglia after axotomy

Histometrical analysis of the actual number of nerve cells were neither performed in the present investigation nor by Nagata and Tsukada but it is obvious that the swelling of the ganglia will dilute the neuronal component thus making the nerve cells appear less frequently A peripheral zone of intact nerve cells were actually described by the latter authors and the present fluorescence histochemical results clearly demonstrates the presence of a number of noradrenaline neurons sufficient fo a more than complete reinnervation of the iris. Furthermore, the large increase in the number of fluorescent axons must add to the amount of nerve cell cytoplasm present after axotomy thus partially making up for th lost neurons.

The histochemistry of the axon reaction of th superior cervical ganglion following postganglionic axotomy has been thoroughly studied by Härkönen (1964) The lowered NA fluorescence intensity of most cell bodies described by Härkönen s in accordance with the present findings. However more servere and long lasting decreases of NA as well as of MAO and cholinesterases were noted by the latter author and led him to

suggest that "when contact with the effector organ is severed, these substances loose their importance and the energy normally required for their synthesis is perhaps then used for protein synthesis in the interest of regeneration" The present experiments does not support such an hypothesis as far as NA is concerned since, in the case of transplanted ganglia, complete disappearance of the transmittor from the cell bodies was rarely observed and reappearance of normal fluorescence intensities faster Furthermore, the axons of the transplanted ganglia were strongly fluorescent at all times. It has also been shown that sympathicoblasts display a considerable fluorescence intensity very early during ontogenesis (Enemar Falck and Håkansson 1965 Olson, de Champlain, Malmfors and Sachs 1970) when these cells hardly can be supposed to need NA for neuromuscular transmission. Thus, the accumulating evidence suggests that the synthesis and storage of the transmittor is an intrinsic mechanism of the neurons basically unrelated to and independant of the growth regulating mechanisms. Further support for this concept will be presented (see VI)

Although there was a reduced number of ganglion cells surviving the transplantation those that remained were more than enough needed for reinnervation of the iris. This is of course to be expected since the iris is normally only a part of the innervation area of the superior cervical ganglion. However when very small pieces of the ganglion were transplanted the ground plexus did not become as dense and complete as when the whole ganglion was transplanted. This demonstrates that a single adrenergic neuron indeed has a limited capacity for growth.

Not only the ipsilateral superior cervical ganglion from the same animal had the ability to reinnervate the iris when transplanted into the anterior chamber of the eye. Other autologously and homologously transplanted ganglia reinnervated a denervated host irides in a similar way No quantitative difference was observed between autologously and homologously transplanted superior cervical ganglia which illustrates the good compatibility between *adrenergic neurons and effector organs from different animals* of the present rat strain. Furthermore, the similarity in outgrowth between ganglia from different locations shows that there is no topographical specificity of the adrenergic neurons. Whether neurons from different types of sympathetic ganglia (paravertebral, prevertebral or even more peripherally located) have slightly different growth properties is unclear The fact that the new nerves coming from transplants of the small hypogastric ganglia formed a normally dense plexus only in close neighbourhood of the attachment while small pieces of the superior cervicale ganglion of approximately the same size gave rise to a plexus which extend-

ed over a larger area but was less dense might indicate a difference in properties between the two different types of ganglion cells. The nerve cells of the hypogastric ganglion have been called "short neurons" (see Sjöstrand 1965).

When any sympathetic ganglion is transplanted to the anterior chamber of the eye many nerve cells survive and axon regeneration starts. If the adrenergic nerves in the host iris have degenerated the host iris is rapidly reinnervated by the transplanted ganglion. The new adrenergic nerves are quantitatively and qualitatively similar to the normal ones independantly of which ganglion that has been transplanted.

V TRANSMITTER MECHANISMS OF THE NEWLY FORMED NERVES

The adrenergic transmitter mechanisms synthesis storage, release, uptake and metabolism of NA have been throughly studied in the adult organism with biochemical and isotope methods (for references see Axelrod 1964 Carlsson 1965 Iversen 1967 Jonsson, Hamberger Malmfors and Sachs 1969 Sachs 1970) and in the adrenergic nerves with the fluorescence histochemical method (Malmfors 1965a, Norberg 1965 Hamberger 1967) Similar information has recently been obtained about growing adrenergic nerves during ontogenesis (Iversen, de Champlain Glowinsky and Axelrod 1967 Sachs, de Champlain Malmfors and Olson 1970). The purpose of the present experiments was to study the transmitter mechanisms of growing noradrenaline nerves in the adult animal. This information was needed to be able to evaluate the functional experiments (see VII) and for a proper interpretation of the results of the ^{3}H NA incubations performed.

Iris transplants together with their host irides (two weeks) and ganglion transplants together with their reinnervated host irides (one and four weeks) were examined following *in vivo* treatment with the NA synthesis inhibitor H44/68 or reserpine and/or nialamide. Most experiments were carried out using the combined *in vitro* isotope-fluorescence method (Olson, Hamberger Jonsson and Malmfors 1968)

1 Iris transplants and their host irides

Fluorescence microscopy (see Table 2)

Twenty four hours after inhibition of NA synthesis with H44/68 only a very faint fluorescence was left in the adrenergic plexuses of the two irides while decentralization of the ipsilateral superior cervical ganglion, performed at the same time as the H44/68 injection, counteracted the depletion, leaving the nerves with essentially unchanged fluorescence intensities. Electric stimulation of the preganglionic sympathetic trunk (10 impulses per sec) during 80 min beginning one hour after H44/68 pretreatment caused a marked reduction of the fluorescence intensity compared to the

unstimulated side. This reduction was prominent in the varicosities of both transplants and host irides while the smoother nonterminal axons and the somewhat more beaded axons connecting the host iris and transplant were very little affected by the stimulation (*cf* Fig 51 52)

Table 2

Schematic representation of the fluorescence intensities in the newly formed adrenergic nerves and cell bodies following different in vivo drug treatments

Two weeks old iris transplants and their host irides and four weeks old ganglion transplants and the reinnervated host irides were used. Each estimation is based on 2—10 observations.

" + NA	+++[2])	+++	+++

[1]) The doses and times before killing when not indicated in the table were *H44/68* 500 mg/kg i.p.; NA; 0.2-0.5 mg/kg, 15 min reserpine 10 mg/kg, 4 hrs, i.p.; nialamide 100 mg/kg, 2 hrs, p.

[2]) Symbols for the average fluorescence intensities +++ strong, ++ moderate; + weak; 0 none. The number of plus signs are not quantitatively related, but are comparable to controls in the same experiment. +++ corresponds roughly to the fluorescence intensity of an iris from an untreated rat. When the fluorescence intensity of an individual iris preparation could not be definitely determined as belonging to one intensity grade or to the next, this was indicated by bracketing the last plus sign of the higher grade. See also Olson, Hamberger Jonsson and Malmfors 1968.

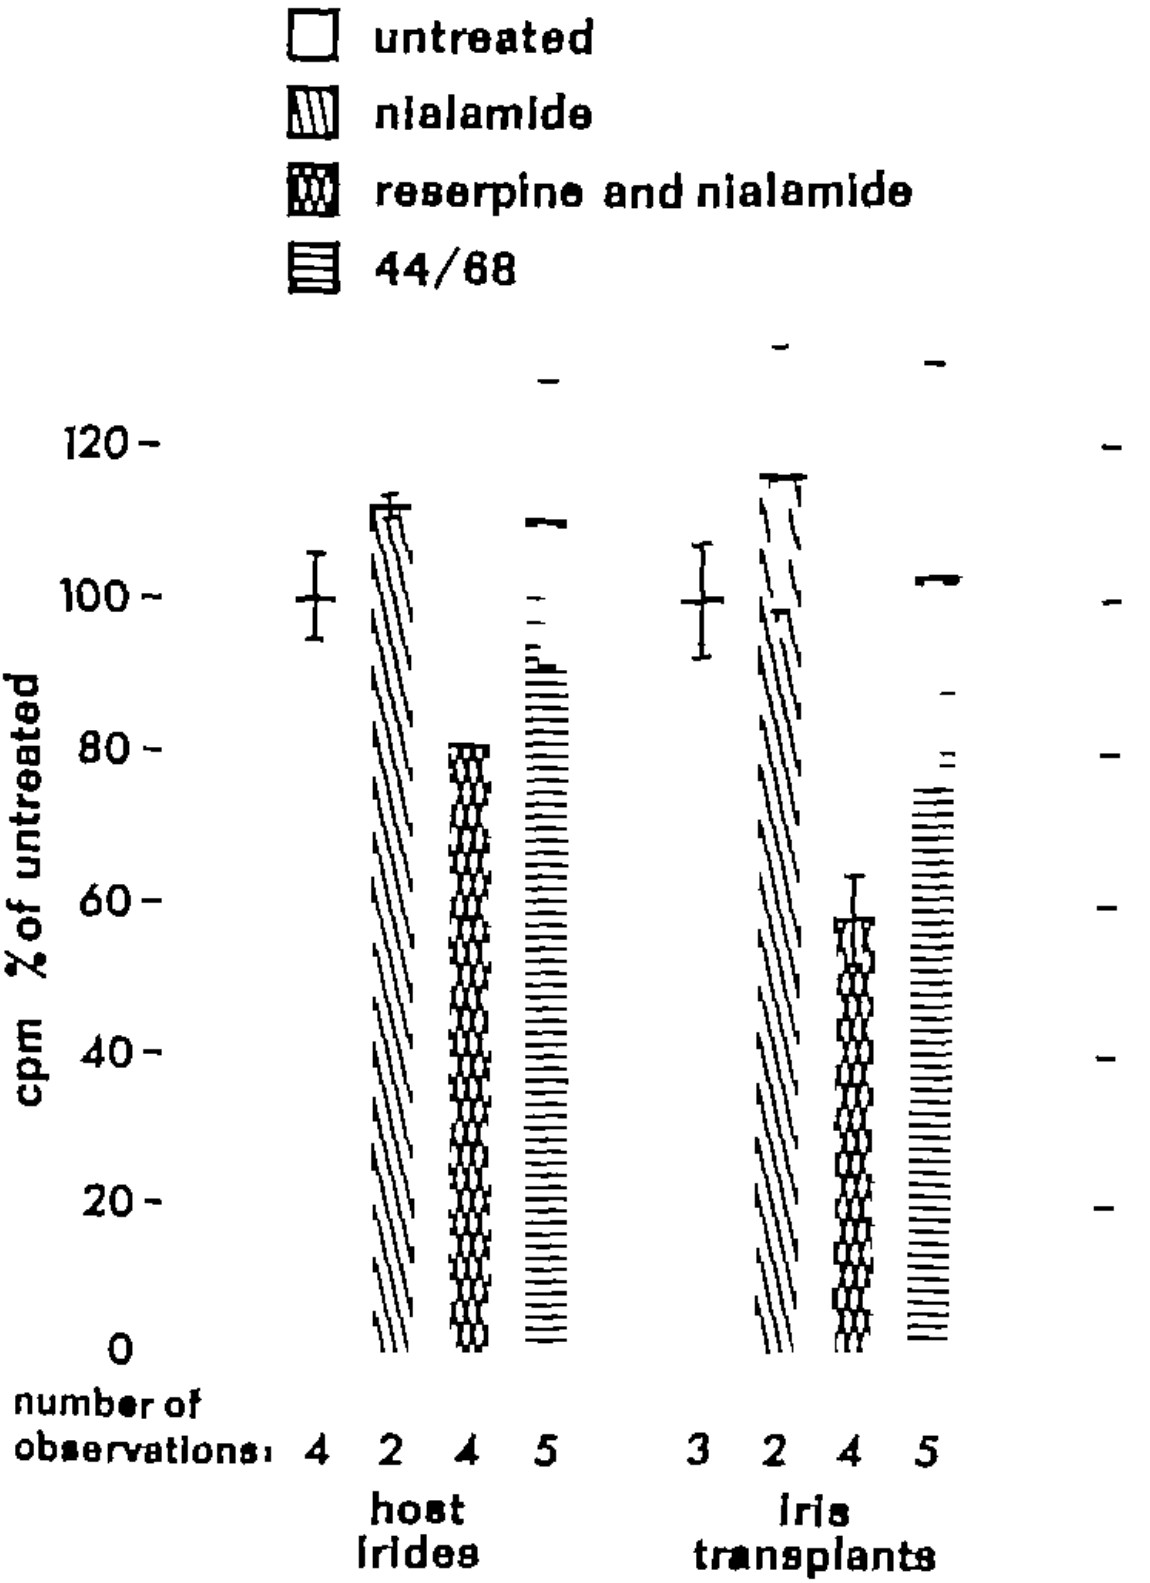
[3]) for detailed description see text.

[4]) varicose appearance of fluorescent nerve terminals.

[5]) varicosities seemed preferentially depleted.

[6]) smooth appearance of fluorescent nerve terminals.

When an H44/68 treated rat was given NA (0.2—0.5 mg/kg i.v. 15 min before death) or the transplant and the host iris if such an animal were incubated in NA (10^{-7} — 10^{-6}M) the nerves regained a fluorescence intensity and appearance comparable to that of a control iris treated in the same way (Fig 41 42)



Reserpine (4—24 hrs) either used alone or in combination with nialamide (1—2 hrs) caused a complete disappearance of the neuronal fluorescence of both transplants and host irides. In tissues from animals treated with only reserpine no or almost no fluorescence restitution could be seen after *in vivo* or *in vitro* administration of NA. The addition of nialamide (1—2 hrs before the NA) caused a marked restitution of the fluorescence (Fig 43 44). However the appearance of the nerves after the reserpine-nialamide-NA treatment was different from normal. After the *in vivo* administration of NA, the nerve terminals showed the same smooth appearance and the non-terminal axons the same strong fluorescence in the host iris as earlier described for non-operated eyes (Malmfors 1965a). In the transplant the adrenergic nerve terminals were smoother than in the untreated but not as smooth as in the host iris. Furthermore, the non terminal axons, especially those in the connections between the host iris and iris transplant, had a somewhat beaded fluorescence, which was comparable in form to that of normal iris but of a stronger fluorescence intensity. When NA was administered *in vitro* the appearance was principally the same but the varicosities were somewhat more pronounced than after the *in vivo* treatment in the host irides, the transplants and the controls (*cf* Hamberger and Malmfors 1967).

The amount of nerves regaining fluorescence after reserpine and nialamide or H44/68 was about the same as in transplants and host irides from untreated rats. After preincubation in DMI (10^{-6}M) no restituted fluorescence could be observed following incubation.

^{3}H NA Incubations

Textfig 7 shows the radioactivity found, after ^{3}H NA incubation in the host irides and the transplanted irides after certain drug treatments. Nialamide or

H44/68 slightly increased the radioactivity while reserpine and nialamide slightly decreased it as compared to the untreated control. This was especially true for the transplants.

When tissues from untreated animals were further rinsed for three hours in NA free buffer after the initial ^3H NA incubation there was a marked decrease in the radioactivity both in control irides and in iris transplants and host irides (Textfig 8) The wash-out rates in the host irides and transplants were similar and thus loss was somewhat greater than in the control irides. Separation of the transplant from the host iris before the three hours wash did not seem to influence the disappearance from the host irides but the amount of radioactivity found in the transplants was reduced after detachment from the host irides. The reduction may be due either to lack of transport of radioactivity from the host iris to the transplant or to a leakage from the cut nerves of the detached transplant. — If the control iris was divided into four pieces the loss of radioactivity was greater than in the intact iris.

2. Ganglion transplants and irides reinnervated from them

Fluorescence microscopy (see Table 2, 3)

After H44/68 (24 hrs) the fluorescence was weak in the cell bodies of the intact and transplanted ganglia and in the terminals of the intact iris. How

8. Radioactivity recovered in control irides, host irides and iris transplants after incubation for 30 min in ^{3}H NA (10^{-7}M) and rinsed for 10 min. One group of control irides were further rinsed for 180 min undivided while in another group the irides were divided into four pieces and then rinsed for 180 min. Host irides and iris transplants were incubated in ^{3}H NA attached to each other. After the first 10 min rinsing one group of preparations were left intact during further rinsing for 180 min while in another group the transplants were separated from the irides before the 180 min rinsing. Values are expressed as the cpm in per cent of the cpm found after only 10 min rinsing in the three different groups.

ever the axons in the transplanted ganglia (Fig 47) and the nerve terminals in the reinnervated host irides had about the same fluorescence intensity as untreated controls. The difference between the nerves in the intact iris and those in the reinnervated one was probably due to the lack of nerve activity in the latter (*Corrodi and Malmfors* 1966)

Reserpine (10mg/kg) was given at different times (4—96 hrs) before death to animals killed one or four weeks after unilateral transplantation of the ipsilateral superior cervical ganglion. In the terminals and axons of the iris and the cell bodies both in the transplanted ganglia and the intact ganglia the fluorescence was very weak or absent four hours after the reserpine administration. After 16 and 24 hrs there was an increase in the fluorescence of the cell bodies especially around the nucleus (*cf* Dahlström 1967) while no fluorescence could be detected in the axons of the ganglia (Fig. 48) or in the nerve terminals of the irides. After 48 hrs the cell bodies had regained a fluorescence intensity similar to that of the untreated controls while the axons and the nerve terminals in the reinnervated irides showed a weak but distinct fluorescence. Thus the intensity of the cell bodies was higher than that of the axons during the recovery 16 to 48 hrs after reserpine which clearly illustrates that the NA fluorescence recovers faster in the cell bodies than in the axons. The fluorescence in the cell bodies of the transplanted ganglia 48 hrs after reserpine was sometimes even stronger than in the untreated controls, especially four weeks after transplantation. Apart from this there were no obvious differences between one and four weeks old transplants and reinnervated irides. After 96 hrs the fluorescence of the terminals in the reinnervated iris was moderate to nearly as strong as in untreated controls. Axons in transplanted ganglia showed a stronger fluorescence than the cell bodies as was the case also in control transplants.

A high dose of NA (0.5 mg/kg i.v 15 min) caused a general increase in the specific fluorescence, both in intact and transplanted neurons but most marked in the non terminal axons and the cell bodies. If NA was given to animals pretreated with reserpine (four hours) there was no or almost no restitution of the fluorescence in the nerve terminals, while there was a slight restitution of the fluorescence of the non-terminal axons and the cell bodies. In reserpine-nialamide pretreated animals NA caused a marked restitution of the fluorescence The nerve terminals in the intact and reinnervated irides had about the same fluorescence intensity as in untreated animals but they were smoother (*cf* Malmfors 1965a) The non-terminal axons were more intensely fluorescent than those in untreated animals. In the transplanted and intact ganglia the cell bodies had about the same or a somewhat higher fluorescence intensity than in untreated

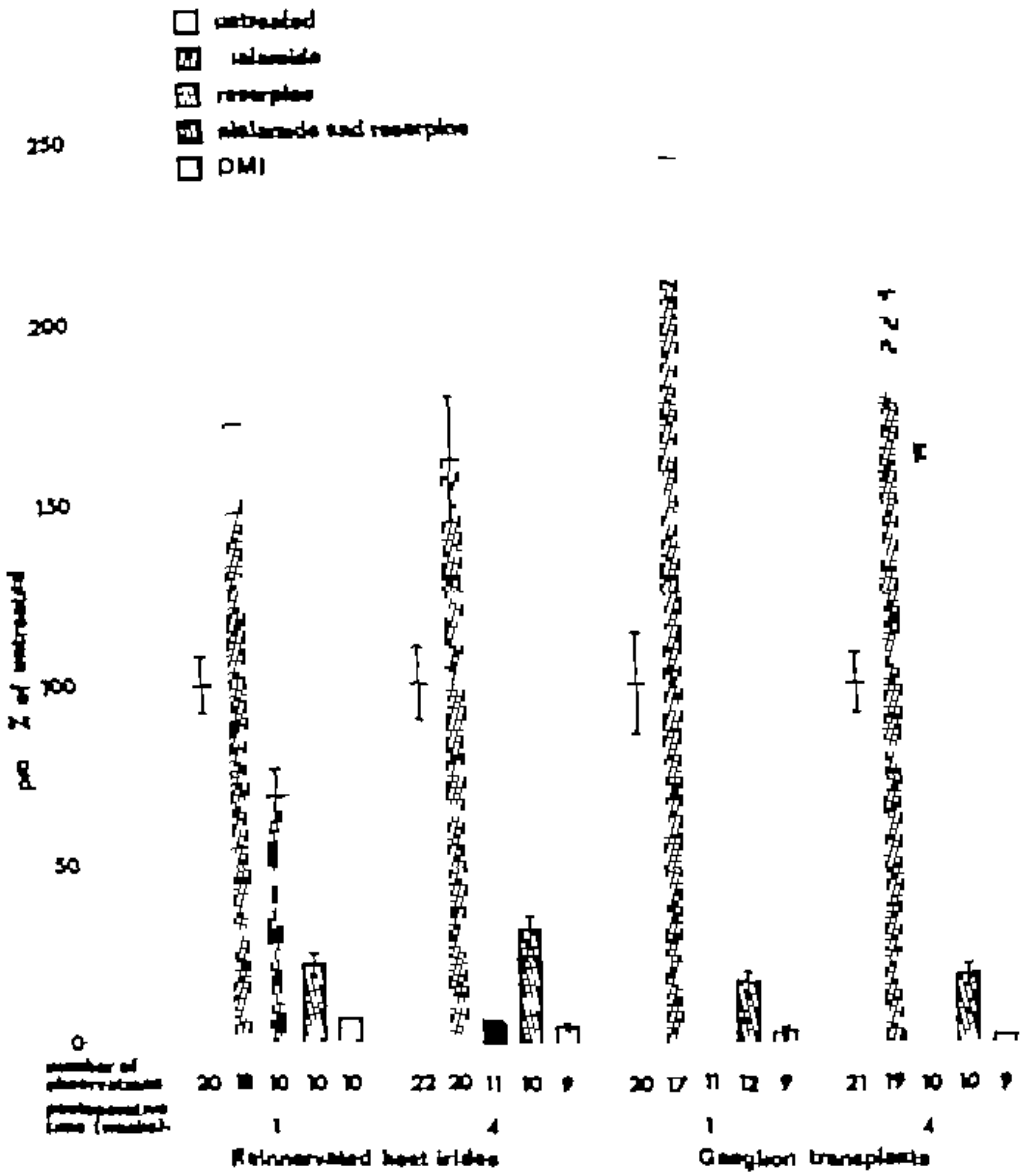
controls. The axons were brighter than the cell bodies in the transplants giving a fluorescence distribution pattern similar to that of untreated controls (*cf* Fig 45 46)

In untreated animals the nerve terminals in the reinnervated host iris one week after the transplantation lacked pronounced varicosities. After four weeks the varicosities were more prominent. The same difference persisted after *in vivo* administration of NA (Fig 49 50) but if the NA was preceded by reserpine and nialamide no such difference could be observed.

The morphology of the nerves in the reinnervated host irides after *in vitro* incubation in ^{3}H NA (see below) was changed in the same way as described above for the nerves in the iris transplants. However the varicosities did not become as pronounced as in the iris transplants and the non terminal axons were never beaded.

^{3}H NA incubations (see Textfig 9)

After DMI-preincubation the amount of radioactivity found was very low Also four hours after treatment with reserpine the radioactivity found was low

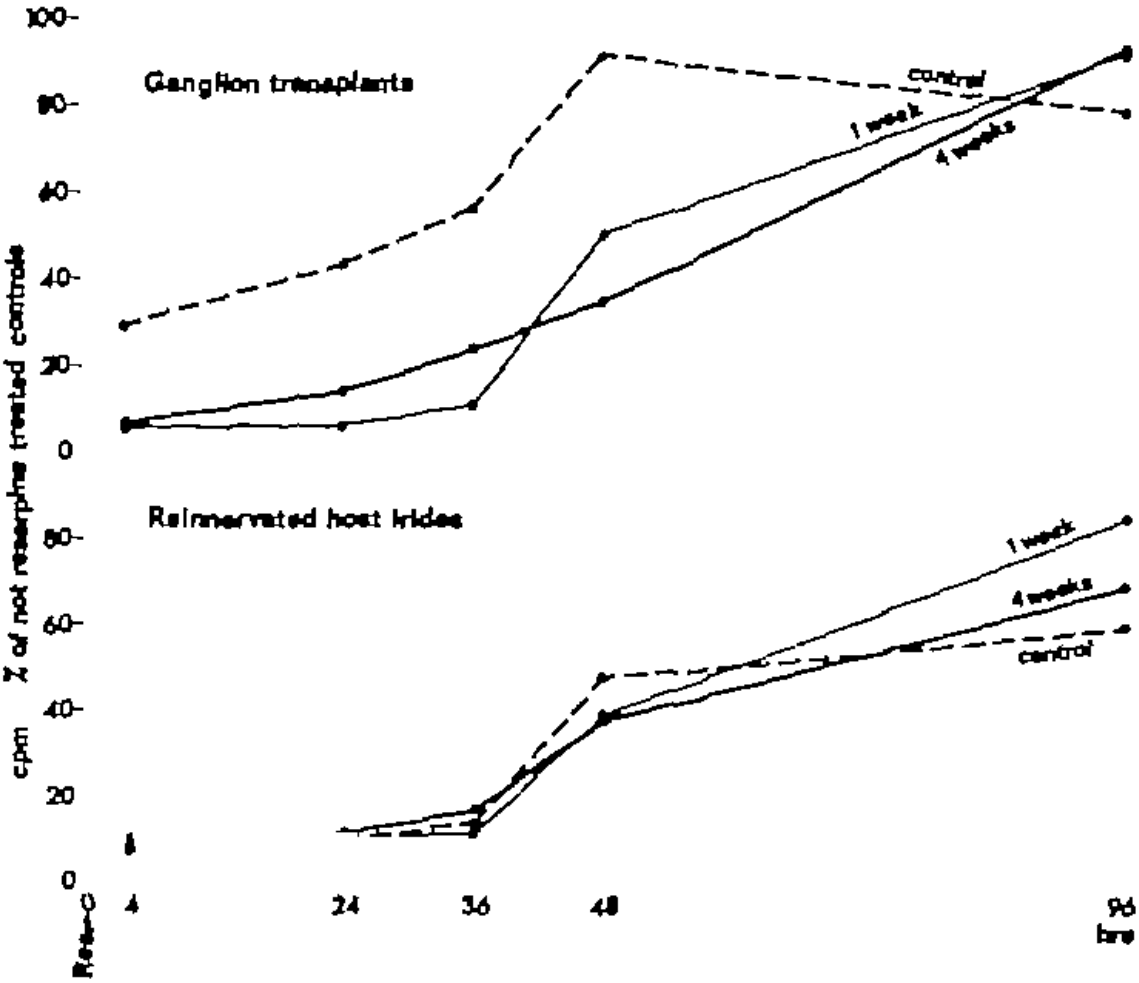


After nialamide treatment (one hour) the radioactivity found was higher than in the untreated animals, especially in the transplanted ganglia.

When the animals were given both reserpine (four hours) and nialamide (one hour) the radioactivity was higher than after treatment with reserpine alone, but less than after nialamide alone.

The recovery of the ability to take up ^{3}H NA after reserpine was followed in young and older ganglion transplants and their host irides (Textfig 10)

In the untreated animals the radioactivity was about the same in the four different tissues examined. In intact ganglia the relative amount of radioactivity was markedly higher than in the other tissues during th first 48 hrs after the reserpine treatment and reached maximum, near 100 per cent, already after 48 hrs. In the other tissues th radioactivity found up to 36 hrs after reserpine was low and there was a more rapid increase between 36 and 48 hrs than between 48 and 96 hrs.



Between 36 and 48 hrs the val for the intact iris ran bout parallel to the other while between 48 and 96 hrs the increase in the intact iri was markedly slower than in the transplanted ganglia and reinnervated irides. At 96 hrs the transplanted ganglia had reached the highest level while the reinnervated irides were higher than the intact irides. The ratio between the amount of radioactivity found in the transplants and the host irides was the sam 48 and 96 hrs after eserpine as in untreated controls.

9 Radioactivity recovered in ganglion transplants and reinnervated host irides after incubation in ^{3}H-NA (10^{-7}M) for 30 min and 10 min rinsing. Animals were untreated or pretreated with nialamide 100 mg/kg 1—2 hrs and/or reserpine 10 mg/kg 4 hrs. In one group the tissues were preincubated in DMI (10^{-5}M). Values are expressed as cpm in per cent of the cpm found in untreated host irides and ganglion transplants.

3 Discussion

The material used for this part of the study was chosen in order to obtain the most favourable conditions for detection of any alternation in the transmitter mechanisms of outgrowing nerves. The iris transplants and their host irides were studied after two weeks when the number of nerves

10. Radioactivity recovered in a) reinnervated host irides and control irides and b) transplanted ganglia and control ganglia. Ganglia after incubation in ^{3}H NA (10^{-7}M) for 30 min and 10 min rinsing. The animals were given reserpine (10 mg/kg) at different times before the preparation. Values are expressed as cpm in per cent of cpm found in control irides and ganglia respectively

in the transplants was sufficiently high. The transplanted ganglia and the reinnervated irides were studied one week after the transplantation when there was a substantial amount of nerves which were fairly young and with an appearance that differed from that of normal nerves. They were also studied after four weeks when the nerves had an almost normal appearance. The preparations thus contained outgrowing adrenergic nerves from different origin, stage of growth and age.

The total radioactivity found in the ^{3}H NA incubated tissues has been shown to consist mainly of ^{3}H NA both in iris and in the upper cervical ganglion in adult animals (Jonsson Hamberger Malmfors and Sachs 1969 and unpublished observations) as well as in developing animals (Sachs,

de Champlain Malmfors and Olson 1970) Therefore, the total radioactivity recovered can be considered as a reliable measurement of the ^{3}H NA in most cases.

When the endogenous NA is greatly reduced with reserpine the uptake of exogenous NA in the adrenergic nerves can be directly observed as a restitution of their specific fluorescence provided that the MAO has been inhibited (Malmfors 1965a) No signs of NA fluorescence was detected in the nerves after preincubation in DMI, which inhibits the neuronal uptake (Hertting, Axelrod and Whitby 1961 Hamberger 1967)

It is reasonable to believe that most of the radioactivity found after preincubation with DMI represents ^{3}H NA or initiated metabolites located outside the nerves but not visible in the fluorescence microscope. Thus the difference in radioactivity between tissues not incubated in DMI and those incubated in DMI represents ^{3}H NA located in the adrenergic neurons. The extraneuronal uptake was very small compared to the neuronal uptake also in tissues containing growing nerves. These findings agree with similar studies in adult tissues where the extraneuronally located NA has been determined after sympathetic denervation (Hertting, Axelrod, Kopin and Whitby 1961 Jonsson Hamberger Malmfors, Sachs 1969 Sachs 1970) The total radioactivity in tissues not preincubated with DMI may thus be considered representative for the adrenergic nerves.

The qualitative properties of the adrenergic nerves in taking up and accumulating NA are well developed very early during the outgrowth both in nerves formed in the iris and in a transplanted ganglion after cutting its axons close to the nerve cell bodies. It has been assumed that the membrane mechanism for uptake of NA is established at the moment of formation of the membrane (Iversen, de Champlain, Glowinski and Axelrod 1967) However the quantitative development of the separate functions such as the uptake, storage and release mechanisms is difficult to estimate when all parameters may change simultaneously By selectively affecting the different mechanisms with drugs it might be possible to elucidate the relative importance of the different steps involved during the outgrowth.

NA is normally taken up accumulated by the membrane mechanism (Hamberger Malmfors, Norberg and Sachs 1964 Malmfors 1965a, Hamberger 1967 Malmfors 1967) and then incorporated and stored in the amine storage granules mainly by the ATP Mg^{++} dependent mechanism (Carlsson Hillarp and Waldeck 1963 Stjärne 1964 Carlsson 1966) The storage capacity of the amine granules is of minor importance for the initial uptake of NA but very important for the total storage capacity by protecting the NA from being deaminated by MAO (Jonsson, Hamberger Malmfors and Sachs

1969). The ATP Mg^{++} dependent uptake and storage of the amine storage granules can be effectively blocked by reserpine (see Carlsson 1966) which does not affect the membrane mechanism (Malmfors 1965a, Hamberger 1967) To demonstrate the NA uptake after reserpine a MAO-inhibitor must be given in order to protect NA from being deaminated intraneuronally The relative importance of the membrane mechanism and of the granular uptake in the out growing nerves was found to be similar to that of mature nerves. The same has been found also for nerves during ontogenesis (Sachs, de Champlain, Malmfors and Olson 1969) The quantitative relations between the membrane mechanism, the amine storage granules and the MAO is thus established very early This is further illustrated by the fact that no certain differences can be found when comparing the reinnervated irides one and four weeks after the ganglion transplantations. The ability of the newly formed nerves to retain NA was about the same as shown by rinsing the irides in an amine free solution for three hours.

In intact and transplanted ganglia, the fluorescence from endogenous NA reappeared in the cell bodies already 24 hrs after the administration of reserpine, markedly earlier than in the non terminal axons and adrenergic terminals (*cf* Norberg 1965). At the same time intact ganglia were able to accumulate NA but not the transplanted ganglia. In the transplanted, the host, and the reinnervated host irides the fluorescence of the nerves reappeared 48 hrs after the administration of reserpine. Simultaneously there was marked increase in NA uptake in the irides compared to the corresponding value 24 hrs after reserpine, when no fluorescence could be observed. Thus the ability to accumulate NA was well correlated with the reappearance of fluorescence.

The recovery of the storage function after reserpine might be achieved either by newly formed amine storage granules or recovery of the old ones. This problem has been very much discussed in combination with the axonal transport of new-formed granules from the cell body (see Dahlström and Häggendal 1969). The amine storage granules are formed in the nerve cell body and transported down the axon at a rate of 5—10 mm/hr in the rat (Dahlström and Häggendal 1966). Axonal flow is illustrated also in the present paper as the fluorescence recovered first in the cell bodies and later in the non terminal axons and terminals. Also the initial accumulations in the severed axons is explained to the axonal flow The rapid recovery of the granular storage function in the intact ganglion seems to be linear between 4 and 48 hrs. The corresponding recovery of the storage capacity in the intact iris is very low up to 36 hrs. The recovery of the NA uptake in the transplanted ganglia was slower than in the intact

ganglia. The transplanted ganglia were instead more similar to the irides during the first 4—36 hrs. These observations are explained by the fact that the transplanted ganglia contain fewer nerve cell bodies and more nerve fibres than the intact ganglia. In the reinnervated iris the recovery of the storage capacity was about the same between 36 and 48 hrs as in the intact iris but then it was faster and reached a greater part of the normal value after 96 hrs than the intact iris. The one week old reinnervated iris reached a higher level than the four week old one. The reasons might be several for these observations. There might be

a more rapid formation and transport of newly formed granules in growing nerves than in mature nerves or

a greater recovery of young granules from reserpine block or

a proportionally higher uptake in new formed granules in growing nerves after reserpine.

The adrenergic transmitter in the newly formed nerve terminals is mainly released from the varicosities as earlier observed in adult terminals (Malmfors 1965a)

The fluorescence of the enlargements of the non terminal axons in the connections between the host iris and the transplant were not affected by the stimulation. Thus because they are not sites of transmitter release they do not seem to be true varicosities.

The transmitter mechanisms of newly formed adrenergic nerves in adult rats are similar to those in normal adult ones and to those in developing and growing animals.

VI ATTEMPTS TO INFLUENCE THE GROWTH RATE OF THE ADRENERGIC NERVES

1 Outgrowth of adrenergic nerves to non-denervated irides from transplanted ganglia

It was shown in the previous chapters that, under certain experimental conditions, the rat iris could easily harbour a larger amount of adrenergic nerves than it normally does. It would then seem of interest to investigate the outgrowth of new nerves from ganglia transplanted to host irides with an intact adrenergic innervation as compared to the outgrowth from ganglia transplanted to denervated irides (*cf* IV) The former situation can be obtained either by autologous transplantations of one ganglion to the contralateral eye or by homologous transplantations. Since no indications of any differences between auto- and homologous transplantations have been found in the present experiments these two types were used simultaneously according to the various experimental needs.

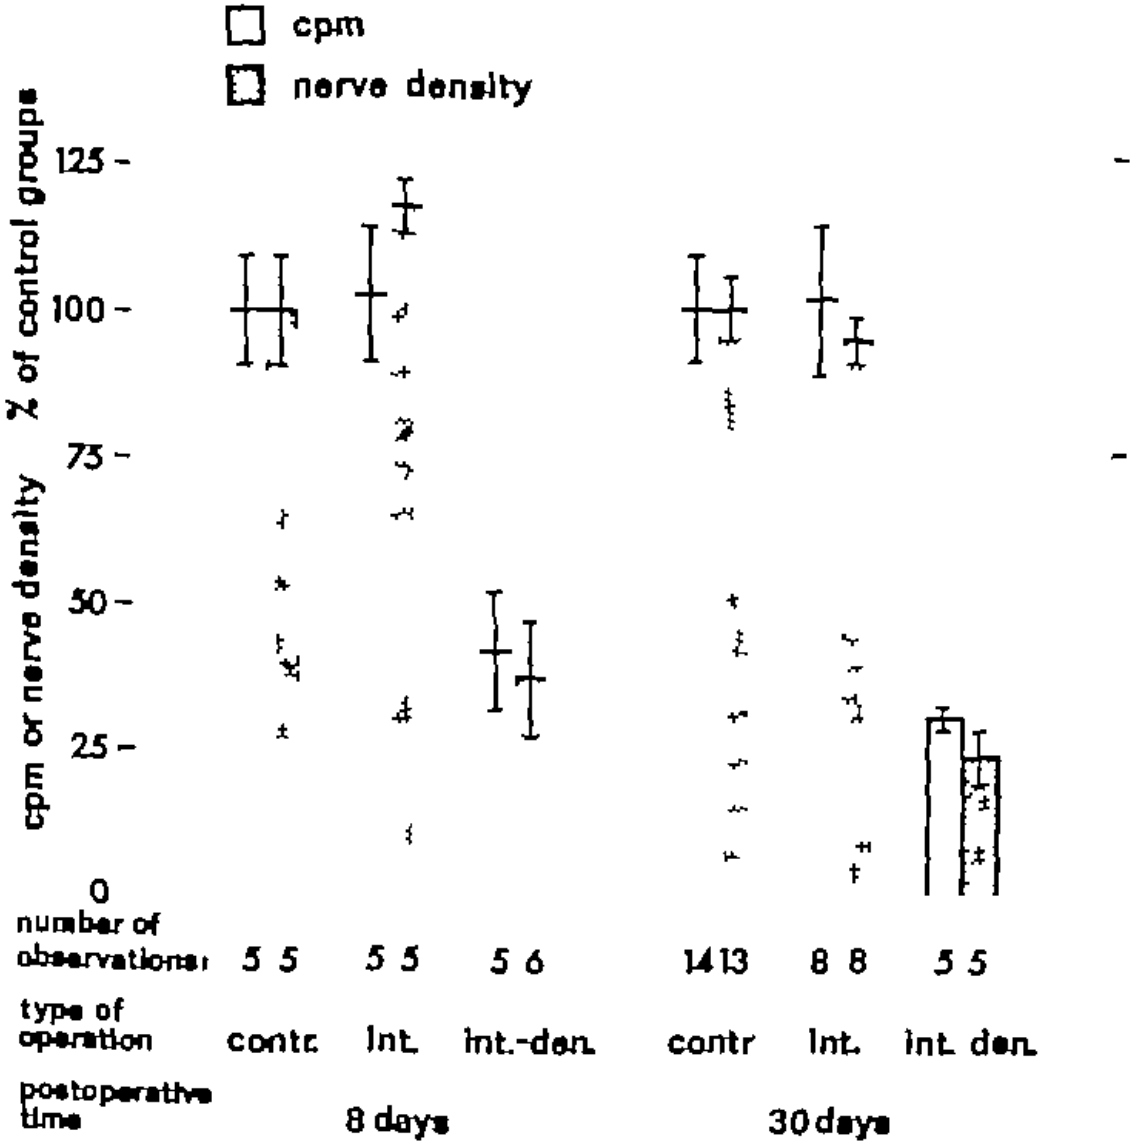
Ganglia transplanted to sympathetically innervated eyes became vascularized in the same way as when transplanted to denervated eyes. No differences could be detected between the two types of experiments when examined *in vivo*

The animals with ganglia transplanted to eyes with innervated host irides were divided into two groups. In one group the adrenergic ground plexus derived from the normally located superior cervical ganglion was left intact, while in another group this plexus was removed by exturpation of the ganglion 48 hrs before sacrifice. The latter procedure was used to detect only those fluorescent sympathetic nerves which had derived from the transplanted ganglion.

The principal finding of these experiments was that adrenergic nerves grew out to a much lesser extent into innervated irides than into denervated ones. This finding was evident using both types of experiments and could be demonstrated both by fluorescence microscopy and by isotope measurements (Fig 55, 56)

The total amount of nerves found in intact irides after eight days was only slightly larger than that found in the control group after the same

time (Textfig 11) Removal of the original ground plexus two days before sacrifice revealed that the amount of nerves coming from the transplant was only about 40 per cent of the values from the control group Almost exactly the same relations between the three experimental groups were found after 30 days. Furthermore, the isotope measurements and histochemical estimations were almost identical. Also the radioactivity found in the transplants was lower in the intact groups.



The fact that the acutely denervated groups contained more than the intact group minus 100 per cent indicated that the ganglion transplants started to grow during the last two days. To elucidate this possibility another experiment was designed where a 14 days intact group was compared to a group where the host iris was denervated after seven days and sacrifized seven days later It was clear from this experiment that such a delayed growth from the ganglion transplants as suggested in the first experiments really could be induced. Thus, the host irides which were denervated after seven days and left only with their transplants during the following seven days contained almost as large an amount of nerves as these denervated at the time of transplantation.

2. Chronic treatment with some drugs affecting the adrenergic transmission

Little is known concerning the importance of undisturbed transmitter mechanisms for the regulation of growth of the adrenergic nerves. Chronic treatment with drugs known to interfere with the synthesis, uptake, storage and metabolism of noradrenaline was therefore screened for their possible effects on outgrowth of new nerves into transplanted irides. Also the α-receptor blocking drugs phentolamine and phenoxibenzamine and the β-receptor stimulant isoproterenol were tried. The results of incubations are summarized in Textfig 12. The important conclusion from these experiments is that none of the chronic drug treatments used influenced the outgrowth of new nerves into the iris transplants to any great extent. The results of the fluorescence histochemistry parallelled the isotope uptake data.

The low uptake observed in host irides after chronic tyrosine hydroxylase inhibition was unexpected and cannot be satisfactory explained for the time being However these host irides did not differ from untreated controls when examined in the fluorescence microscope.

Almost all host irides and transplants contained somewhat less radioactivity after chronic drug treatment when compared to the chronically treated control irides than did the untreated host irides and transplants

11 Impairment of outgrowth from transplanted superior cervical ganglia when transplanted to host irides with an intact adrenergic ground plexus.

The following three groups were compared 8 or 30 days postoperatively

control: Host irides denervated at the time of transplantation. This is the type of transplantation used in chapter IV when determining the time course of the reinnervation.

Intact: The normally present adrenergic ground plexus left on the host irides until sacrifice.

Intact-denervated: The normally present adrenergic ground plexus left on host irides until 2 days before sacrifice. At this time the host irides were denervated by extirpation of the normally located superior cervical ganglion.

Each staple represents the mean ± s.e.m. from 4—14 observations expressed as per cent of the mean values from the control groups. Cpm found after ^{3}H-NA incubation and nerve density was determined in each iris.

when compared to normal irides. It should be mentioned in this connection that animals in most chronically treated groups were markedly affected by their respective treatments. Their general condition was impaired, evident as a decrease in body weight, drowsiness etc. Animals receiving α-blocking agents showed constant ptosis.
treated control irides than did the untreated host irides and transplants

A combination of α- and β-blocking agents was tried chronically on ganglion transplants. Ganglia were homologously transplanted to innervated eyes and left for one week. During the second week half of the animals received both phentolamine (50 mg/kg twice daily) and the β blocking drug H56/28 (25 mg/kg once daily) Both treated and untreated groups were further divided by adrenergic denervation of the host irides in half of the animals in each group after one week. Ptosis was observed in drug treated animals.

A small but constant decrease of ^{3}H NA uptake and amount of nerves was found in reinnervated host irides of drug treated animals (values being 10—30 per cent lower than corresponding untreated) The decrease could be observed both in irides with intact normal innervation and in those denervated after one week. No clear effect of the drug treatment was observed in unoperated animals.

3 Chronic treatment with cortisone or testosterone

Animals with autologous iris transplants were treated daily with hormones for two weeks beginning at the day of operation. They were then sacrificed and analyzed by the combined fluorescence-isotope technique

Cortisone, in a high dose (25 mg/kg) led to a body weight decrease of 10—15 per cent after 14 days in the treated animals. In the same period an increase of 10—15 per cent took place in the untreated animals. No difference in the rate of vascularization of the transplants were observed in between the cortisone treated and control animals. No effects of the cortisone treatment were observed on the NA uptake (Table four) or with the fluorescence microscope.

Testosterone was given in a dose of 5 mg/kg to male rats, castrated four days before the transplantation and the beginning of the drug treatment. The effectiveness of the different treatments were evaluated by measuring the weight changes of the seminal vesicles. Castrated groups decreased their seminal vesicle weight to 15 per cent of the untreated controls while the castrated testosterone treated groups increased the weight of the seminal vesicles 250 per cent. No effects of the testosterone treatment were obtained on the NA uptake (table 4) or in the fluorescence microscope.

Table 4

Effect of chronic treatment with cortisone or testosterone on the ^{3}H NA uptake in host irides and iris transplants

Hormones were given daily during the whole postoperative period, which was 14 days. All irides were incubated in ^{3}H NA 10^{-7}M and analyzed by the combined isotope fluorescence technique. Effectiveness of hormone treatments were monitored by following the body and seminal vesicle weights. Each value is the mean ± s.e.m. expressed as per cent of the cpm found in ^{3}H NA-incubated normal irides. Number of observations within brackets.

treatment	body weight / of start weight		weight of seminal vesicle /o of normal		cpm of normal irides		
	controls	operated	controls	operated	control irides	host irides	iris transplants
none	116	113			100±11 (6)	124±9 (4)	38±7 (4)
cortisone (25 mg/kg once daily)	89	85			100± 8 (6)	130±7 (6)	41±2 (6)
castration 4 days before transplantation			12	15	102± 7 (6)	116±8 (6)	36±3 (5)
castration + testosterone 5 mg/kg once daily)			236	259	106±11 (6)	121±7 (7)	38±4 (7)

4 Effects of certain decentralization and denervation experiments

It has been suggested that a normal impulse flow is requested for proper regeneration of certain types of nerves (Emmelin and Perec 1968 Hoffman 1952) and that the outgrowth of new nerves is stimulated by factors liberated from degenerating nerves (see Edds 1953). The following experiments were performed in order to find out f these suggestions would apply also to adrenergic nerves.

Decentralization of the superior cervical ganglion was obtained by excision of approximately f ve mm of the cervical sympathetic trunk below the ganglion. All decentralized an mals developed ptosis immediately and the

Table 5

Effects of certain decentralization and denervation experiments on the NA uptake and the amount of adrenergic nerves in two weeks old iris transplants and their host irides

Irides were incubated in ^{3}H NA and analyzed by the combined isotope-fluorescence technique. Values are expressed as per cent of the cpm and nerve density respectively found in control host irides and transplants not exposed to any additional decentralization or denervation. Each value is the mean ± s.e.m. Number of observations within brackets.

type of operation	time after transplantation weeks	cpm % of control		nerve density % of control	
		host iris	transplant	host iris	transplant
decentralization of the host iris at the time of transplantation	2	100±10 (8)	99±11 (7)	82±5 (7)	66±13 (7)
	15	134±11 (9)	137±15 (9)	90±3 (9)	100 (9)
decentralization of the iris to be transplanted 4 weeks before transplantation	2	95± 5 (6)	111± 8 (6)	100±4 (6)	99± 4 (7)
denervation of the iris to be transplanted 4 weeks before transplantation	2	85± 6 (8)	87± 9 (8)	95±3 (8)	67± 8 (8)

ptosis was present also at the longest postoperative time studied indicating that no or almost no reinnervation of the ganglion had occurred. Denervation of the eye was obtained by exturpation of the whole ganglion. Also denervated animals developed a persistant ptosis. Neither decentralization of the host iris nor chronic denervation or decentralization of the iris to be transplanted, caused any dramatic changes in the isotope or nerve density parameters (Table 5). Most values are relatively close to the corresponding controls, no change exceeding 40 per cent. It is noteworthy that decentralization of the host iris at the time of transplantation causes a discrepancy between nerve density estimations and ^{3}H NA uptake, the latter always exceeding the former relative to their control values.

However the NA uptake was found to increase 20 per cent without any observable increase of the fluorescent histochemical estimation of nerve density also in irides from animals without transplants (NA uptake in 12 normal irides 100 ± 5 0 in 12 chronically decentralized 121 ± 9 4).

The experiments indicate a somewhat delayed outgrowth of new nerves in two weeks old iris transplants following decentralization of the host iris at the time of transplantation or when transplanting a chronically denervated host iris. Ganglia were also transplanted to chronically denervated host irides (15 weeks) They were left to reinnervate the host irides during four weeks. It was found that the amount of nerves formed in the chronically denervated host irides was similar to or slightly larger than that formed in control irides after the same time. Fluorescence histochemistry and isotope measurements were similar

5 Discussion

Ganglia transplanted to eyes with an intact adrenergic innervation gave rise to a much smaller number of nerves in the host irides than when transplanted to reinnervated denervated host irides. This inhibition of the ganglionic regeneration did not seem to be merely a decreased growth rate since practically the same small amount of nerves was produced by the ganglia after 8 as after 30 days when transplanted to intact irides.

It should be mentioned that the host iris has been found always to react with a slight hyperinnervation whenever a transplant is connected to it (see VI) If this is true also for ganglion transplants the calculated amount of nerves produced by the transplant would be even smaller that is to say the growth inhibition even stronger The fact that the presence of a normal amount of nerves greatly inhibited the growth response of a balance between the outgrowth of nerves and the demands of the recip ent tissues applies also to regenerating adren rgic nerves in the adult individual. The inhibition of the ganglionic output is the more interesting when it is realized that the transplant certainly represents a large overcapacity when compared to the demands of the host iris.

The findings are in accordance with the results (IV and VII) that the ingrowth of new adrenergic n rves in an iris transplant as well as after outgrowth of nerves from a ganglionic transplant to a denervated host iris reaches a stable niveau which is close to the normal level of the receptor organ. It was also possible to induce a delayed growth response in the ganglion transplant initially inhibited by the p esence of the normal adrenergic plexus, simply by removal of this plexus.

Table 5

Effects of certain decentralization and denervation experiments on the NA uptake and the amount of adrenergic nerves in two weeks old iris transplants and their host irides

Irides were incubated in ^3H NA and analyzed by the combined isotope-fluorescence technique. Values are expressed as per cent of the cpm and nerve density respectively found in control host irides and transplants not exposed to any additional decentralization or denervation. Each value is the mean ± s.e.m. Number of observations within brackets.

type of operation	time after transplantation weeks	cpm / of control		nerve density / of control	
		host iris	transplant	host iris	transplant
decentralization of the host iris at the time of transplantation	2	100±10 (8)	99±11 (7)	82±5 (7)	66±13 (7)
	15	134±11 (9)	137±15 (9)	90±3 (9)	100 (9)
decentralization of the iris to be transplanted 4 weeks before transplantation	2	95± 5 (6)	111± 8 (6)	100±4 (6)	99± 4 (7)
denervation of the iris to be transplanted 4 weeks before transplantation	2	85± 6 (8)	87± 9 (8)	95±3 (8)	67± 8 (8)

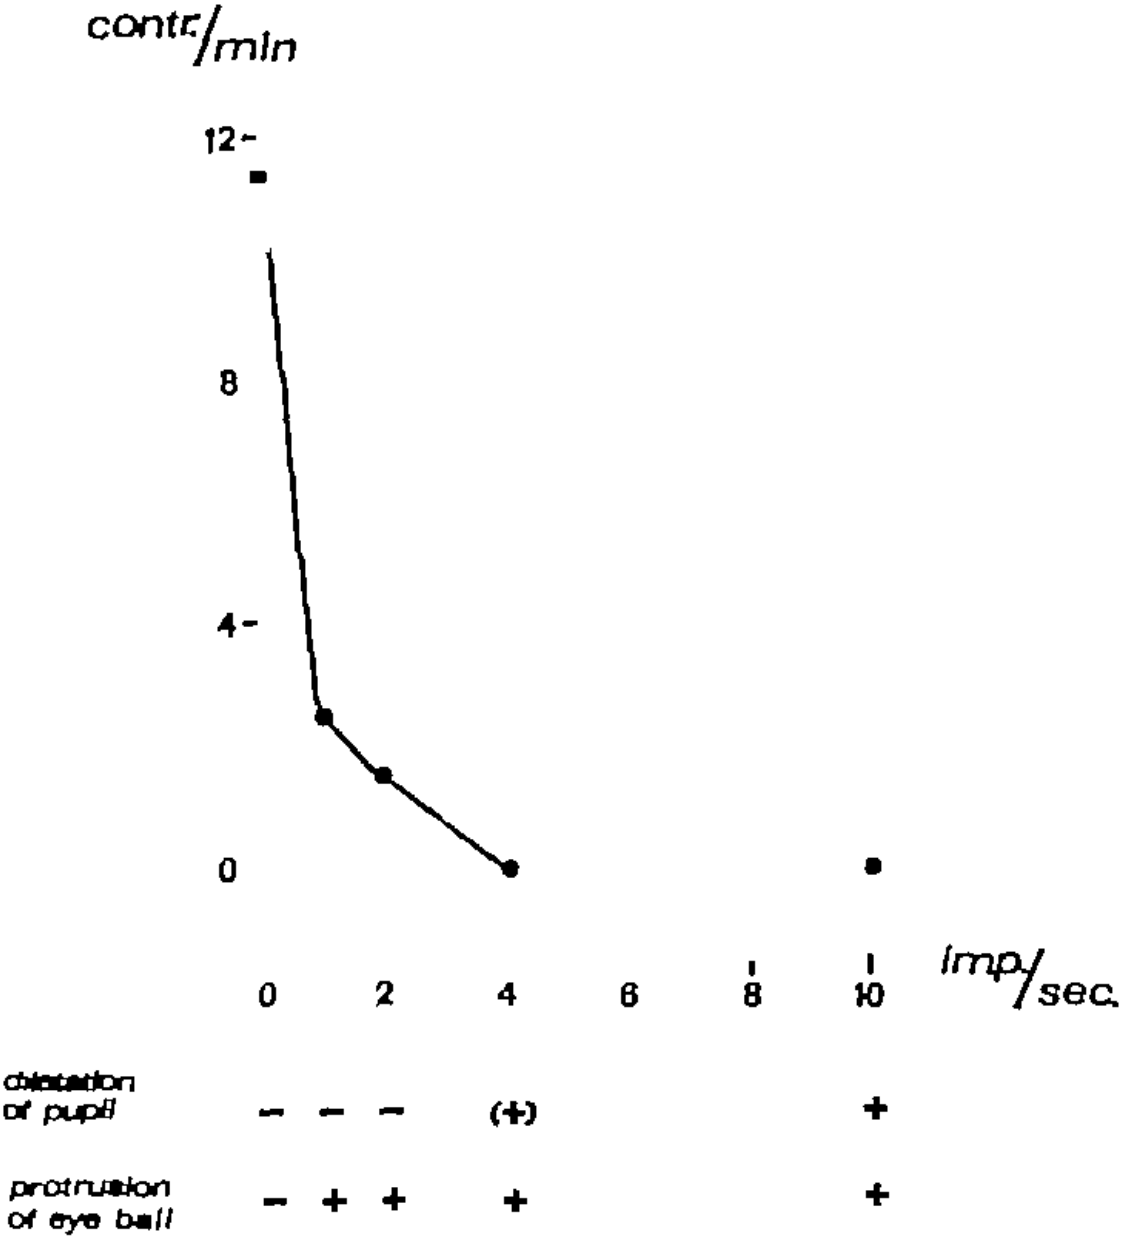
ptosis was present also at the longest postoperative time studied indicating that no or almost no reinnervation of the ganglion had occurred. Denervation of the eye was obtained by extirpation of the whole ganglion. Also denervated animals developed a persistant ptosis. Neither decentralization of the host iris nor chronic denervation or decentralization of the iris to be transplanted, caused any dramatic changes in the isotope or nerve density parameters (Table 5) Most values are relatively close to the corresponding controls, no change exceeding 40 per cent. It is noteworthy that decentralization of the host iris at the time of transplantation causes a discrepancy between nerve density estimations and ^3H NA uptake, the latter always exceeding the former relative to their control values.

It has been suggested that an undisturbed impulse traffic is a prerequisite for collateral sprouting of parasympathetic nerves (Emmelin and Perec 1968) and that electrical stimulation accelerates collateral sprouting of motor fibres (Hoffman 1952) However decentralization of the host iris had very small effects on the outgrowth of new adrenergic nerves into an iris transplant. Similarly cultured embryonic CNS tissue will continue to grow and form complex synaptic interconnections during chronic exposure to agents which completely prevent bioelectric activity (Crain, Bornstein and Peterson 1968)

The independence of presynaptic input and, also of the presence of effector organ demonstrated by growing neurons, is in fact the necessary explanation for the successful *in vitro* culture of nervous tissues. Embryonic sympathetic ganglia readily survive in tissue cultures (chick *e g* Burdman *1968* England and Goldstein *1969* rat and mouse Sano, Odake and Yonezawa 1967 see also Levi-Montalcini and Angeletti 1968) and demonstrate efficient uptake mechanisms for NA.

The outgrowth of adrenergic nerves is inhibited by the presence of adrenergic nerves. Interference with the adrenergic transmission or transmitter mechanisms does not alter the outgrowth. Cortisone and testosterone do no affect the outgrowth of adrenergic nerves.

VII RESTITUTION OF ADRENERGIC NEUROTRANSMISSION IN THE ANTERIOR CHAMBER TRANSPLANTS



In the preceding chapters the histochemical characteristics of growing peripheral adrenergic nerves in the adult rat have been described under various experimental conditions. The reestablishment of apparently normal relationships between the nerve terminals and their effector organs suggests that return of function has also occurred. The studies of the pharmacology of the newly formed nerves demonstrated that these nerves were able to take up, accumulate and release NA. If now by electrical stimulation of the newly formed nerves, a proper response of the reinnervated tissue could be observed, the above mentioned results could be definitely linked to return of neurotransmission.

Since functional observations are technically difficult to perform in transplanted irides, three other effector organs were chosen for these studies, namely the small intestine, the portal vein and the vas deferens.

1 In vivo experiments on intestinal smooth muscle transplants

Observations of contractions, effect of electrical stimulation. Smooth muscle strips from any part of the intestine were found to survive well when homologously transplanted to the anterior chamber Duodenal strips were used for the stimulation experiments. They contained both muscle layers with the outer longitudinal layer running along the strip and the circular layer running transversally Thus, the plexus of Auerbach situated in between the muscle layers, was included.

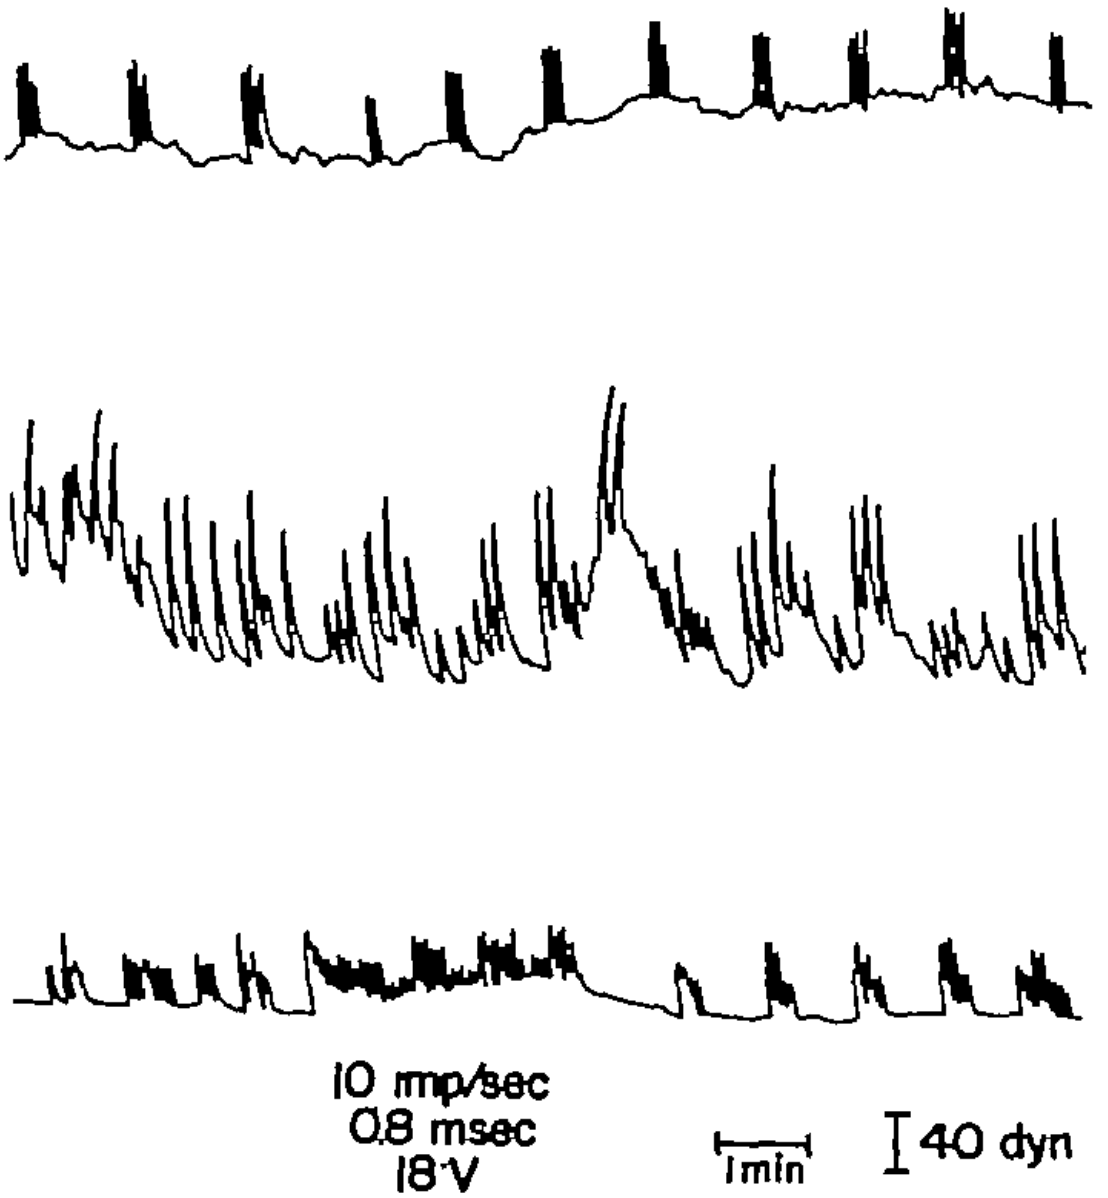
Spontaneous contractions were observed in some transplants within one week postoperatively and in several after 14 days. Later most of the transplants developed spontaneous contractions. Those which contracted did so during the whole postoperative period (more than six months) The rate of contractions and mode of rhythmicity were determined in non stimulated animals under ether anaesthesia The range of the rate of contraction was 5—25 per min. Some transplants showed bursts of activity con

13 Effect of electrical stimulation of the cervical sympathetic trunk on spontaneous contractions of a duodenal smooth muscl strip transplanted to the anterior chamber of the eye as observed *in situ*.

sisting of 2—6 contractions at a rate of approximately one per sec with up to 30 sec intervals while others exhibited regular contractions. It was noted that handling and restraining the animals under too light ether anaesthesia sometimes caused cessation of contractions as well as dilatation of the pupil.

Electrical stimulation of the sympathetic trunk at a frequency of 4—6 per sec or more caused a prompt inhibition of the contractions of all active transplants. Textfig 13 demonstrates a typical experiment with a 15 days

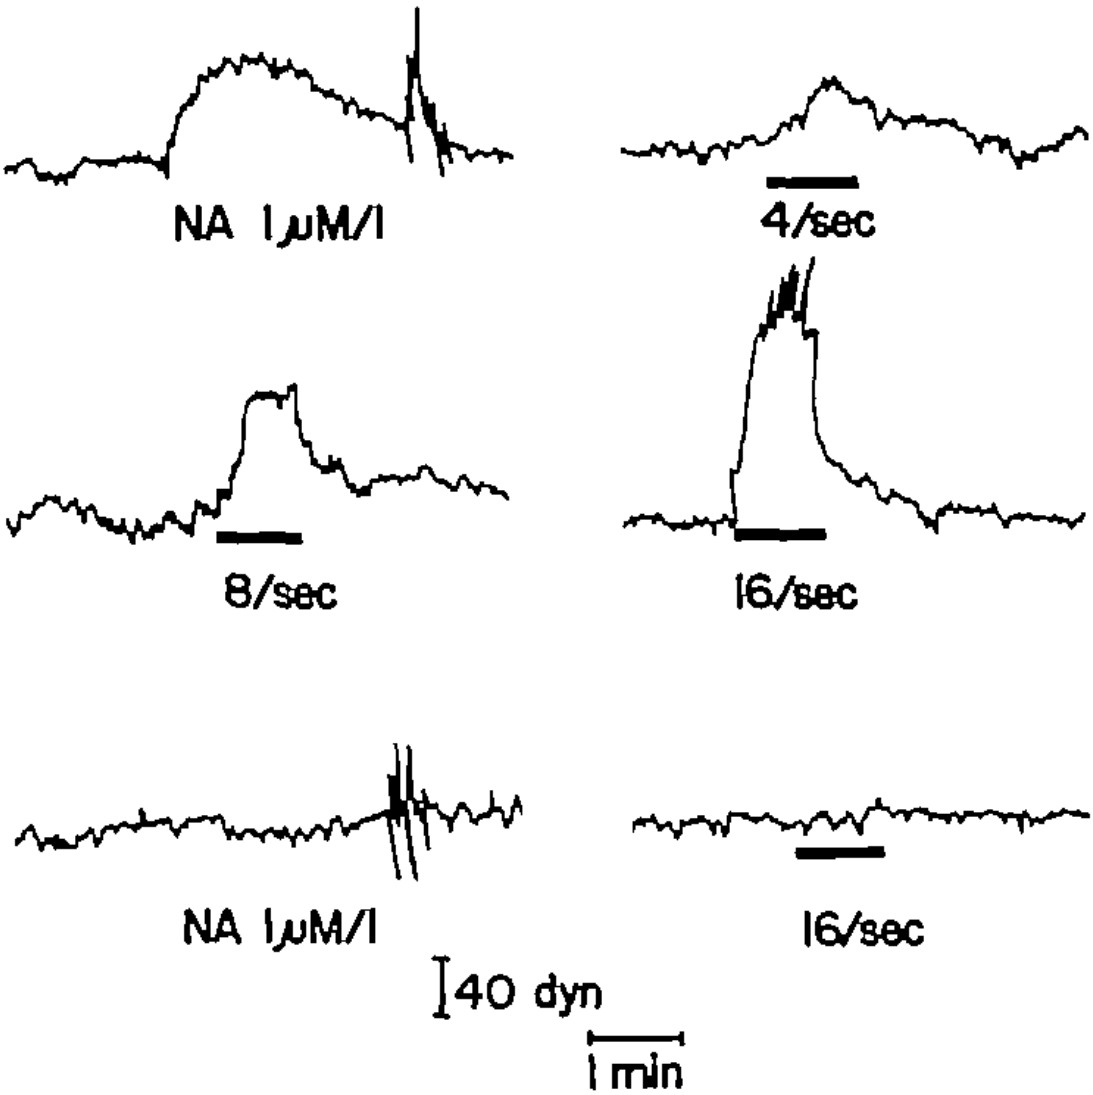
old transplant. An almost total inhibition of the contractions was obtained with stimulation at 2 impulses per sec when no or almost no dilatation of the pupil was observed. Protrusion of the eye ball was evident, however at this frequency The effect could be easily repeated and was evident, at higher stimulation frequencies, even before the beginning of the dilatation.



It seemed as if the muscle strips contracted at higher rates during "off minutes" following "on minutes with higher frequences than after low frequency stimulation.

Fluorescence microscopy Muscle transplants showed an essentially normal gross organization of their two muscle layers and the intervening plexus of Auerbach, as revealed in the fluorescence microscope (5μ serial sections) They were well supplied with fluorescent nerve fibres from the 14th day on (Fig 54) Fine, varicose NA nerves were always found surrounding the non fluorescent cell bodies of Auerbach s plexus, as in the intact animal (Norberg 1964) A certain amount of fluorescent fibres were also found among the smooth muscle cells without any direct relation to the nerve cell bodies. Some of the latter fibres were less varicose and exhibited a lower fluorescence intensity than the former

2. In vitro experiments of portal vein and vas deferens muscle strip transplants



Portal vein. The longitudinal smooth muscle of the rat portal vein has a spontaneous rhythmic activity which can be well demonstrated *in vitro* (Funaki and Bohr 1964 Axelsson, Wahlström Johansson and Jonsson 1967) This activity was found to be present also in the transplants although some contracted more irregularly when examined after 2,5 months in the anterior chamber A prompt and persistant contraction could be elicited by field stimulation (Textfig 14) and this effect could be completely inhibited by adding phenoxybenzamine (10^{-6}M) to the bath Fluorescence microscopy of the transplanted vessel musculature revealed a reinnervation by adrenergic nerve fibres which resembled the normal pattern (Johansson, Ljung, Malmfors and Olson 1970)

Vas deferens. The smooth muscle of the vas deferens has a rich adrenergic innervation and is easily accessible for physiological recordings of contractions *in vitro* Longitudinal strips from the muscle wall were found to survive well in the anterior chamber and could then be tested *in vitro* with the technique similar to that used for the portal vein

14 Spontaneous contractions recorded isometrically *in vitro* from three transplants of the portal vein musculature after 2,5 months in the anterior chamber Note variation in mode of contraction, the upper and lower transplants contracting at fairly regular intervals whil the middle one contracts in more irregular manner The effect of field stimulation is demonstrated on the lower transplant. This effect wa abolished by phenoxybenzamine (10^{-6}M)

The transplants responded with prompt and sustained contractions both to added noradrenaline (10^{-6}M) and to f'eld stimulation. These effects were abolished by phenoxybenzamine (10^{-6}M) A representative experiment is shown in textfig. 15 where 13 months old transplant was used.

15 Contractions recorded isometrically *in vitro* from a vas deferens transplant after 13 months in the anterior chamber
Uppe left The effect f added noradrenaline
Upper right and middl left and right The effect f field stimulation
Lower left and right Inhibition of both the NA-effect and the ffect of electrical stimulation by α-blockade.
(Rapid pen movements following NA in the bath are running artefacts)

When examined in the fluorescence microscope, the vas deferens muscle transplants were found to contain a rich adrenergic innervation Strongly fluorescent varicose nerve terminals were distributed throughout the muscular tissue generally running parallell to the muscle fibres (Fig 53) The innervation pattern was thus similar to that normally found.

3 Discussion

The functional studies in the present work serve two different purposes. It was desired firstly to test the response of the effector cells, mainly smooth muscle cells, and secondly to study the restitution of the adrenergic neurotransmission by the newly formed nerves. The *in vivo* observations of e g transplanted intestinal smooth muscle strips, which showed spontaneous contractions, clearly indicated that the smooth muscle cells survived and retained their contraction ability after the transplantation. Furthermore, the isolated transplant of portal vein showed spontaneous activity even if more irregularly than normally and vas deferens transplants contracted when NA was added. Thus there is at least no qualitative change of the properties of the smooth muscle cells a long time after the transplantation. The vas deferens and the portal vein transplants became reinnervated to about the normal extent. The normal innervation of these organs has been described (Falck 1962, Norberg and Hamberger 1964 Ungvåry and Donáth 1969 Johansson, Ljung, Malmfors and Olson 1970)

The response in the isolated portal vein and vas deferens transplants to electric field stimulation was with all certainty due to NA released from the adrenergic nerves in th transplants as the effect was blocked by phenoxybenzamine. The experiments clearly show that these nerves are capable of restituting the adrenergic neurotransmission. Thus the portal vein and the vas deferens transplants become reinnervated both morphologically and functionally by excitatory adrenergic nerves.

An extensive network of adrenergic terminals have normally been found around the ganglion cells in the nerve plexuses of the intestinal wall. The amount of adrenergic nerve terminals directly innervating the muscle layers is generally less although great variations exists between different parts of the intestinal tract and between different species (Norberg 1964 1967; Norberg and Sjöqvist 1966 Hollands and Vanov 1965 Jacobowitz 1965 Cabella and Costa 1967 Baumgarten 1967; Baumgarten and Lange 1969 Read and Burnstock 1968 a, b, c). The plexus of Auerbach in the duodenal transplants became reinnervated by adrenergic nerves and a few nerve fibres were found also in the muscle layers.

The sympathetic nerves of the intestine are generally inhibitory in function and t has been proposed that this inhibitory effect is mediated via the adrenergic innervation of the nerve cells in the plexus of Auerbach (Norberg 1964)

The smooth muscle transplants developed spontaneous contractions in the eye. These contractions were promptly inhibited by preganglionic electrical stimulation of the superior cervical ganglion The contractions stopped nearly completely at a frequency as low as four per sec which caused only a slight bulb protrusion and pupil dilatation. At ten imp per sec there was a clear protrusion and dilatation as well as relaxation of the transplant. Although these results clearly linked the activity of the superior cervical ganglion to inhibition of contractions in the transplant, the interpretation of this finding is somewhat unclear NA, from the adrenergic nerve terminals around the ganglion cells or within the muscle layers or possibly from the adrenergic ground plexus of the host iris, can then act either via the ganglion cells or directly on the muscle tissue.

However the most prominent factor in inhibiting the mobility of the intestine has recently been claimed to be a system of neurons in the intestinal wall, separate from both the adrenergic and the cholinergic neurons. It has been called the non adrenergic inhibitory system and has been shown also in other organ systems. Activation of the neurons in this system by transmural stimulation at rather low frequencies (1—4/sec) stops the spontaneous contractions of the intestinal wall (Burnstock, Campbell, Bennet and Holman 1963 1964 Holman and Huges 1965 Bennet, Burnstock and Holman 1966; Burnstock, Campbell and Rand 1966, Furness 1969) Due to the sensitivity of the transplants to very low frequency stimulation the presence of this non adrenergic inhibitory system in the transplants cannot be excluded. The non adrenergic inhibitory component has recently been demonstrated in muscle transplants from the guinea pig taenia caeci to the anterior chamber of the eye (Burnstock Gannon Malmfors and Rogers 1970)

Thus the true nature of the relaxation induced by sympathetic stimulation in the duodenal transplants remains to be disclosed but the present model system should be useful in further experiments.

The newly formed nerves in adult rats are able to restitute the adrenergic neuromuscular transmission.

VIII COMPARATIVE TRANSPLANTATION EXPERIMENTS USING DIFFERENT TISSUES LOCATIONS AND SPECIES

The purpose of the present experiments was to perform comparisons of the growth of the adrenergic nerves after the following types of transplantations. 1 Adrenergically innervated versus non innervated organs. 2 Rats versus hamster and mouse. 3 Auto- or homologous transplantations versus heterologous. 4 The anterior chamber versus other sites of transplantation. 5 Immature versus mature adrenergic neurons.

1 Transplantation of other organs to the anterior chamber of the rat eye.

All tissues hitherto tried became vascularized and maintained in most cases structural integrity relatively well for long periods of time. No differences were observed between autologous and homologous transplants.

It seems appropriate to list here all different tissues tried, including those mentioned in earlier chapters, in a more systematic way

superior cervical ganglion, coeliac ganglion, lumbar sympathetic chain ganglia, hypogastricus ganglia

iris, choroidea

submaxillary gland sublingual gland, panchreas, kidney

portal vein, femoral artery intestinal smooth muscle layer vas deferens muscle layer uterus muscle layer auricle of heart, ventricle of heart, quadriceps muscle

adrenal medulla, ovary hypophysis, epiphysis.

The list of transplantations presented demonstrated the applicability of the method and since in fact no failures have hitherto been recorded in the taking of transplants it seems that any peripheral tissue can be used.

It is beyond the scope of the present investigation to describe in detail the ingrowth of adrenergic nerves in all the different receptor organs tried. Instead some general conclusions will be made which are valid for all transplants. A few experiments which demonstrate specific points of interest will be described in more detail.

transplants. The ganglia appeared normal in all respect
tion. They contained nerve cell bodies without specific fl
fluorescent nerve fibres were found inside the ganglia.

2. Confirmatory experiments on the growth of adrenergic nerves in hamsters and mice

Albino hamsters: Iris and ganglion transplantations were performed. The results were in all respects similar of those obtained in rats. Vascularization was rapid. Iris transplants became reinnervated in the same way as in rats. The organization of the adrenergic nerves in the hamster iris is very similar to that of the rat. This pattern was copied by the growing nerves in the hamster transplants (Fig. 59, 60). Thus, for instance the blindly ending nerves extending from the ciliary body radially for a short distance into the choroid membrane were reformed in the transplants. The hamster host irides became hyperinnervated.

Ganglion transplants rapidely innervated denervated host irides. The appearance of the new nerves formed by ganglion transplants resembled that seen in rats. They were thus somewhat smoother than the normal ground plexus after two weeks.

Albino mouse: Iris transplantations were performed. The small size of the mouse eyes was not found to cause any difficulties. Transplants became vascularized in the usual way. The organization of the adrenergic ground plexus of the mouse iris differs from that of the rat in having fewer fluorescent fibres in each strand of the plexus. No detailed analysis was performed on mouse iris transplants but it seemed as if the characteristics of the normal mouse plexus was kept in the transplant. Mast cells were frequent on the host irides.

3. Heterologous transplantations

Mouse irides and superior cervical ganglia were transplanted to the anterior chamber of the rat eye. The heterologous transplants caused more severe and long lasting reactions of the host eyes. Miscoloration was often persistant and vascularization was delayed. It seemed however as if ganglia were better tolerated than irides.

Most animals were sacrificed after 14 days. The mouse iris transplants had then become reinnervated by rat nerves (Fig. 60). The extent of innervation varied, but plexuses were often formed only on limited areas. Interestingly

the newly formed plexuses were more similar to the normal mouse plexus than to the normal rat plexus (*cf* Malmfors 1965a) The host irides were swollen and contained large amounts of cells which were interpreted as being macrophages. These cells were readily identified in the fluorescence microscope due to their heavy cytoplasmic inclusions of brownish-fluorescence granules. Some host irides were hyperinnervated while others had less nerves than normally Eventually the transplants were invaded by macrophagic cells from the host irides and had begun to desintegrate.

Superior cervical ganglia from the mouse were capable of reinnervating denervated rat irides (Fig 62) The initial outgrowth rate was similar to that found after auto- or homologous transplantations in the rat. Large areas of the rat iris could be found innervated after 14 days but the fluorescence intensity of the outgrowing nerves was low

4 Transplantation of the anterior half of the eye to other locations

The anterior half of the eye was unilaterally transferred as described (II.2) to the submaxillary gland, the vas deferens and the sciatic nerve. *In vivo* observations could be performed only before sacrifice by free-dissection of the corneal surface. In successful cases the cornea was clear the anterior chamber filled with a clear fluid and the iris visible in its original position. It was then easy to prepare the iris for fluorescence microscopy

At all three locations, a new plexus of fluorescent varicose nerves was established in the transplanted iris which was similar to the normal adrenergic plexus. A certain hyper reinnervation of the transplanted iris was often noted after transplantation to the submaxillary gland (Fig 63) or the vas deferens (Fig 64) when the transplanted irides were compared to the control eyes of the same animals.

5 Special transplantations of the superior cervical ganglion e.g. to different locations

Transplants of different parts of the superior cervical ganglion.

A comparison was made between the outgrowth from the cranial and the caudal ends of the ganglia by transplanting small pieces of about the same sizes to the anterior chamber It was found that both ends easily reinnervated the host irides as did the longitudinally cut halves which was usually used. The apical pool, however seemed to give rise to a more sparse innervation than the caudal one.

Superior cervical ganglion transplants from newborn rats: Whole ganglia from newborn rats were transplanted to the anterior chamber of adult animals. The host eyes were sympathetically denervated at the time of transplantation. The transplants survived well in the anterior chamber but no increase in size could be observed *in vivo* during the postoperative time studied. On the contrary many transplants seemed to have decreased their size during the longest intraocular period which was six months, while corresponding ganglia left *in situ* during the same time had grown to adult size.

Although no macroscopical growth was observed the transplants re innervated the denervated host irides. The early course of this growth was not closely followed but new nerves were observed *e.g.* at the ninth day. Detailed examinations after three and six months revealed a relatively well developed plexus of fluorescent nerves in the host irides (Fig 65). It covered 50—100 per cent of the iris. The density of the meshwork was sometimes less than normal but the nerve fibres were indistinguishable from fibres produced by adult ganglion transplants. Thus, both typically varicose terminals and beaded non terminal axons were found. The choroid membrane was reinner vated to a varying extent.

Small transplants were sometimes left on the host irides during stretch preparation. Single fluorescent nerve cell bodies could then occasionally be observed. The initial part of the axon could be followed. It was smooth ly outlined and had the same fluorescence intensity as the cytoplasm of the large rounded cell body. Also the small intensely fluorescent so called SIF cells typical of normal sympathetic ganglia, were found in the transplants. They were arranged in small clusters and had a few short processes.

Transplantation of the superior cervical ganglion to other locations. Ganglia were bilaterally transplanted under the bulbar conjunctiva of the ipsilateral orb t. The transplants and its local surroundings, the iris of the corresponding eye and the salivary glands were examined at postoperative times *up to six months. The ganglia survived and could be recovered from* the submucosa also after six months (Fig 66). The cell bodies generally showed a low fluorescence intensity and often excentric nuclei. The transplant was surrounded by large numbers of strongly fluorescent bulgy fibres, many of which was encircling the whole transplant. An increased number of mast cells was found around the transplant. The adjacent rudimentary nictitating muscle of the rat was sometimes reinnervated. Fluorescent nerves, which could be safely regarded as coming from the transplant, were not found in the iris or choroid membrane.

The superior cervical ganglion was also autologously transplanted to the sciatic nerve. In spread preparations of the nerve 14—28 days later a large number of axons were found emanating from the ganglion and running in both directions of the nerve (Fig 67). The fibres had the same appearance as the normally present non-terminal fluorescent axons of the nerve. The normal population of fluorescent fibres was removed by compression of the sciatic nerve cranial to the site of transplantation either at the time of transplantation or 1—2 days prior to sacrifice. It was found that the presence of the normal amount of fluorescent nerves inhibited the outgrowth from the transplant to a certain extent. This inhibition was difficult to estimate, but was by no means as great as that obtained by transplanting the ganglion to the anterior chamber of an adrenergically innervated eye.

6 Transplantation of adrenal medulla to the anterior chamber

The fluorescence technique cannot disclose any possibly existing adrenergic ganglion cells within the normal adrenal medulla, due to the extremely high fluorescence intensity of the endocrine cells, but it was hoped that if some nerve cells were present, fluorescent nerve fibres would be produced by the transplant.

As far as can be judged from the fluorescence histochemistry the endocrine adrenal medullary cells themselves gave rise to fluorescent nerve fibres reinnervating the denervated host iris (see Olson 1970).

The transplants were similar to the normal adrenal medulla, showing the characteristic strong yellowish fluorescence of the NA cells and the somewhat weaker but still quite strong yellow green fluorescence of the adrenaline cells. The transplants were often less compact than the normal medulla and many cells were elongated and showed fluorescent processes. (Fig 68).

Small groups of adrenal medullary cells were always found attached to the host irides when the main transplants had been pulled away and the irides stretch prepared (Fig 69). The cell clusters were often found at considerable distances from the sites of attachment of the transplant. In several cases, fluorescent fibres could be followed in their whole length from an origin in the soma of the medullary cells to the peripheral ramifications. These fluorescent fibres were capable of forming plexus like meshworks over large areas of the host irides and were in all respects similar to the normal iris nerves with the one exception of their peculiar cellular origin. The fluorescent cells attached to the iris surface had the

same appearance as those found in the transplants. Thus they were smaller than adrenergic ganglion cells and had a much stronger fluorescence intensity

Due to the remarkable findings described, it was not possible to definitely answer the initial question whether true adrenergic nerve cells existed in the medulla. Cells similar to the normal adrenergic nerve cells were however not found, although it can be assumed that it would have been easier to detect them among the often more loosely arranged medullary cells of the transplants or on the host irides than in the normal adrenal medulla.

7 Discussion

All peripheral organs transplanted to the anterior chamber became reinnervated to an essentially normal extent. The important conclusions from these results are twofold

1 The amount of ingrowing nerves is specifically and precisely regulated by the effector organ The transplantation of the adrenergically innervated submaxillary gland as compared to the non innervated sublingual gland (Norberg and Hamberger 1964 Norberg and Olson 1965 Fujiwara, Tanaka, Hoojo and Okegawa 1965) illustrates this fact. Although the glandular parenchyma underwent marked changes (*cf* Andén, Norberg and Olson 1966) it was clear that the submaxillary gland became well reinnervated, while the sublingual gland remained devoid of parenchymal innervation. It is interesting to note that fluorescent nerves from the host iris encircled the sublingual transplant but were unable to penetrate into it.

2 Organs normally innervated by adrenergic nerve from different parts of the sympathetic nervous system became equally well reinnervated by the iris plexus. Thus, there is no specificity between the various para and prevertebrally sympathetically innervated organs in this aspect. These findings are complementory to the results of transplanting various adrenergic ganglia to the anterior chamber (see IV) which demonstrated that any part of the sympathetic nervous system could reinnervate the iris.

The remarkable results of transplanting the adrenal medulla prompted a more detailed fluorescent histochemical study which is reported elsewhere (Olson 1970) The outgrowth of fluorescent fibres, in all respects similar to normal adrenergic nerves from the medullary cells is an indication of the ontogenetic relationship between these cells and adrenergic nerve cells. It could not be determined from the present experiments if

IX GENERAL DISCUSSION

1 Methodological considerations.

The histochemical fluorescence method The chemistry and specificity of the fluorescence histochemical method is well established and has been discussed at length in several papers (Falck 1962, Falck Hillarp Thieme and Torp 1962 Corrodi and Hillarp 1963 1964 Corrodi, Hillarp and Jonsson 1964 Corrodi and Jonsson 1965 1966, 1967 Caspersson, Hillarp, Ritzén 1966, Jonsson 1966 1967 a, b c, 1969 Ritzén 1966 1967 Norberg, 1967) The practical performance including freeze-drying, air-drying, paraformaldehyde reaction and the optical equipment needed has also been described in detail by several authors (Dahlström and Fuxe *1964b* Malmfors *1965a*, Falck and Owman 1965 Hamberger Malmfors and Sachs 1965 Hamberger 1967 Norberg 1967 Eränkö 1967 Olson and Ungerstedt 1970)

It can be concluded with certainty from the references above that the formaldehyde-induced yellow-green fluorescence derives from cellular stores of biogenic monoamines or some of their immediate precursors (see especially discussion by Hamberger 1967 and the review by Corrodi and Jonsson 1967) Thus in the case of the postganglionic sympathetic adrenergic neurons which were studied in the present investigation, the specific fluorescence observed is due to NA

It is very likely that the fluorescence technique reveals the axon ramifications of the adrenergic neurons in their full extent in the pharmacologically untreated animal also during the conditions of growth studied here. This assumption was discussed by Olson (1969) in the case of regenerating non-terminal axons in rat sciatic nerve and is supported by the following facts:

1 The adrenergic neurons contain adequate concentrations of NA for histochemical visualization very early during the ontogenesis (see de Champlain Malmfors, Olson and Sachs 1970)

2 The *number* of visible fluorescent nerves does not significantly change following pharmacological treatments which increase the fluorescence *intensity* of the already visible nerves (*cf* de Champlain Malmfors, Olson and Sachs 1970)

3 The rate of transport of NA storage granules (Dahlström and Häggendahl 1966) exceeds by far the nerve growth rates and electron microscopical studies demonstrates the presence of such amine storage granules in growth cones (Blümcke and Niedorf 1965) and axonal sprouts (Kapeller and Mayor 1966)

4 The morphology of the growing nerves studied by the fluorescence technique is similar to the classical descriptions of various regenerating nerves using classical staining methods (*e g* Cajal 1928)

Quantification of nerve growth All possible precautions were undertaken in order to obtain reliable quantitative estimations of the amount of nerves in the iris preparations. ^{3}H NA uptake measurements were always combined with fluorescence microscopy (Olson, Hamberger Jonsson and Malmfors 1968) on the same irides and the fluorescence microscopical estimations of amount of nerves were performed on coded slides, sometimes independently by the two authors. The experiments described in II 9 proved that the two estimators reached almost identical estimations of nerve amount in partially denervated irides and that these estimations were very well correlated to the radioactivity recovered in the same irides after ^{3}H NA incubations. Using the present technique of ^{3}H NA incubation the total radioactivity recovered represents almost exclusively ^{3}H NA taken up into the adrenergic nerves (Jonsson, Hamberger Malmfors and Sachs 1969) It can be concluded that the ^{3}H-activity recovered very well reflects the amount of nerves in the irides under these circumstances. Furthermore, it was shown (see V) that the transmitter mechanisms of the newly formed nerves were similar to those of normal adrenergic nerves in the adult animal. Assuming an essentially unchanged uptake and retention of ^{3}H NA, the radioactivity parameter would be a good measurement of the total amount of nerves also during growth A good correlation between the ^{3}H NA uptake and fluorescence histochemical estimations was in fact found also in the growing nerves.

While the ^{3}H NA uptake measurements possibly better reflects the total amount of nerves in certain situations such as *e g* in hyperinnervated host irides, the fluorescence histochemical estimations are needed for the exact morphological description of the nerve growth.

Quantitative aspects of the fluorescence intensity The fluorescence histochemical method can provide semiquantitative measurements of changes in CA content. Estimations of fluorescence intensities after different pharmacological treatments as compared to controls have been used *e.g.* by Malmfors (1965a) Norberg (1965) and Hamberger (1967)

A good correlation between the NA content and the fluorescence intensity of the adrenergic nerves has later been demonstrated up to a certain NA

concentration both when observing the fluorescence intensity with the eye (Olson, Hamberger Jonsson and Malmfors 1968) and when using microfluorometric techniques (Jonsson 1969) Jonsson states "if changes in fluorescence intensity as compared with the control are observed this reflects true changes in amine concentrations, but changes in amine concentration may escape detections when the concentration of amine is so high that quenching occurs"

The transplantation technique The anterior chamber of the eye has been utilized as a site of transplantation for a variety of purposes during the last 50 years. The specific advantages of this technique when studying growth of adrenergic nerves were described in I 4

The first fluorescence histochemical evidence for adrenergic reinnervation of intraocular transplants was reported by Owman (1964) using pineal grafts. This was later confirmed by Wragg, Machado Snyder and Axelrod (1967) A preliminary account of parts of the present results was given by Malmfors and Olson (1967)

2. Normal innervation.

The adrenergic innervation of the eye has been extensively studied in many species with the fluorescence technique (Falck 1962, Malmfors 1965 a, b Malmfors and Sachs 1965 a, b, Ehinger 1964 1966 a, b Laties and Jacobowitz 1966) All fluorescent intraocular nerves, apart from the retinal dopamin neurons (Malmfors 1963 Häggendal and Malmfors 1963 Ehinger 1966 c, Ehinger and Falck 1969) derive from the ipsilateral cervical sympathetic chain and certainly almost exclusively from the superior cervical ganglion. Varicose adrenergic nerve terminals are found in most parts of the rat eye. The corpus ciliare and iris contains a relatively dense autonomic ground plexus (for definition of ground plexus see Hillarp 1946 1959 1960, Norberg 1967) and the plexus has been shown to contain also numerous cholinergic nerves (Ehinger and Falck 1966, Laties and Jacobowitz 1966, Ehinger Sporrong and Stenevi 1968).

With the introduction of the potassium permanganate technique of Richardson (1966) and cholinesterase stainings combined with specific denervation experiments, the dual innervation of the iris has also been clearly demonstrated electronmicroscopically (see Csillik, Knyihár and Halász 1968 Hökfelt 1969 Roth and Richardson 1969) The cholinergic and adrenergic fibres run in small bundles close to each other commonly within the same Schwann cell envelope. The vast majority of the cholinergic supply derives from the ciliary ganglion (Richardson 1969) The knowledge of the autonomic inner

vation of the rat eye constitutes the necessary basis for the present experimental studies on growth of the intraocular adrenergic nerves.

The various sympathetic ganglia used for transplantation in the present study have earlier been thoroughly studied with the fluorescence method (Norberg and Hamberger 1964 Norberg 1965 Hamberger and Norberg 1965 Sjöstrand 1965) For a review of the adrenergic innervation of other tissues used in the present study see Norberg (1967)

3 Growth mechanisms of the adrenergic nerves.

Growth of the adrenergic neurons, like that of all other neurons, comprises several different forms which all lend themselves to experimental studies. Distinction should be made between the ontogenesis of the adrenergic neurons and the growth which take place in the adult individual Growth of mature neurons may be further subdivided according to whether the neuron grows in response to injury or extends its field of innervation because of other reasons. The various experimental techniques used (*e g* axotomy transplantation, explantation) provides another basis of division which is useful for clarification of the results hitherto reported in the literature

The fluorescence histochemical method has proved to be an excellent tool also for studying growth of the adrenergic nerves. The early appearance of NA in the sympathicoblasts (Enemar Falck and Håkansson 1965 Olson, de Champlain, Malmfors and Sachs 1970) as well as the ontogenesis of the adrenergic innervation apparatus (see Olson, de Champlain, Malmfors and Sachs 1970) have been described. Other ontogenetical aspects studied include the growth of fetal sympathetic ganglia in tissue culture (Sano, Odake and Yonezawa 1967) and the effect of the nerve growth factor (Olson 1967) and its antiserum (Hamberger Levi Montalcini, Norberg and Sjöq ist 1965) on the neuronal development.

Although growth during ontogenesis may differ in many respects from growth of mature neurons, as the latter was studied in the present investigation, certain fluorescence morphological characteristics are similar Thus, out growing axons look smoother and thicker than mature axons at rest and show a higher fluorescence intensity When the terminal nerve plexuses are being formed they are initially of a weaker fluorescence intensity and the varicosities of th nerves making up th strands of the plexuses less pronounced.

Regeneration of the non terminal adrenergic axons foll wing axotomy in the adult animal (Dahlström 1965 Blümcke and Niedorf 1965 Olson 1969) and of th terminal ramifications following 6-hydroxydopamine-induced

destruction (Jonsson and Sachs 1970) have proved to be comparingly rapid processes.

The present study using the anterior chamber transplantation technique, clearly demonstrates the ability of the adrenergic nerves to grow in the adult animal, not only after axotomy but also from intact nerve endings. The growing nerves do not seem to differ much from normal developing nerves and they reestablish adrenergic neurotransmission in an effector organ deprived of its original nerve supply. Some aspects of the growth mechanisms will now for the sake of clarity be discussed separately although they are intimately interrelated.

a) *Initiation of growth.* An important question is how the intact sympathetic neurons obtain the information to which they respond with growth when they reinnervate *e.g.* an iris transplant. The information originates in the transplant. It was shown by the control experiments that, in all probability it does not reach the sympathetic neurons by the systemic circulation since *this would presumably have caused a bilateral hyperinnervation of the* irides of the host following a unilateral homologous iris transplantation.

A nervous mechanism involving sensory afferents from the eye and efferents to the sympathetic cell bodies in the superior cervical ganglion is ruled out by the fact that the growth takes place in spite of decentralization of the ganglion. The systemic and nervous routes of information are thus improbable, making the local way via the aqueous humor and/or the direct contact between host iris and transplant highly probable.

The proliferation of sympathetic nerves is only one of a series of changes which includes also the rapid formation of connective tissue strands with vessels connecting the transplant to the host iris. It has not been determined in the present investigation whether the connective tissue bridges grow from the host, from the transplant or from both although it seems probable that the bridges are formed mainly from the vascularized host in response to *factors released from the transplant e.g.* by the initial ischemia.

The impetus to growth of the peripheral parts of a neuron is probably a local one, independent of the nerve cell body. This is supported *e.g.* by the fact that after severance of the axon of a motoneuron, *both* ends of the cut axon shows sprouting initially (see Bodian 1947) although after a few days the distal stump degenerates due to lack of axoplasmic flow. On the other hand the changes in the nerve cell bodies following axotomy is a classical feature described already by Nissl 1892 (chromatolysis, swelling of cell body eccentric nucleus) demonstrating that in this case "information" has also reached the cell body. It is now known that the nerve cell

body indeed has a period of increased protein turnover during the regenera tive cycle after axotomy (see Droz 1969)

In the case of reinnervation of transplanted irides from the intact sympa thetic neurons, the increased volume of the terminal parts of the neurons can probably not be due to a local protein synthesis in the axons during regeneration since axonal protein synthesis seems to be minimal (see Droz 1969) Information would then have to reach the nerve cell bodies if they were to respond with an increased protein synthesis. This could be obtained either by a retrograd flow of material (see Dahlström 1965) or simply by an altered hydrodynamic pressure in the cell body caused by the growth of the axons. However it is not necessary to postulate that information of some kind has to reach the cell bodies. An alternative explanation would be that the normal axonal flow of material is sufficiently high and that the terminal parts of the neuron now utilizes parts of it for growth instead of metabolizing it. — In fact, it almost seems to be more difficult to explain how the large amounts of axoplasm produced by the cell body and trans ported down to the terminals is handled under steady state conditions. If however one considers the large number of dichotomous divisions and the enormous increase in total cross section area of th axon ramifications, it is obvious that the flow rate in the most peripheral parts must be considerably slower than in the main axon

Growth of various types of neurons in tissue culture is now a well established technique, which shows that the presence of an effector tissue is not necessary for the proliferation of nerve fibres. However composite growth media, often containing extracts from embryonic sources are needed, and in the case of adrenergic nerves the absolute requirement for proper maintenance and growth has been found to be the nerve growth factor (NGF see Levi Montalcini and Angeletti 1968) A situation similar to tissue culture in the present work was the massive outgrowth of nerve fibres from transplanted ganglia during the first days when no vascularization was established the aqueous humor being the incubation medium. Growth stimulat ing factors may have been present in the aqueous humor or in the transplant. Even if the information for growth is derived from some extraneuronal source t seems that the initial growth is independent of the local surround ings. An exampl of this is the fanshaped arrangement of the outgrowing f bres from the ganglion transplant in the anterior chamber However after a few days, the outgrowing nerves have reached the original nerve trunks with Schwann cells, and the further growth seems to follow the old tracts.

b) *Direction of growth* Apart from th above mentioned mitial sprouting from transplanted ganglia, it seems as if the appearance of the newly formed

destruction (Jonsson and Sachs 1970) have proved to be comparingly rapid processes.

The present study using the anterior chamber transplantation technique, clearly demonstrates the ability of the adrenergic nerves to grow in the adult animal not only after axotomy but also from intact nerve endings. The growing nerves do not seem to differ much from *normal developing* nerves and they reestablish adrenergic neurotransmission in an effector organ deprived of its original nerve supply Some aspects of the growth mechanisms will now for the sake of clarity be discussed separately although they are intimately interrelated.

a) *Initiation of growth* An important question is how the intact sympathetic neurons obtain the information to which they respond with growth when they reinnervate *e g* an iris transplant. The information originates in the transplant. It was shown by the control experiments that, in all probability it does not reach the sympathetic neurons by the systemic circulation since this would presumably have caused a bilateral hyperinnervation of the irides of the host following a unilateral homologous iris transplantation.

A nervous mechanism involving sensory afferents from the eye and efferents to the sympathetic cell bodies in the superior cervical ganglion is ruled out by the fact that the growth takes place in spite of decentralization of the ganglion. The systemic and nervous routes of information are thus improbable, *making the local way via the aqueous humor and/or the direct contact* between host iris and transplant highly probable.

The proliferation of sympathetic nerves is only one of a series of changes which includes also the rapid formation of connective tissue strands with vessels connecting the transplant to the host iris. It has not been determined in the present investigation whether the connective tissue bridges grow from the host, from the transplant or from both, although it seems probable that the bridges are formed mainly from the vascularized host in response to factors released from the transplant *e g* by the initial ischemia.

The impetus to growth of the peripheral parts of a neuron is probably a local one independent of the nerve cell body This is supported *e g* by the fact that after severance of the axon of a motoneuron *both* ends of the cut axon shows sprouting initially (see Bodian 1947) although after a few days the distal stump degenerates due to lack of axoplasmic flow On the other hand, the changes in the nerve cell bodies following axotomy is a classical feature described already by Nissl 1892 (chromatolysis, swelling of cell body eccentric nucleus) demonstrating that in this case "information has also reached the cell body It is now known that the nerve cell

presence of nerves inhibits the outgrowth and that the absence of nerves stimulates the growth. It seems unlikely that inhibition of stimulation of the adrenergic receptors controls the outgrowth One possibility of growth regulation would be that the nerves together with the receptor tissue form an inhibiting factor as the nerves will grow only into organs normally adrenergically innervated.

d) *Specificity of growth* Two general conclusions concerning the specificity of the growing adrenergic nerves vis-a-vis their effector organs can be drawn from the present experiments. Firstly the growth is specific in the sense that the new adrenergic nerves are largely confined to receptor tissues that are normally adrenergically innervated but have become denervated. The new nerves do not grow into areas where adrenergic nerves do not exist normally and they do not grow into already innervated areas. Thus, the adrenergic nerves obey to the same rules as *e g* motor nerves reinnervating muscles (see reviews by Guth 1956, 1968). This type of specificity has also been elegantly demonstrated in ganglion transplantation experiments in insects (Jaklet and Cohen 1967). Secondly the growth is unspecific in the sense that adrenergic neurons from any part of the adrenergic nervous system seem to be able to reinnervate any effector tissue. This unselectivity includes to a certain extent also heterologous transplantations, since a mouse iris became reinnervated in the rat eye and a mouse ganglion could reinnervate a rat iris.

There are indications in the literature that under certain circumstances not even a specificity between the sympathetic and the parasympathetic branches of the autonomic nervous system exists. The hypothesis that collateral sprouting of cholinergic fibres occurs after degeneration of the adjacent sympathetic neurons in the salivary glands was put forward by Nordenfeldt (see Nordenfeldt 1968) He found increases in glandular choline acetylase and cholinesterase following postganglionic sympathetic denervation. His mochemical studies on this subject are few However Roth and Richardson's (1969) interesting observation of what may be interpreted as sympathetic axonal sprouting in irides which had been parasympathetically denervated speaks in favour of such a lack of specificity Similar findings were reported by Taxi (1959) Garrett (1969) suggests that postganglionic parasympathetic sprouting in a retrograd direction from th cat submandibular gland refill the sympathetic trunk along the submandibular artery following sympathetic denervation.

Incidentally observed examples of non-adrenergic (*i.e* non-fluorescent) nerve cells, which apparantly survived transplantation in the present experiments, were the non fluorescent nerve cells in the superior cervical ganglion,

X SUMMARY

The anterior chamber transplantation technique offers unique possibilities for nerve growth studies. Transplants survive well and become rapidly vascularized from the iris of the host eye. The condition of the transplants can be followed in the living animal by microscopic inspection through the cornea. The iris of the host eye contains a thoroughly studied, dense and rich plexus of adrenergic nerves and the iris can easily be sympathetically denervated. All adrenergic nerves in the host irides and transplanted irides can be studied in every detail in stretch preparations.

Growing adrenergic nerves in the adult rat were studied qualitatively and quantitatively by a combination of the Falck Hillarp fluorescence method for cellular localization of monoamines with ^{3}H noradrenaline uptake measurements. Tissue transplantations to the anterior chamber of the eye were used in two principally different ways.

1) Transplantation of various adrenergic receptor tissues. Reinnervation of the transplants took place by collateral sprouting from the adrenergic ground plexus of the host iris. The time course of adrenergic reinnervation of the iris was followed in detail after autologous transplantation of one iris to the anterior chamber of the other eye. The iris transplant, which became sympathetically denervated because of the operation, was rapidly reinnervated by collateral sprouting from the intact adrenergic ground plexus of the host iris. The first adrenergic nerves were found in the transplant after 4 days, and reinnervation was complete within one month. Concomitantly to the reinnervation of the transplant, there was an adrenergic hyperinnervation of the host iris.

2) Transplantation of various sympathetic ganglia. When the host iris was simultaneously sympathetically denervated, the transplanted neurons reinnervated it.

The time course of adrenergic reinnervation was followed in detail after autologous transplantation of the superior cervical ganglion to the anterior chamber of the ipsilateral eye. The operation results in a complete denervation of the iris of the host eye. A large number of nerve cell bodies in the

ganglion transplant survived the close axotomy and immediately began to reinnervate the host iris. The first sprouting adrenergic nerves were found on the iris after one day and reinnervation was complete within one month.

Confirmatory experiments were performed in mouse and hamster. Transplantations of irides and ganglia to other locations than the anterior chamber were also described.

The adrenergic transmitter mechanisms of the newly formed nerves were similar to those of mature nerves at rest. Noradrenaline uptake and storage properties seemed to be well developed from the moment of formation of the new nerves. Release of the transmitter and restitution of adrenergic neuromuscular transmission in the new nerves could be demonstrated.

Sympathetic neurons from any part of the sympathetic nervous system seemed to be able to reinnervate any sympathetically denervated receptor tissue. The innervation pattern was always similar to that normally found in the receptor organ. Adrenergically not innervated tissues remained so after transplantation. Reinnervation could also be demonstrated after heterologous transplantations.

The presence of a normal adrenergic innervation almost completely inhibited the outgrowth of new nerves. On the other hand, the growth was very little affected by chronic treatment with drugs interfering with the adrenergic transmitter mechanisms, chronic adrenergic receptor blockade or chronic treatment with cortisone or testosterone. The nerve growth was likewise independent of a normal impulse traffic. Chronic sympathetic denervation of tissues to be transplanted did not essentially impair adrenergic reinnervation.

The adrenergic neurons of the adult rat have thus been shown to possess efficient growth mechanisms. Growth occurs both from intact neurons and following axotomy close to the nerve cell bodies. A more dynamic role of the peripheral adrenergic innervation apparatus is suggested, the nerves being in a labile equilibrium with the local surroundings. Many different disturbances of this equilibrium such as injury transplantation of denervated tissues and possibly also inflammation will initiate immediate proliferation of adrenergic nerves.

ACKNOWLEDGEMENTS

This investigation was supported by grants from the Swedish Medical Research Council (B69 14x 711-04A B70-14x 714-05 and B70-14x 711-05B), Svenska Livförsäkringsbolags nämnd för medicinsk forskning, Olli and Elof Ericsons Stiftelse and Stiftelsen Therese and Johan Anderssons Minne.

The authors would like to express their sincere thanks to Professor Börje Johansson and Dr Bengt Ljung Dept. of Physiology University of Gothenburg, for generous help with the functional *in vitro* tests reported in chapter VII

Mrs Annika Hamberger Mrs Ulla Flyger Mrs Eva Lindqvist and Mrs Barbro Norstedt are gratefully acknowledged for their skilful technical assistance. The text figures were drawn by Ing. H. J Meuser

For generous supplies of drugs we are indepted to the following companies Swedish Ciba, Stockholm, Sweden (reserpine, Serpasil® phentolamine, Regitin®) Swedish Pfizer Stockholm, Sweden (nialamide, Niamid®), Geigy Basle, Switzerland (desmethylimipramine, Pertofran®), Hässle, Göteborg, Sweden, through Dr H. Corrodi (H44/68 H56/28 Aptin® H59/64).

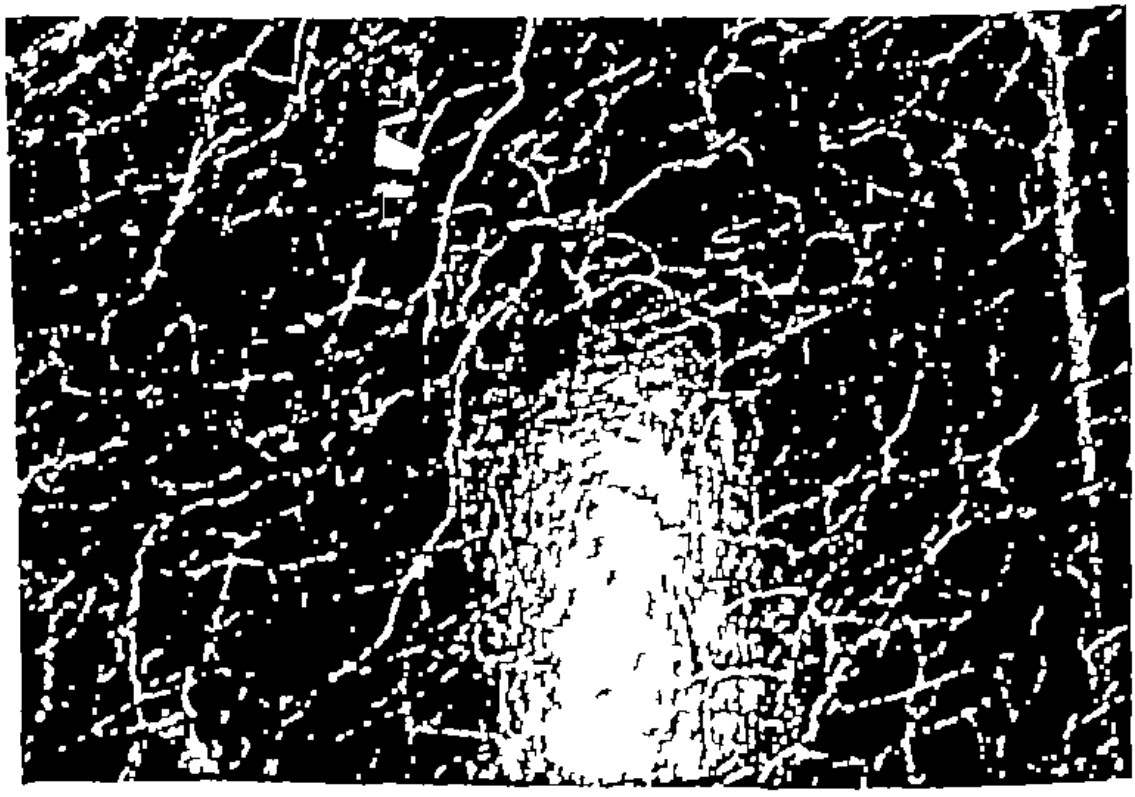
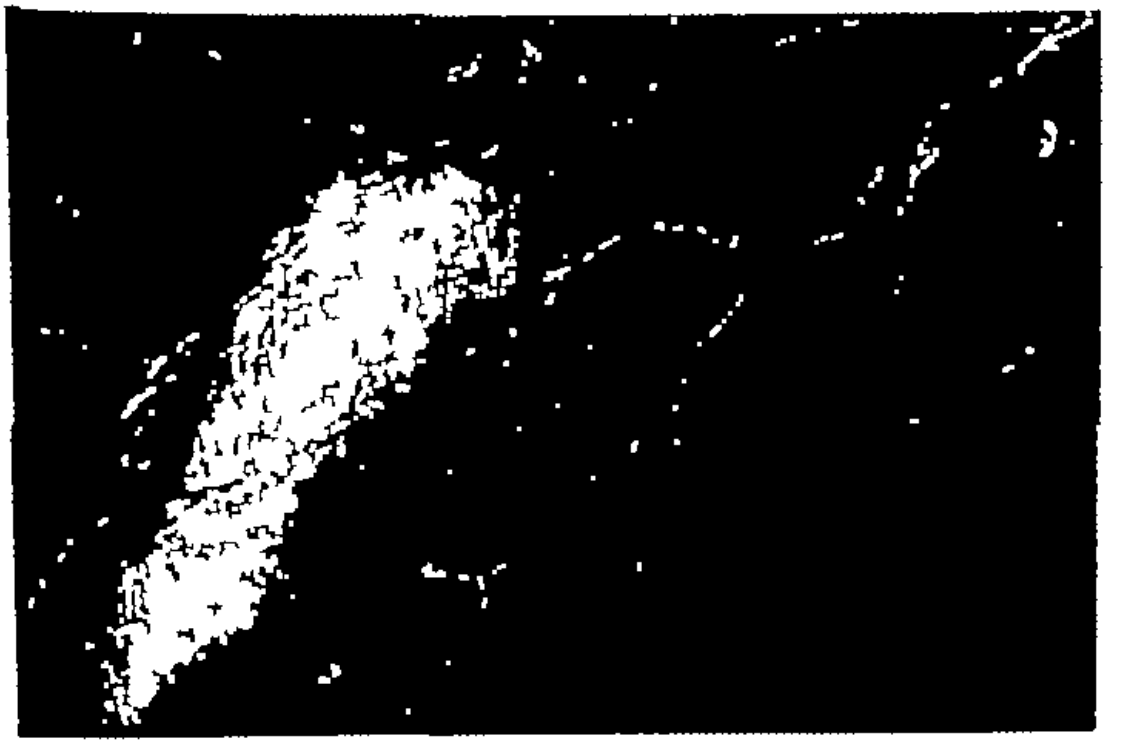
FIGURES

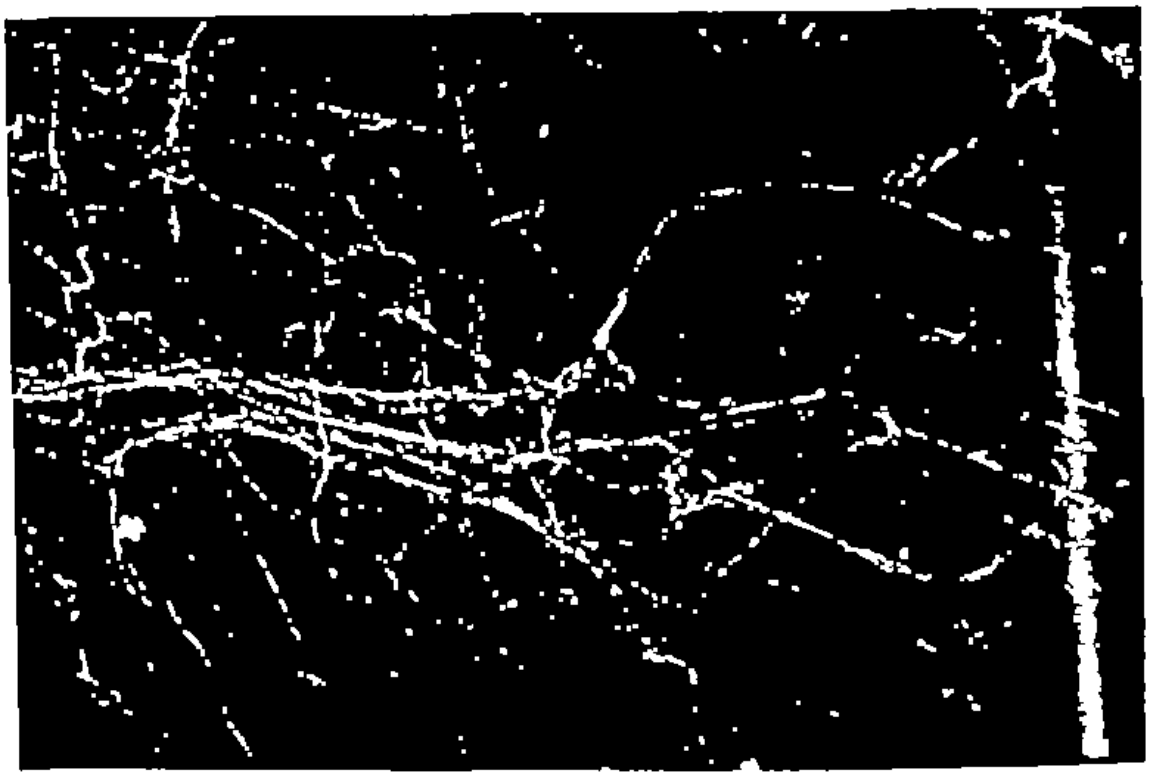


All figures, except Fig 38 are fluorescence microphotographs of stretch preparations (the irides) or 8 μ sections. When not otherwise stated the anterior chamber transplantation technique was used. All figures, except Figs 59—62, demonstrate rat tissues.

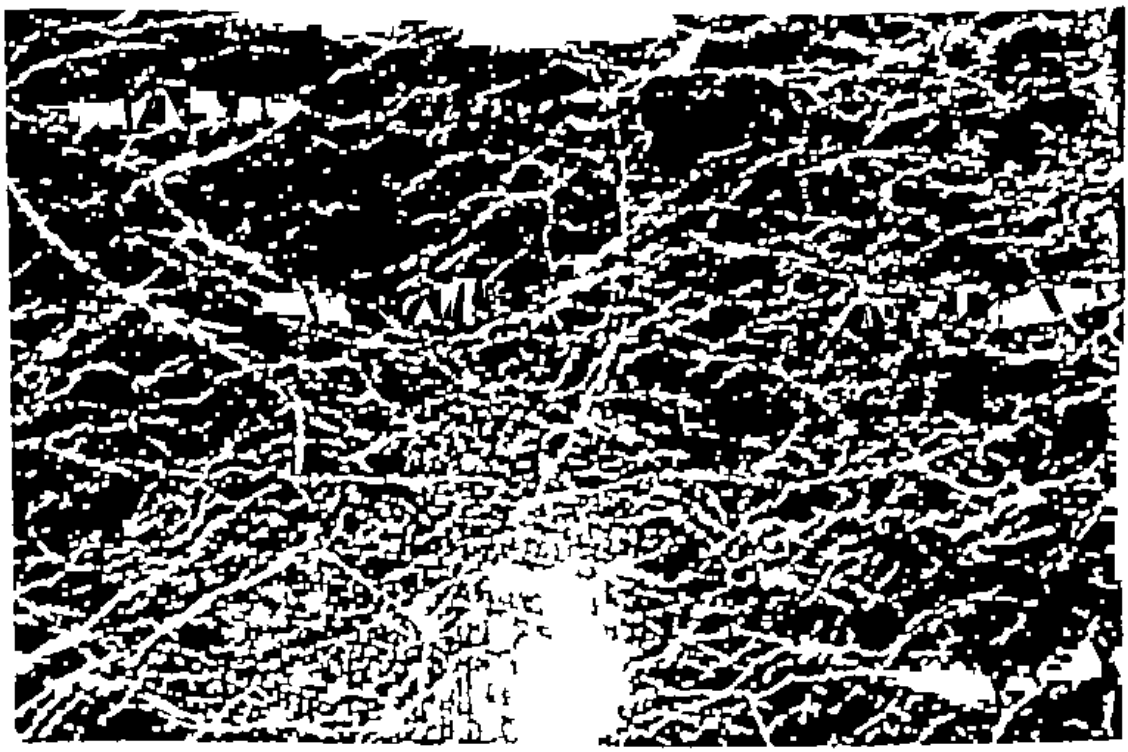
1 Partially sympathectomized denervated iris 2 days after the operation (see II.9). Most of the adrenergic ground plexus has disappeared thereby revealing the ramifications from single neurons of Malmfors and Sachs 1965). One, weakly fluorescent, beaded axon (lower left corner) branches twice to give rise to 3—4 separate systems of varicose strongly fluorescent, branching nerve terminals at different places on the iris. 120.



2. Iris from n rmal animal. The iris was incubated for 30 min in 10^{-7}M ^{3}H NA and rinsed in aminefree buffer for 10 min before the preparation. The adrenergic ground plexus, which consists of varicose nerv terminals and some smooth non-terminal axons, is seen. 140.

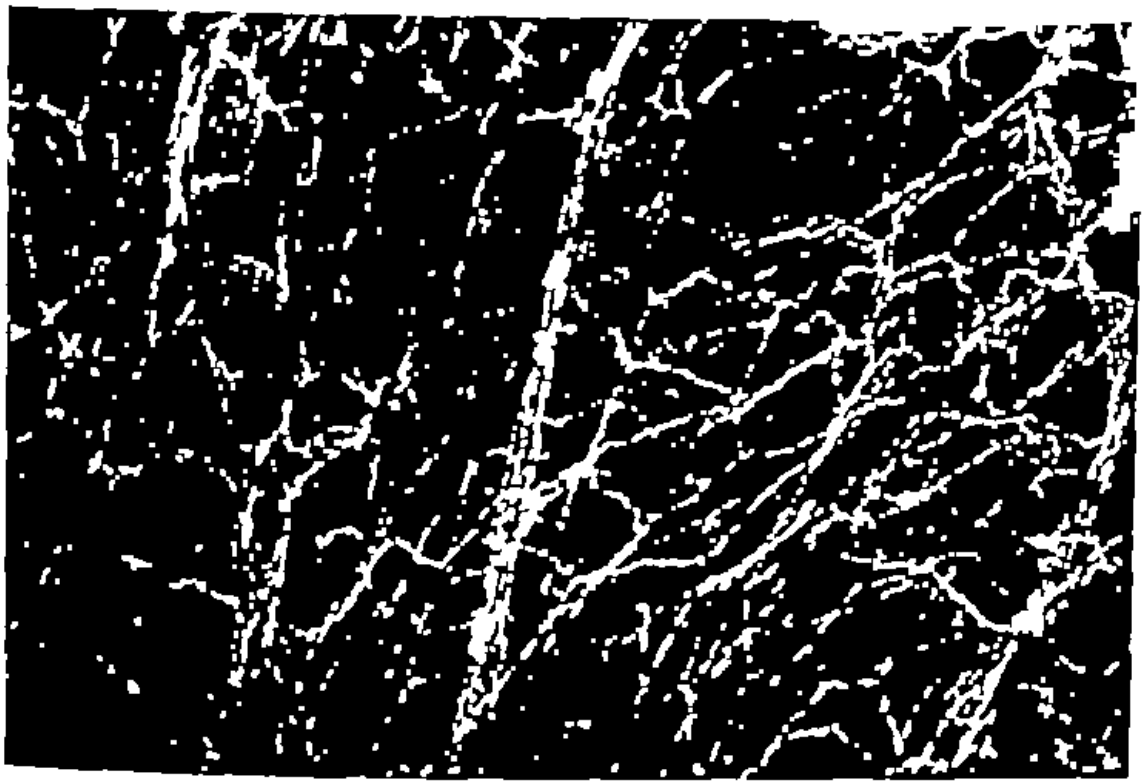


3 Iris from normal animal treated as in 1 y 2. ...5

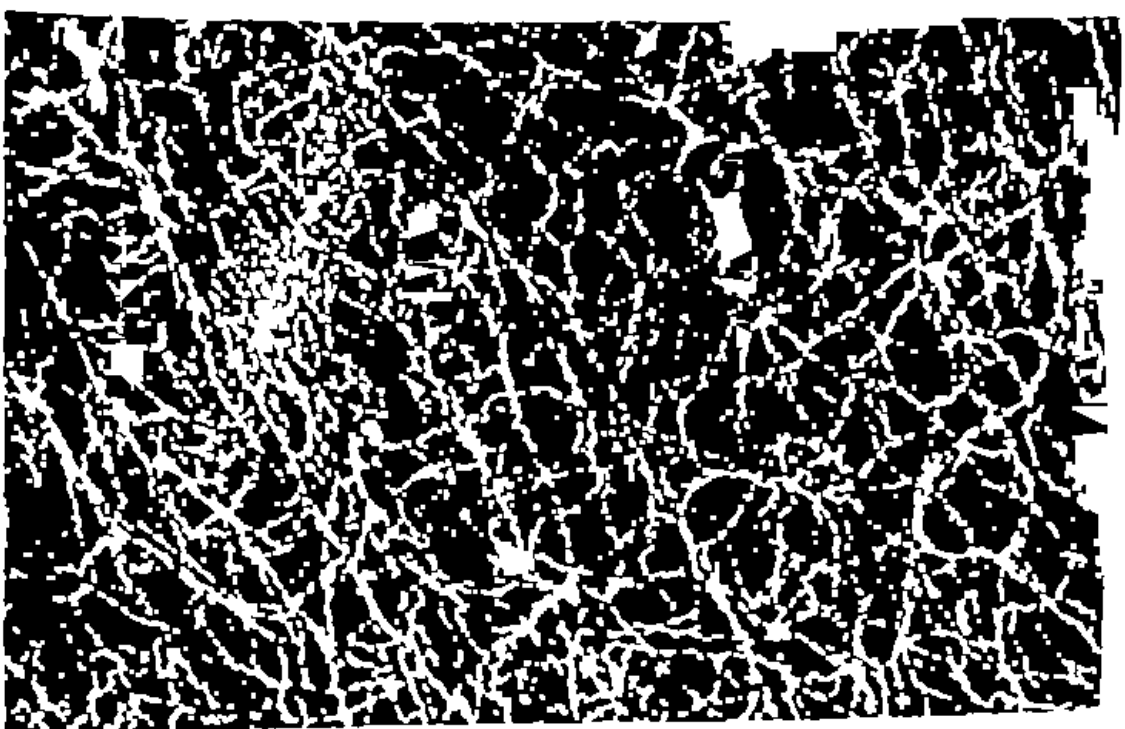


4. Connection between host iris and a transplant, 9 weeks. The new fluorescent axons which have a beaded appearance arise from the sphincter margin of the host iris (left) and bridge over towards the transplant (not demonstrated). In this case a duodenal muscle strip was transplanted. 140.

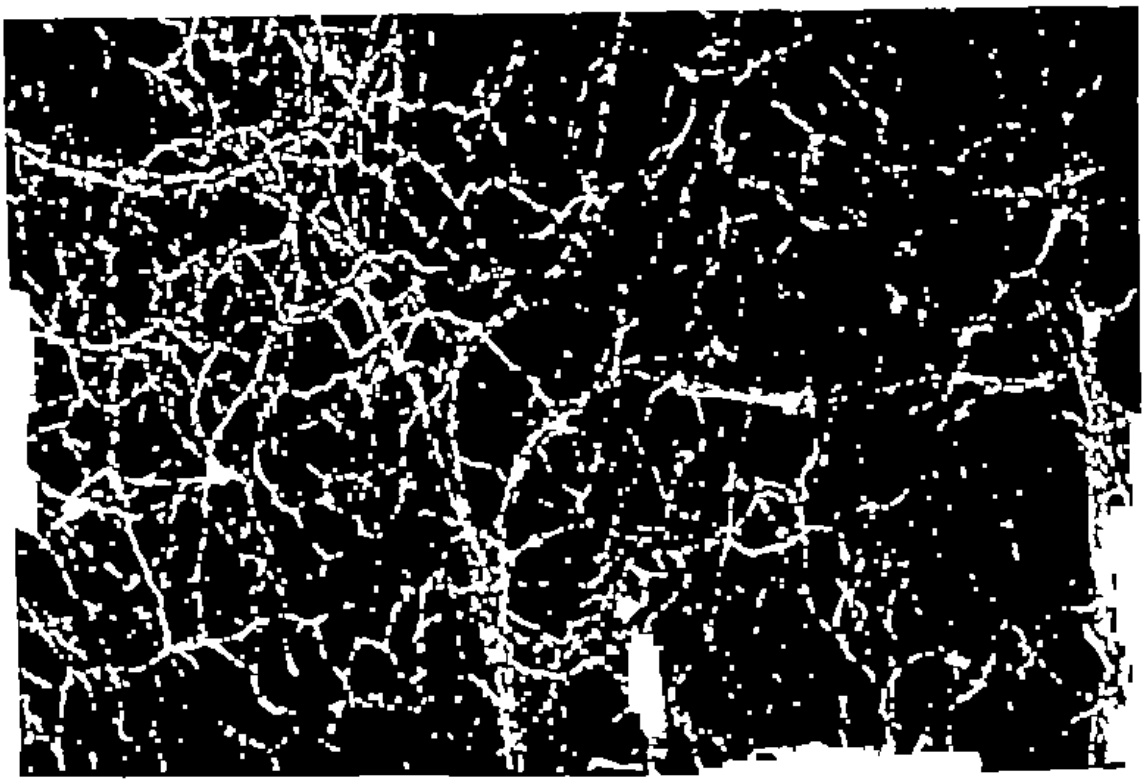
5 Iris transplant, 1 week. New nerves are beginning to form sparse plexus on the transplant. Note variable morphology and fluorescence intensity 225



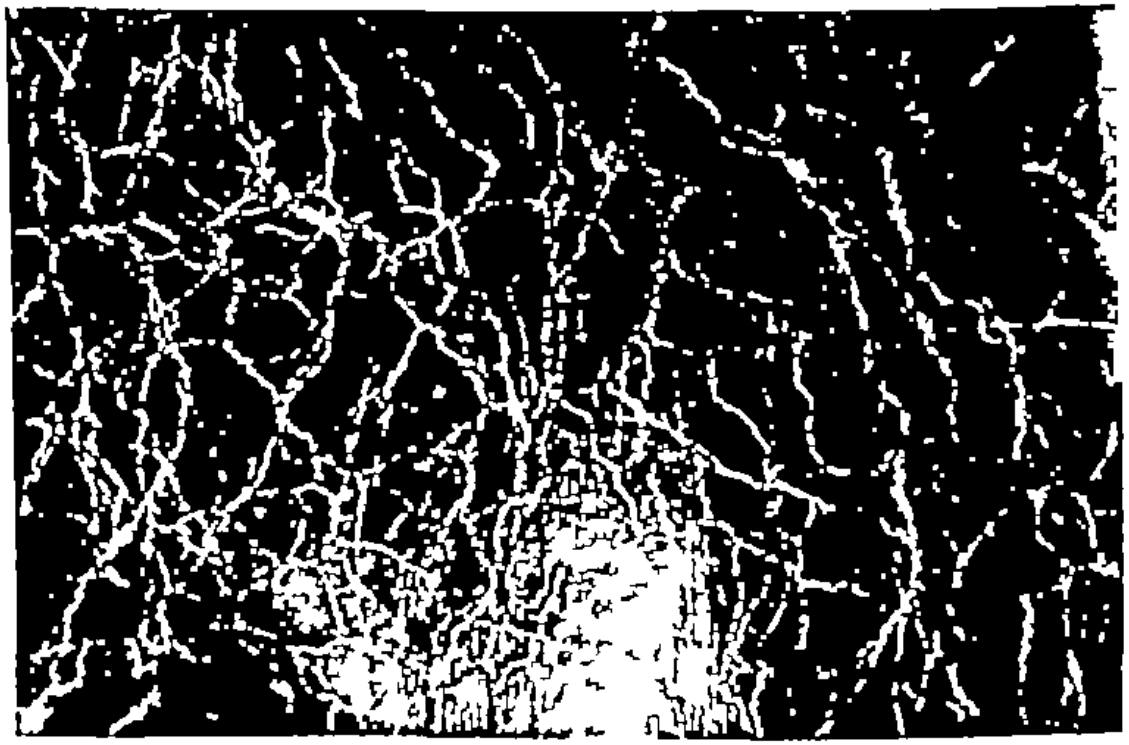
6. Iris transplant, 2 weeks. A relatively well developed plexus of varicose nerve terminals has been formed in the transplant. It is, however more irregularly arranged and less dense than the normal plexus (Fig 2) Several bundles of beaded axons ar seen 140.



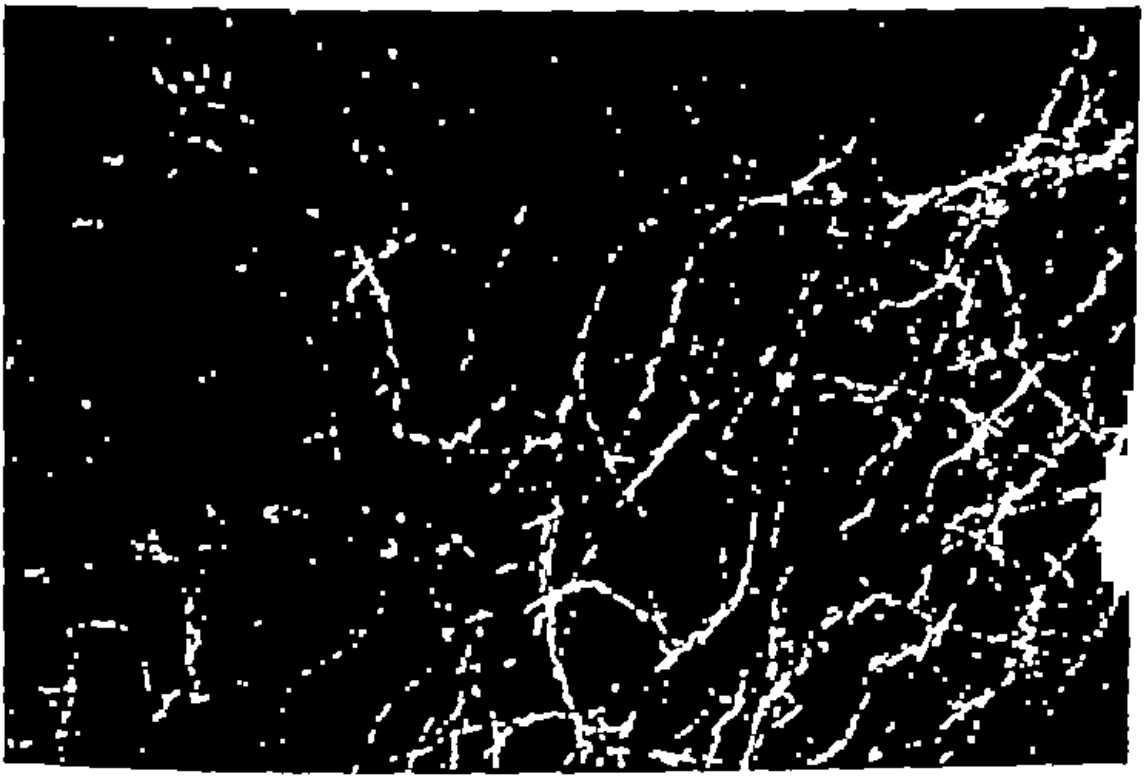
7 Host iris, 2 week
when compari g this in



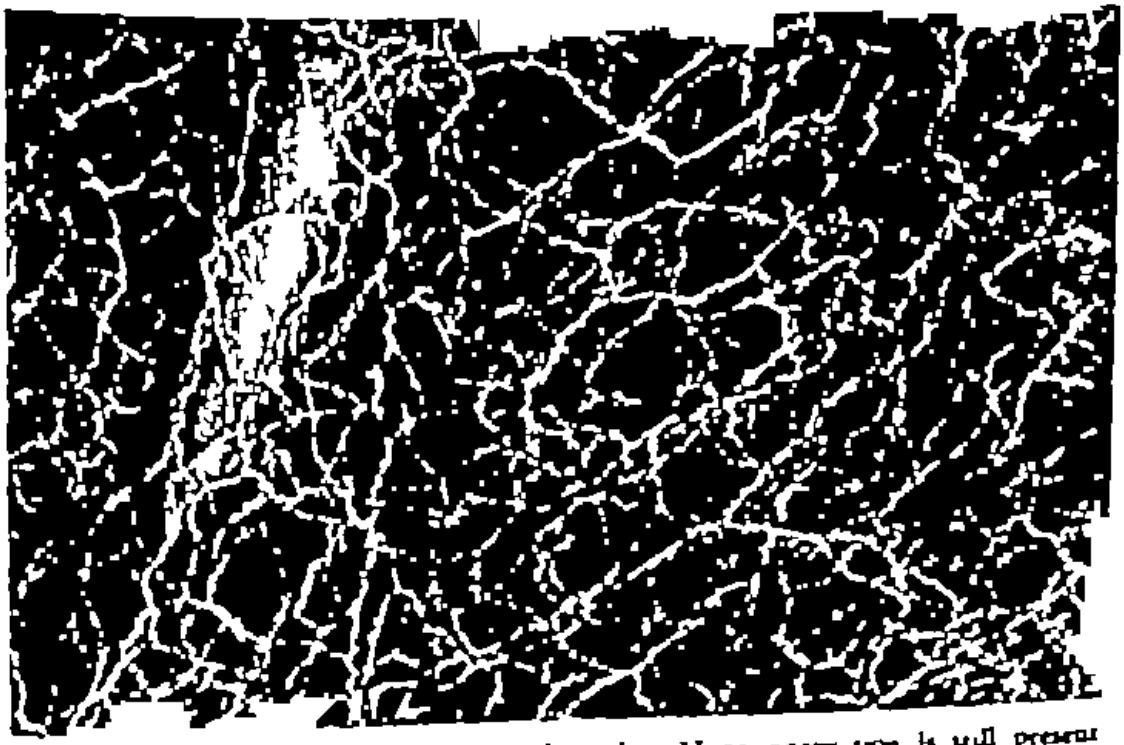
The hyperinnervation is evident



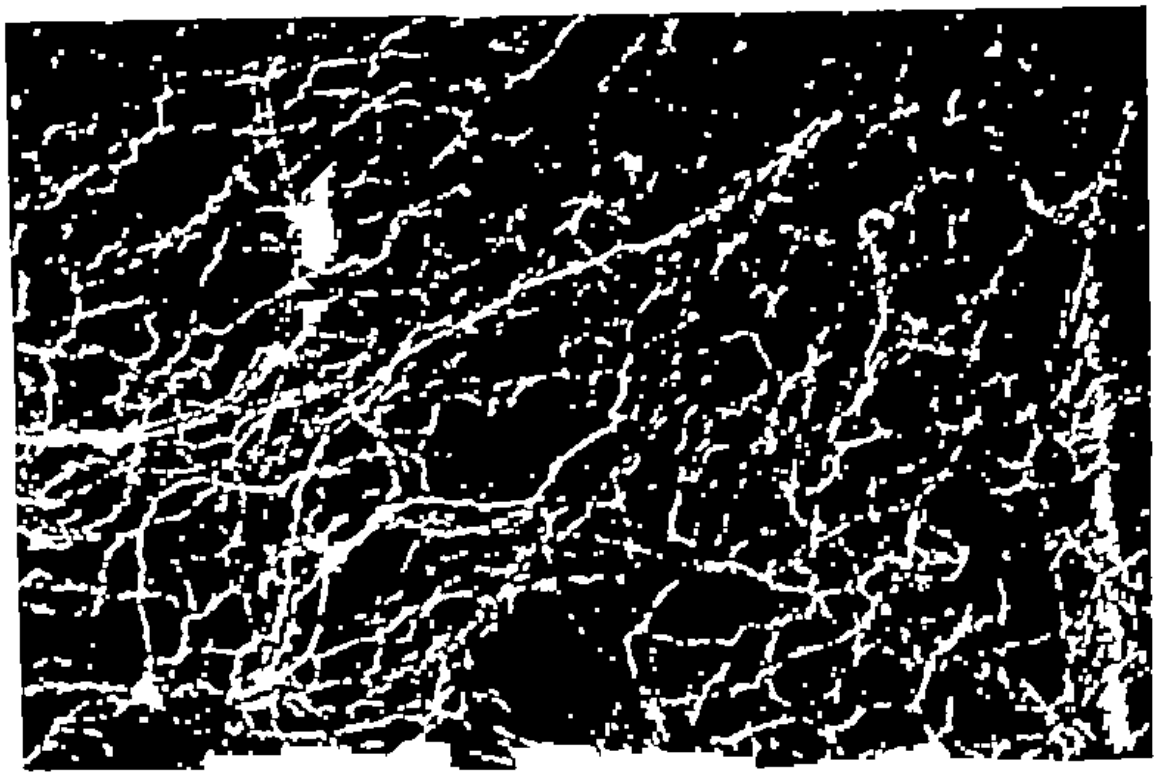
8. Iris transplant, 2 weeks. This particular transplant contained somewhat more nerves than the transplant depicted in Fig 6 and is therefore more similar to the corresponding normal iris (Fig 3). The ground plexus is, however more irregular and bundles of beaded axons can be found. ×25



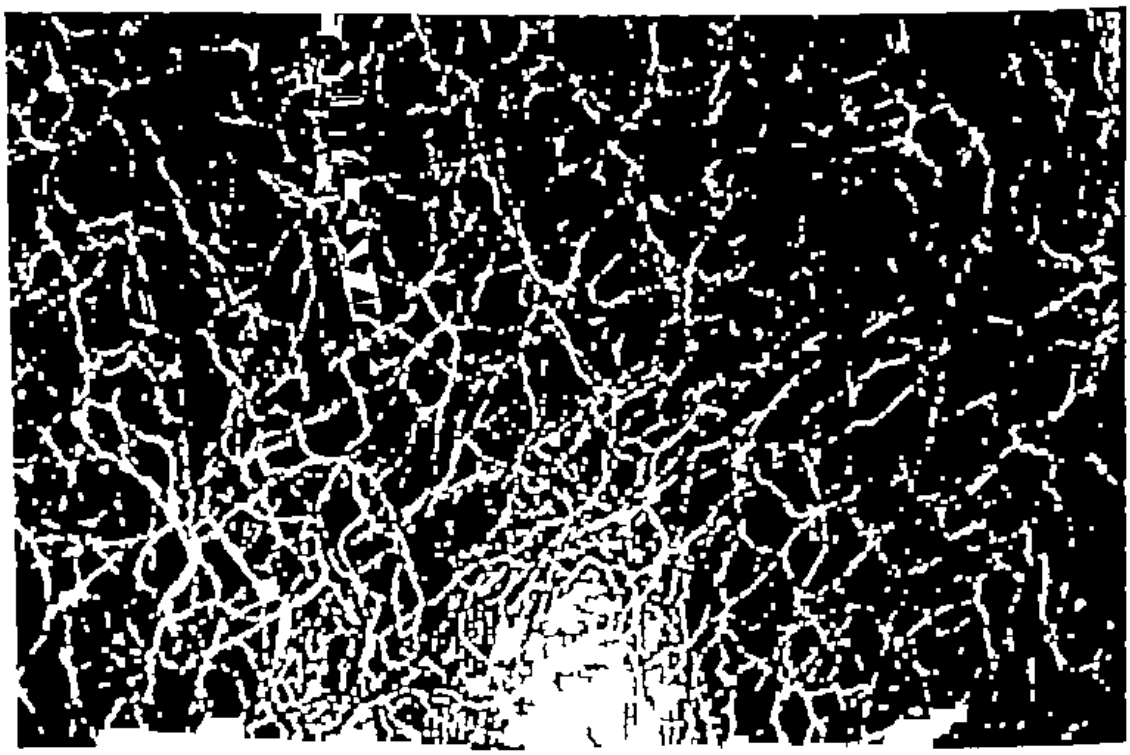
9 Host iris, 2 weeks after iris transplantation. Same magnification as normal Fig 3 and transplan Fig 8. The hyperinnervation is clearly demonstrated. ×25.



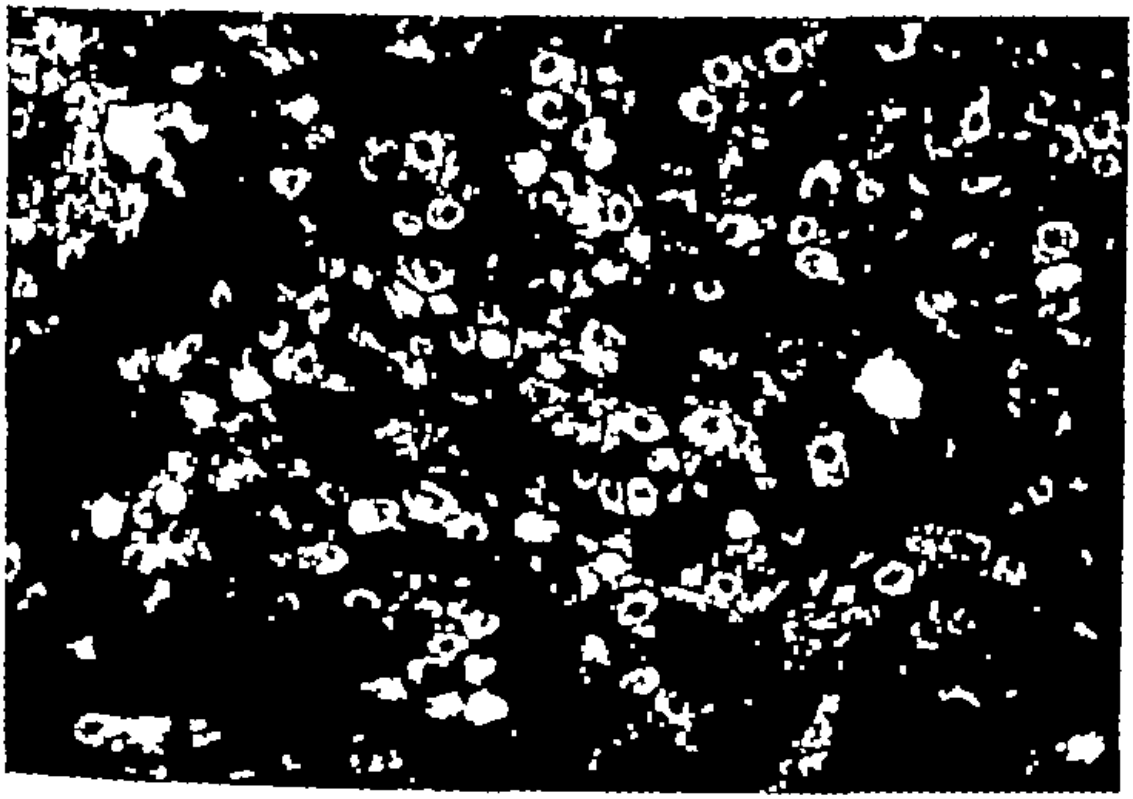
10. Iris transplant, 4 weeks. Well developed fairly regularly arranged ground plexus and larger dividing bundle of axons ar seen. 225.



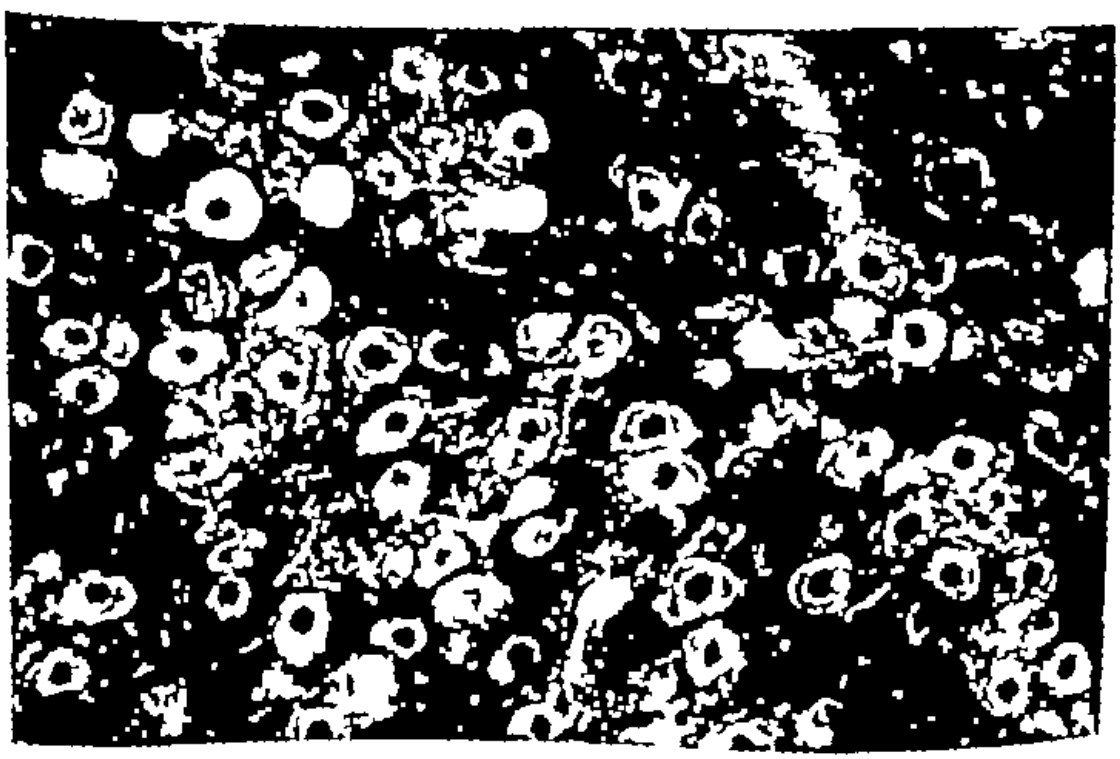
11 Iris transplant, 6 weeks. W ll d l ne gic ground plexus. 225



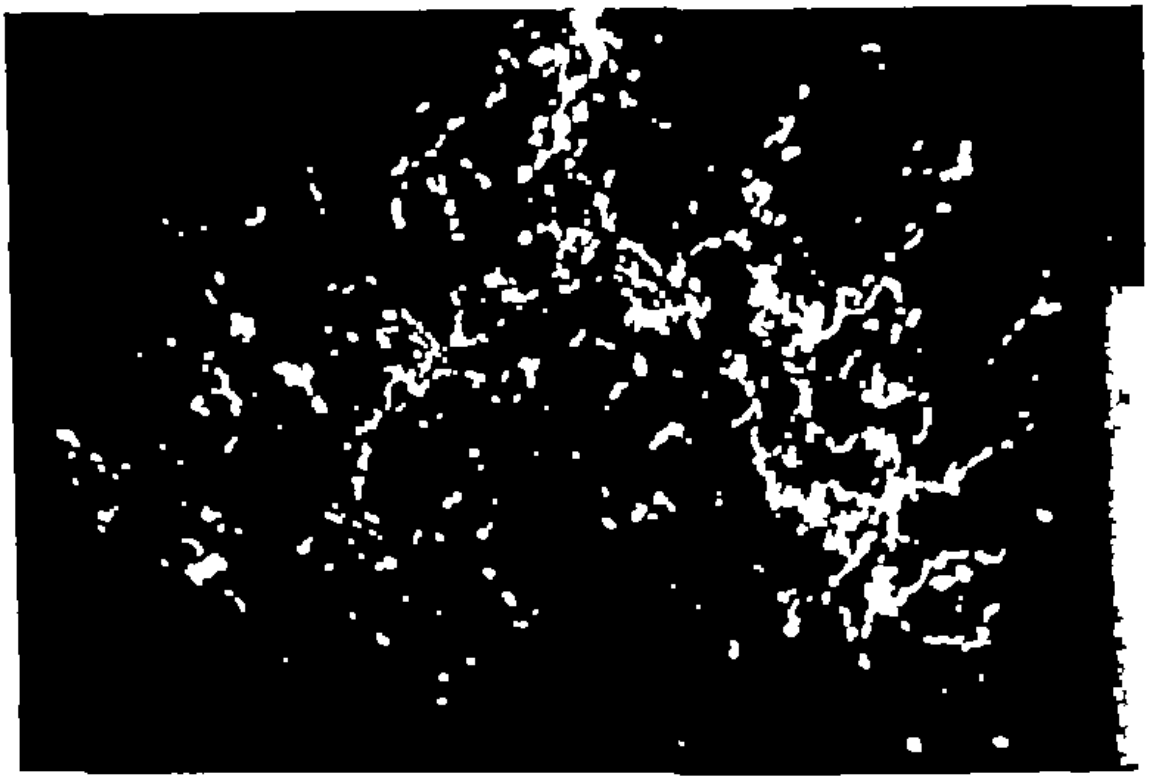
12. Iris transplant, 12 weeks. Well developed adrenergic ground plexus. 225



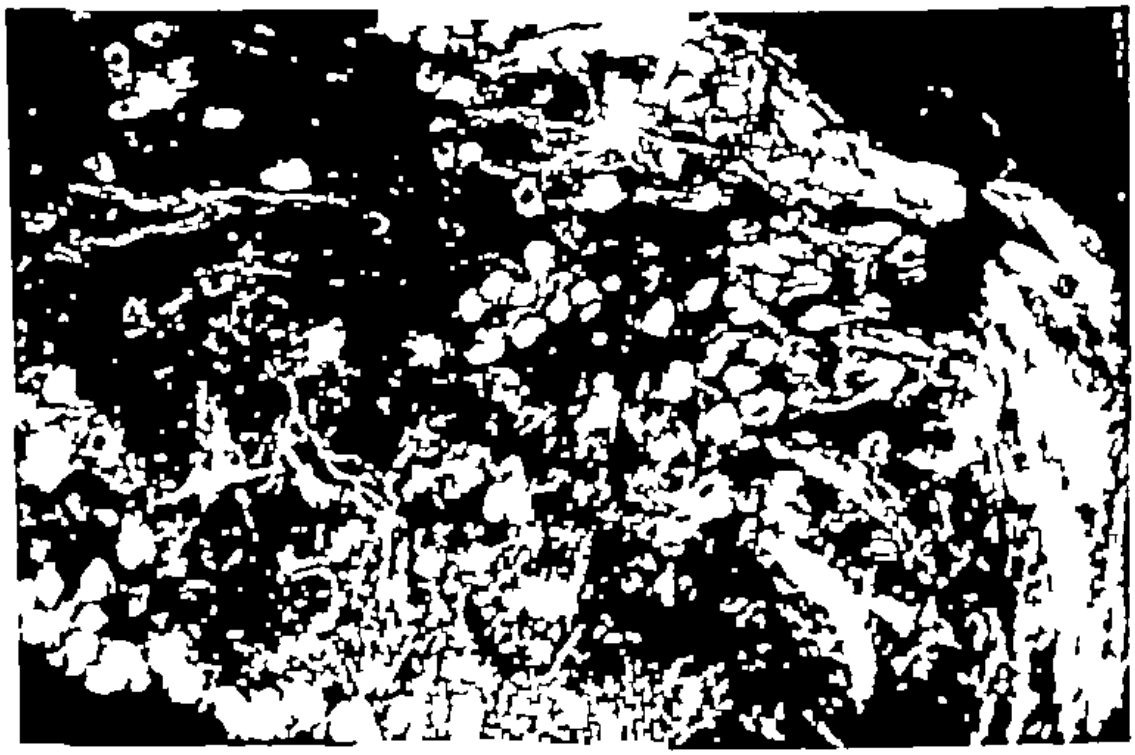
13. Host iris, 12 weeks after iris transplantation. Hypernnerv tion is still present but less conspicuous than after 2 weeks (Figs 7 and 9). 225.



14 Iris transplant, 10 months. A well developed plexus of adrenergic nerves is found. Some of the irregularities in this transplant is probably an artefact due to difficulties in unfolding and stretching older transplants. 140.

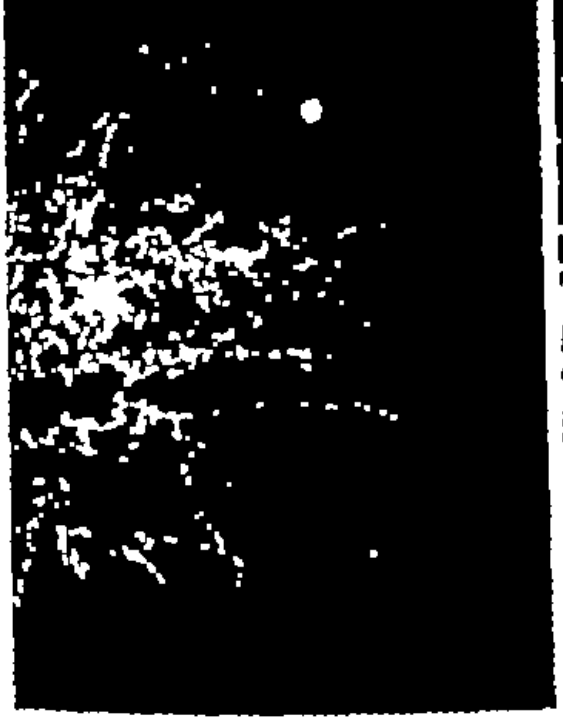


15 Host iris, 10 month ft tion. A slight hyperinnervation is present. 140.



16. Normal superior cervical ganglion. Almost all nerve cell bodies show specific fluorescence although with varying intensities. The nerve cell bodies are closely packed together. A small group of strongly fluorescent small, so called SIF-cells are seen (upper left). 140.

1 Normal superior cervical ganglion. Densely packed cell bodies with varying fluorescence intensities and a few intraganglionic fluorescent axons are seen

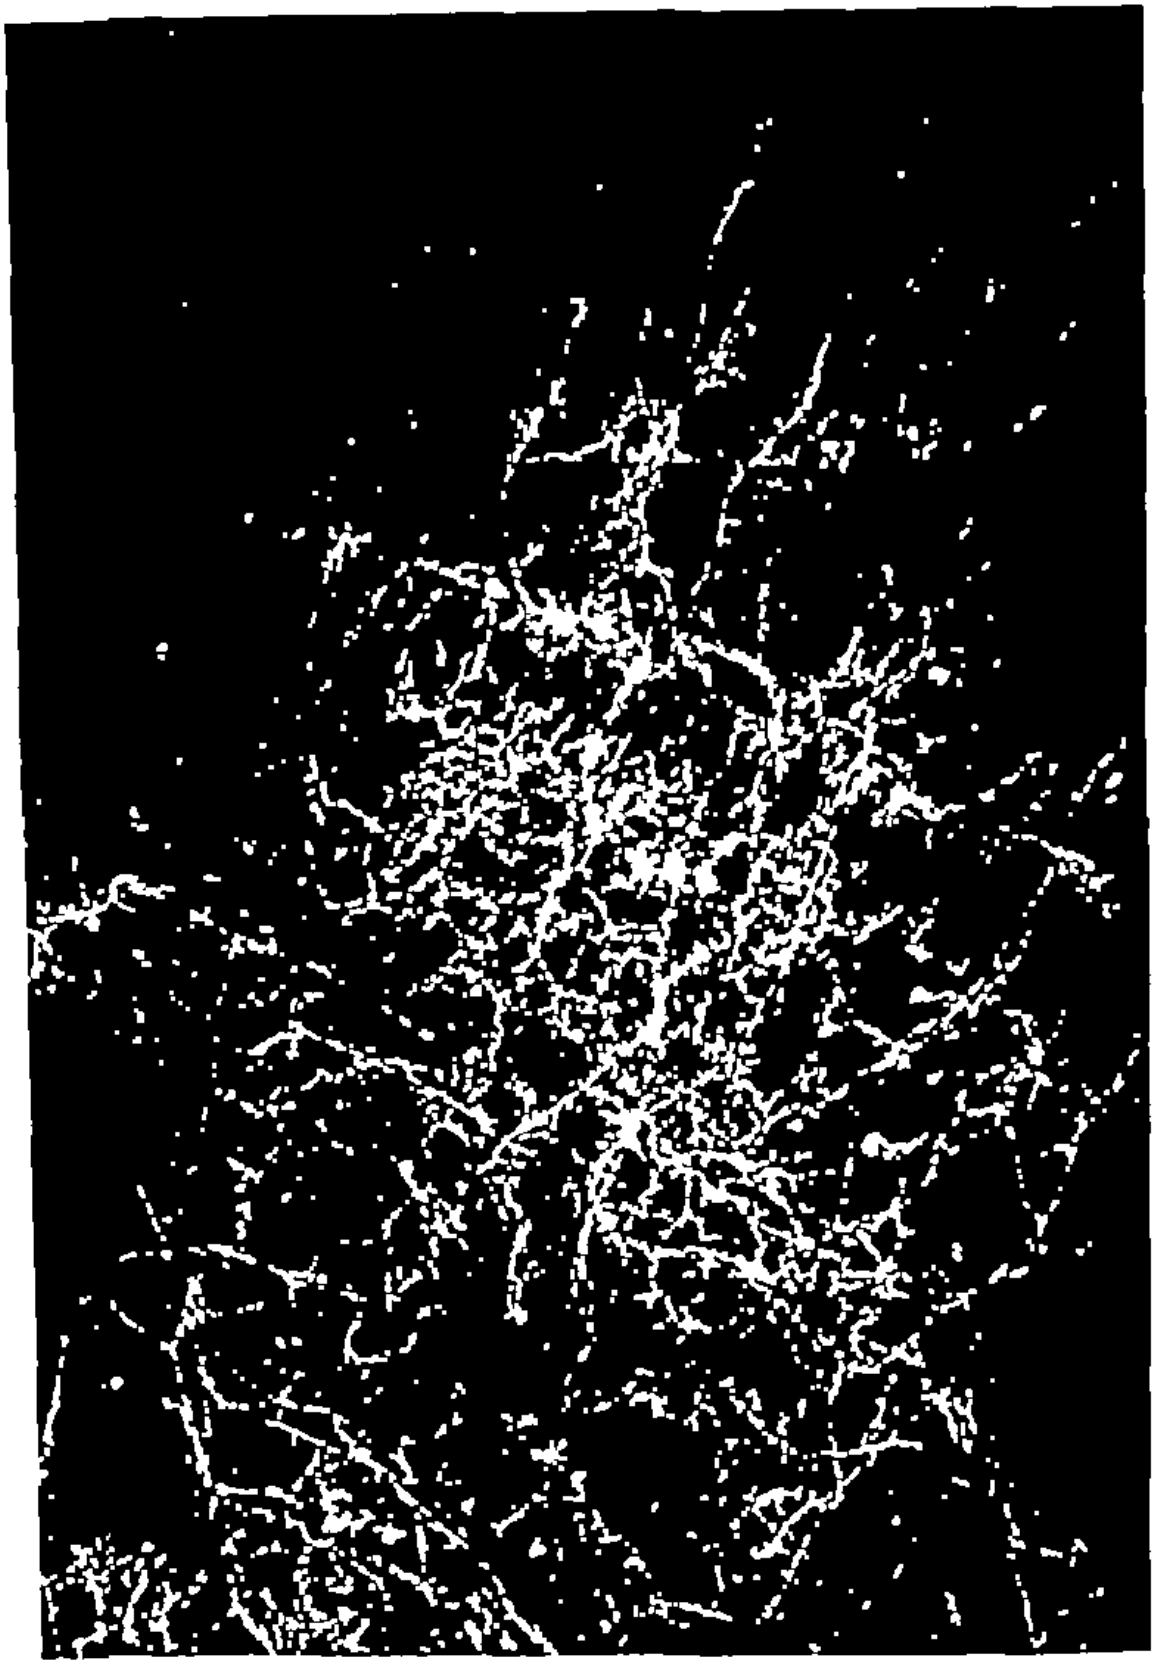


18. Host ris, 1 day fter ipsilateral transplantation of the superior cervical ganglion. The original adrenergic ground plexus has disappeared. The photograph show the site of attachment of a transplant which was peeled way before stretching. Thick, strongly fluorescent, distorted fibers and thinner fibres radiating out on the host iris can be found. 140.

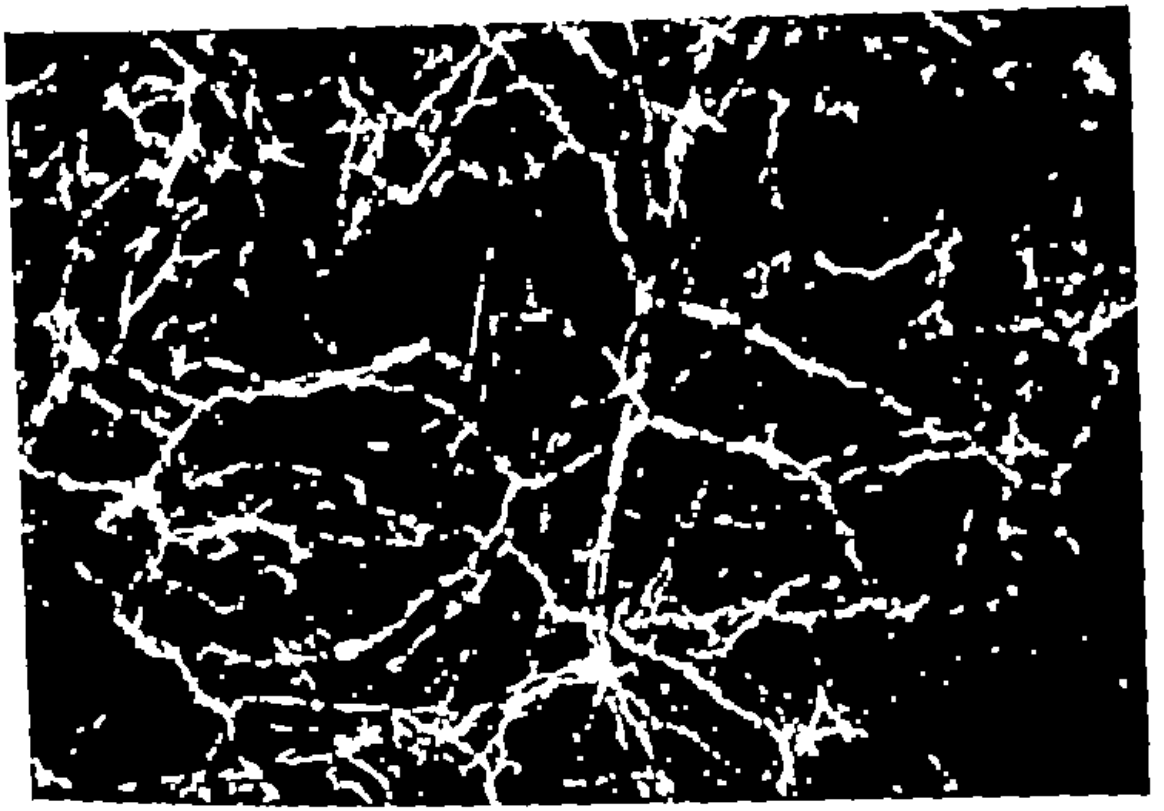
19 Transplanted superior fluorescence intensities, some h fluorescent material re see ganglionic tructure is loos fibres. 140.

l d y The cell bodies have ryling ed tensities H vy accum lations f axon bundles. Note also that the in reased amount of intraganglionic

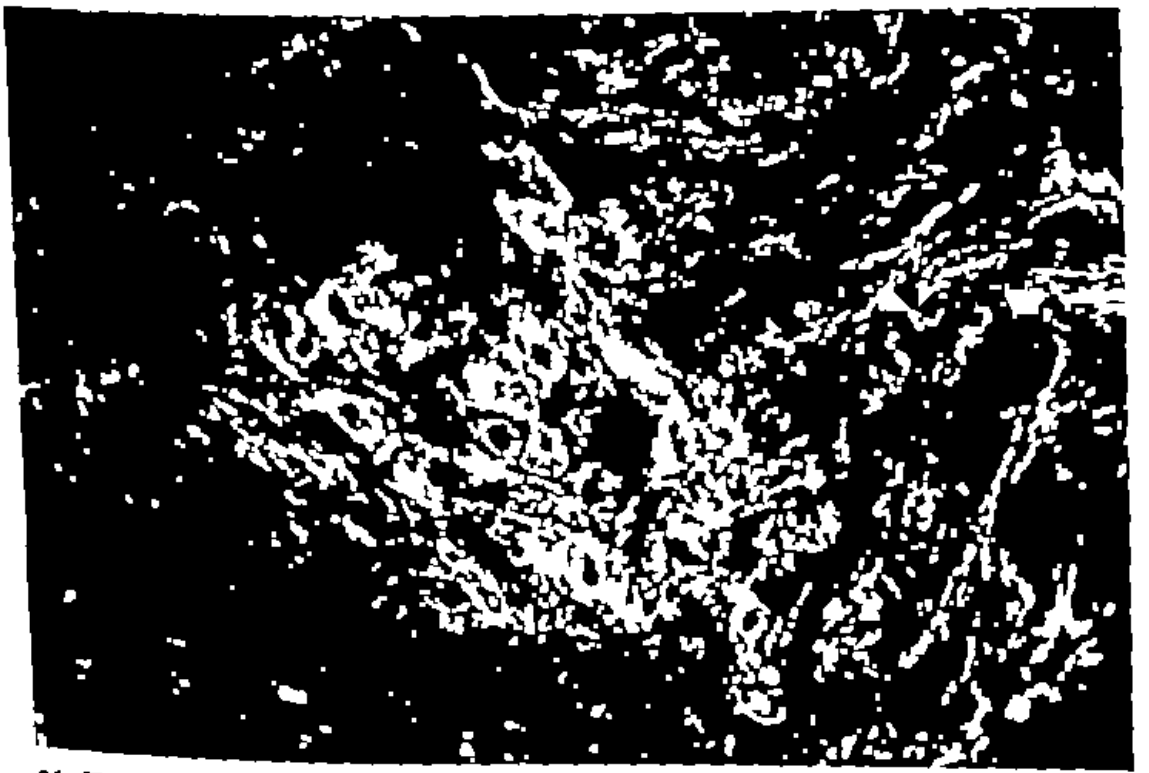
20. Host iris, 2 days after ipsilateral transplantation of the superior cervical ganglion. New fibres radiate out from the site of attachment of a transplant. A large blood vessel is passing through the innervated area. 60.



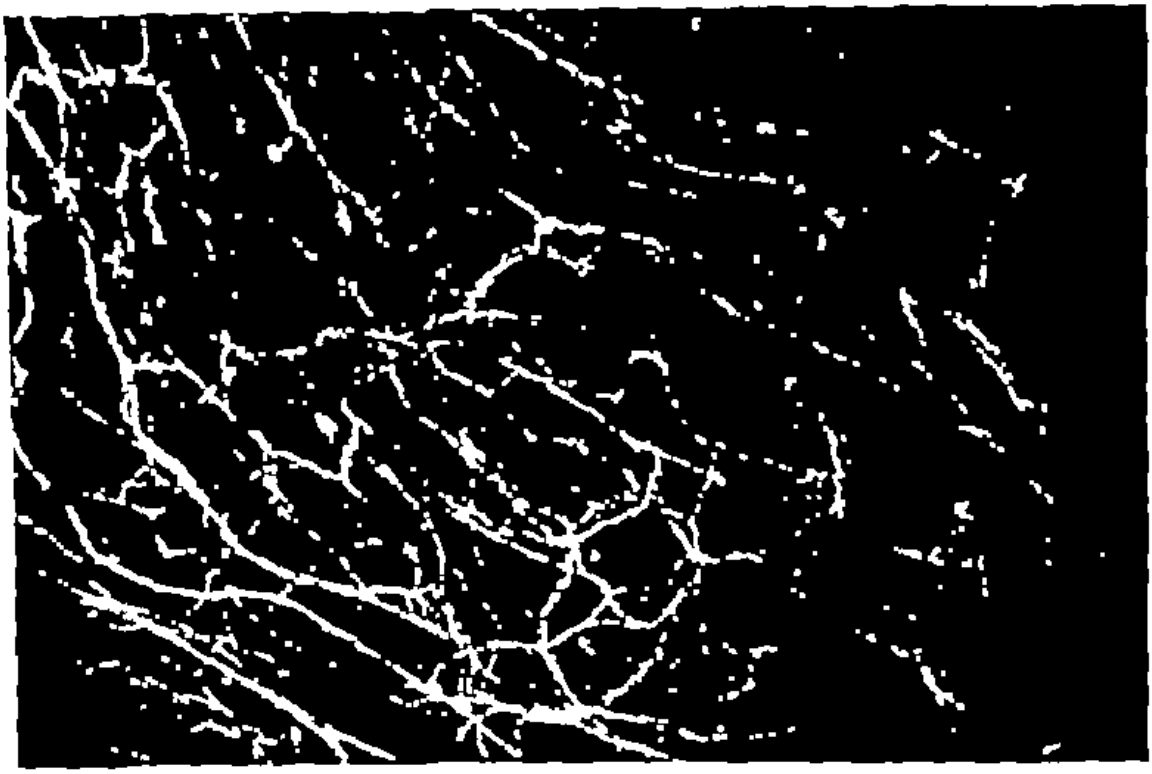
21. Host iris, as in Fig. 20. Distorted, swollen strongly fluorescent fibres and a formation of 4 slender axons with growth cones, leaving the site of attachment together as if they were following a preexisting pattern are found. 155



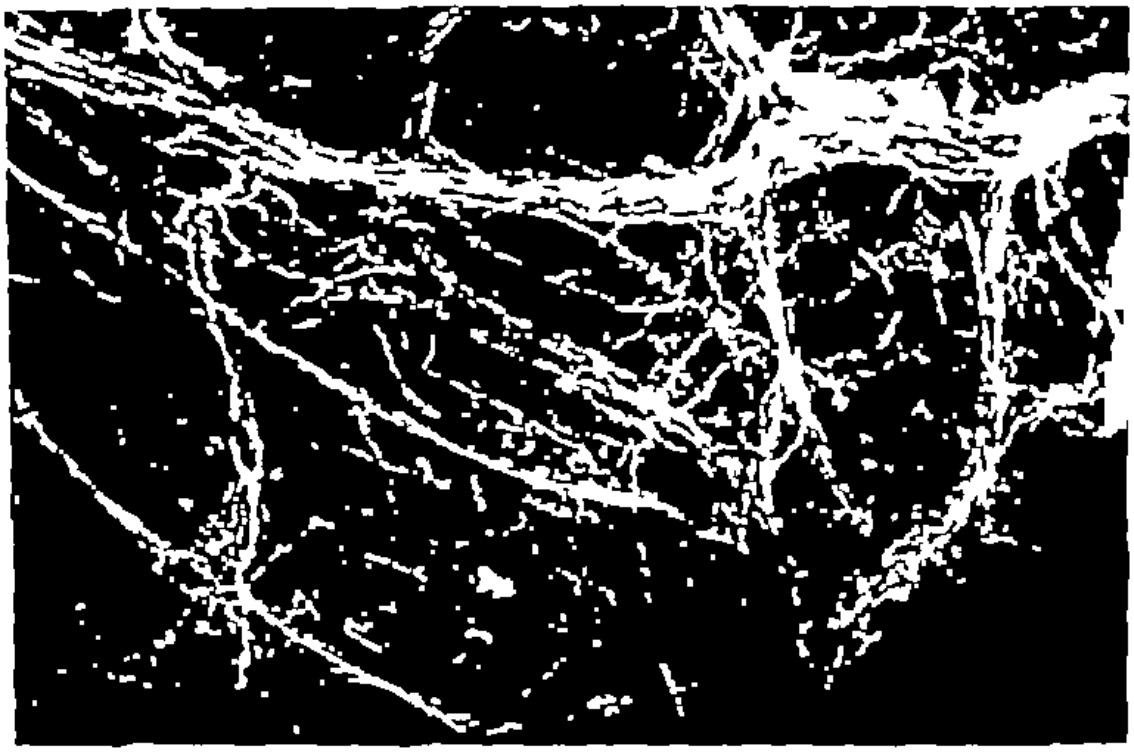
22. Transplanted superior cervical ganglion, 2 days. Numerous bundles of strongly fluorescent axons are seen the ganglion. 125



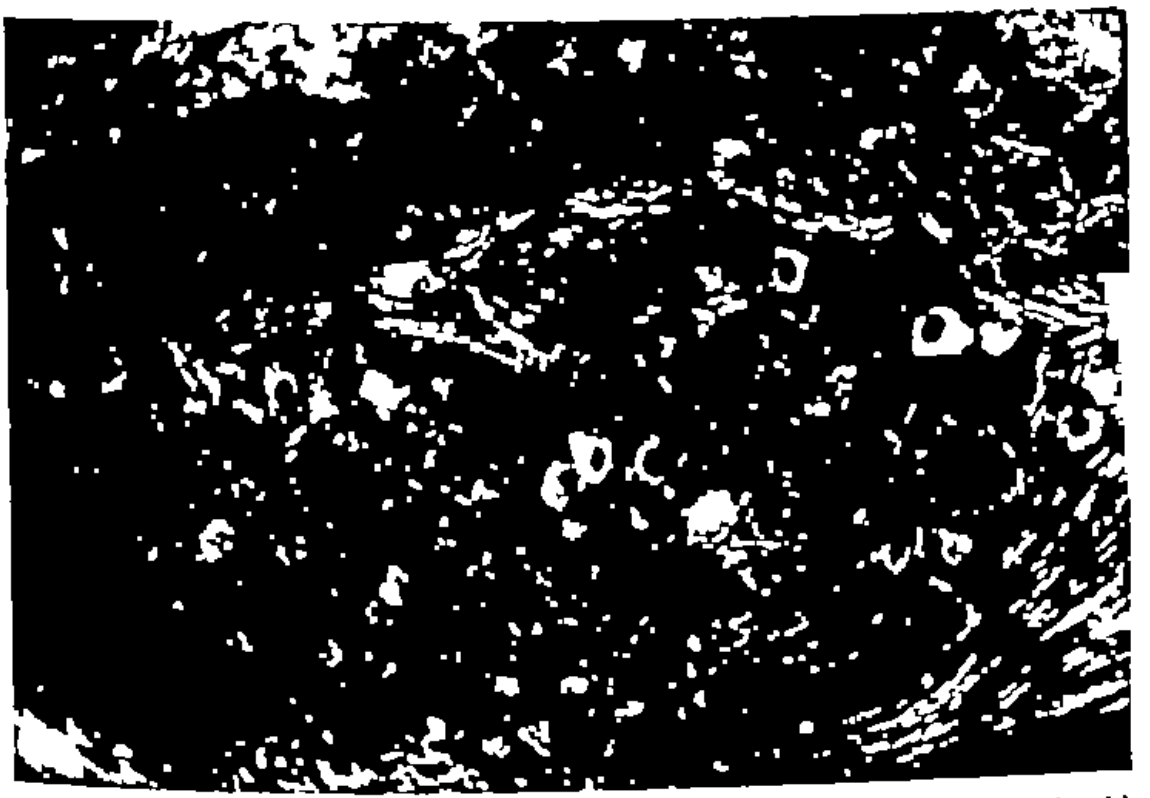
23. Transplanted superior cervical ganglion, 2 days. The cell bodies show strong fluorescence intensities and sometimes eccentric nuclei. Two large bundles of strongly fluorescent axons are cross-sectioned. x 310



24 Host ris, 2 day fter psilateral transplantation f the superior cervical ganglion. Surv y f nnerv ted area. Thick, distorted and slender fibres are seen. Although several beaded f bres are seen, no typical aricose nerve terminals ha yet been formed. A la g blood sel tr erses the innervated area. 135



25. Host iris, 8 days after ipsilateral transplantation of the superior cervical ganglion. A richly innervated area is shown. The irregular plexus is composed of bundles of axons lacking the typical varicose appearance. 225.



26. Transplanted superior cervical ganglion, 4 days. A group of cell bodies generally with relatively low fluorescence intensities and large, strongly fluorescent axon bundles are seen. 225

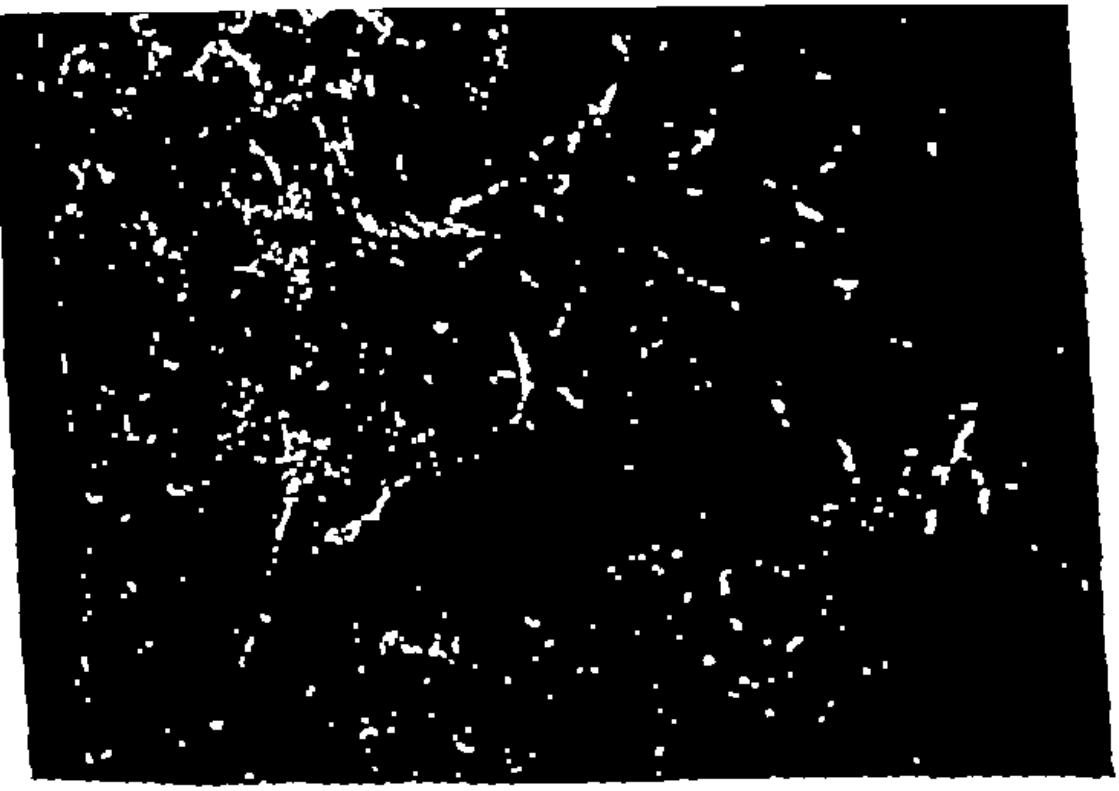
27 Host iris, 2 weeks after ipsilateral transplantation of the superior cervical ganglion. A more regular plexus of fluorescent nerves has been formed. 225

28 Host iris, 2 weeks after ipsilateral transplantation of the superior cervical ganglion. This figure gives the appearance of an host iris closer to the transplant than Fig 27. Thick, strongly fluorescent bundles of non-terminal axons are seen giving off branches over the iris. Such axon bundles are never found on normal irides, where the non-terminal adrenergic axons have a low fluorescence intensity and never form large bundles. 140.

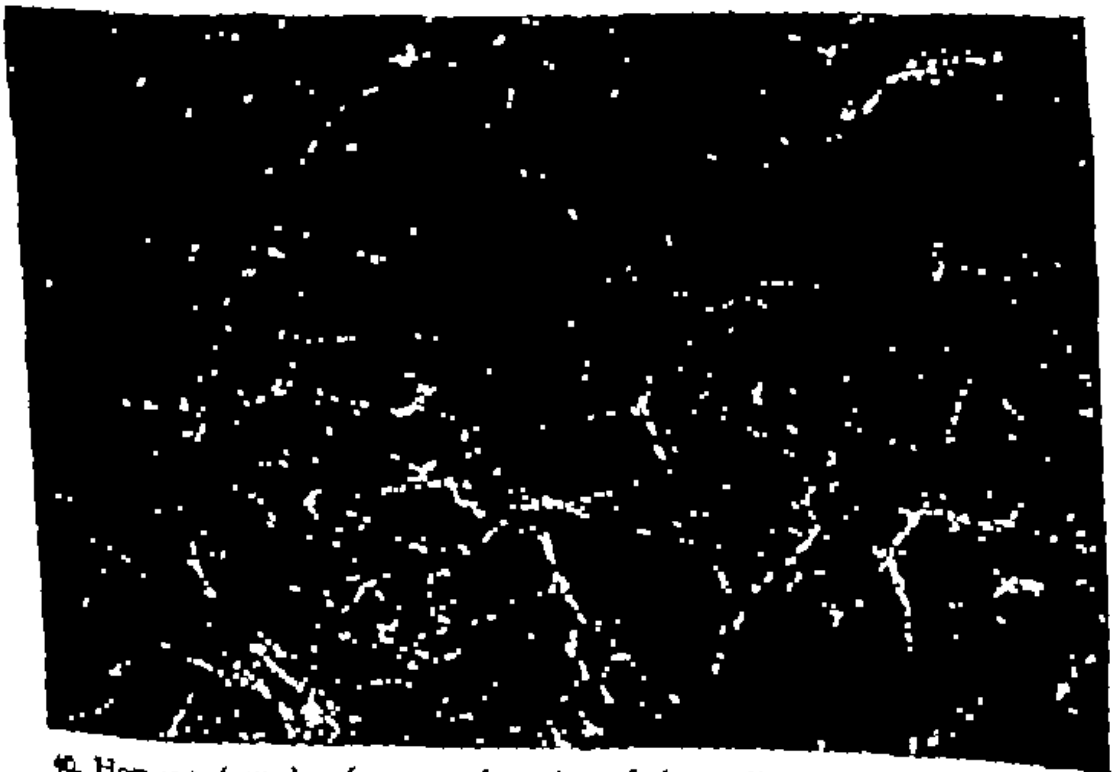
29 Transplanted superior cervical ganglion, 17 days. This figure, which should be compared to Fig 30 below shows an area of a transplant with high nerve cell density The nerve cells ha an almost normal fluorescence morphology A few strongly fluorescent axon bundles are found. 225

30. As Fig 29 P rt of transplan where nerve cell bodies are few and axon bundles dominate. One large group and few solitary small intensively fluorescent c. SIF-cells are found. Figs 29 and 30 together demonstrates the variable nerve cell densities in the ganglion transplants. 225

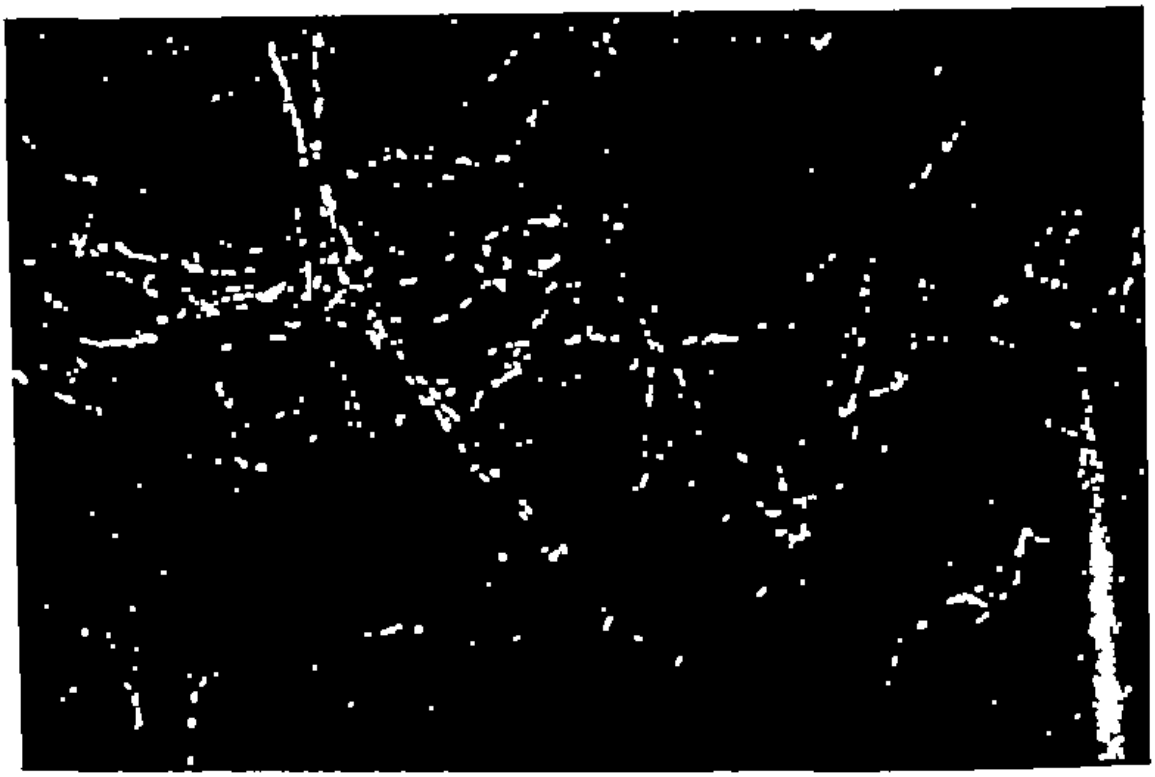
35 Host iris, 6 week after unilateral transplantation of the superior cervical ganglion. The fan-shaped emergence of axon bundles from the site of attachment of the transplant is seen. 70.



36. Host iris, as fig 35 The typical arrangement of fluorescent fibres at the border between the choroid membrane (left) and the ciliary body (right), as reformed on the host iris. 110.



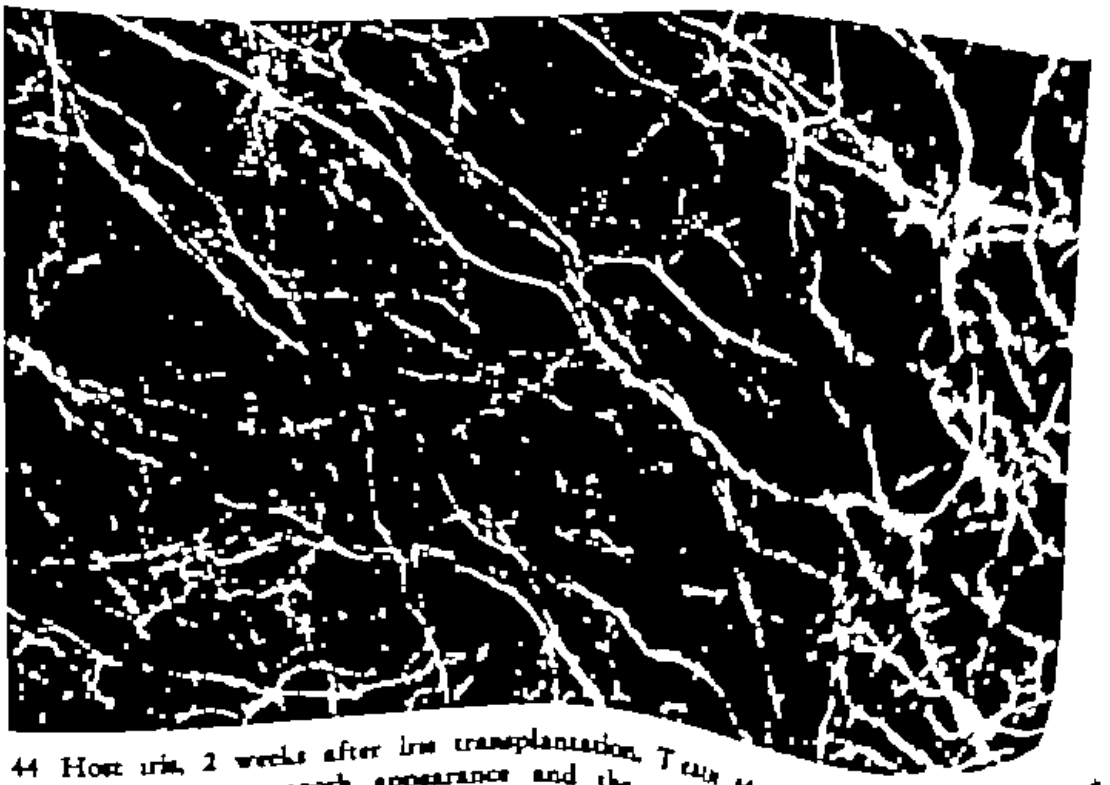
37 Iris transplant, 12 days. Detail of bundle f newly formed axons. Compare with I g 38 which shows the same ar a of the si -d ied Iris in incident light. 270.



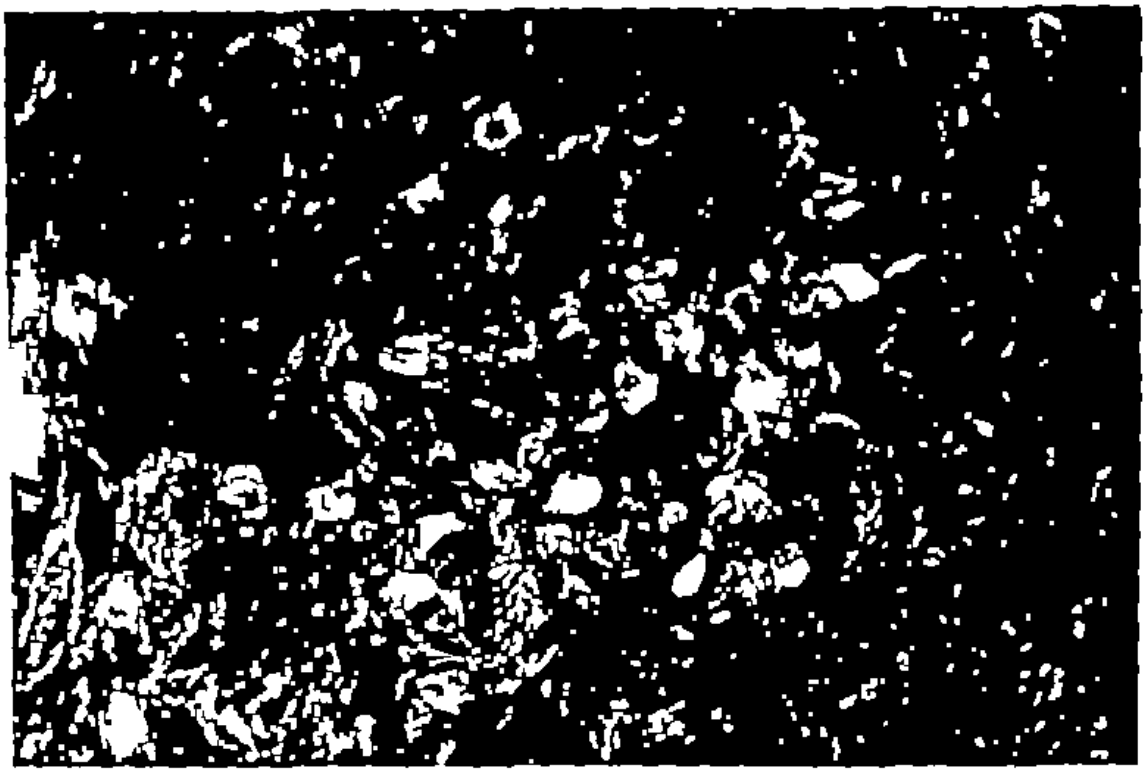
ris transplant, 12 days. Same area as g 37 but photographed in incident A large nerv tract is outlined as on the surface of the iris. The formed nerv bundles (Fig 37) the old nerv tracts. 270.

39 Host iris, 6 weeks after transplantation of a hypogastric ganglion. The transplant was situated immediately to the left of the cut edge of the iris. A plexus of sprouting adrenergic nerves extends from the site of attachment over a short distance towards the right part of the picture. The whole width of the inner zonal area is demonstrated. 140.

40. Host iris, 6 weeks after transplantation of the coeliac ganglion. A well developed, varicose adrenergic ground plexus has been reformed in the iris. Several axon bundles are also seen. 140.

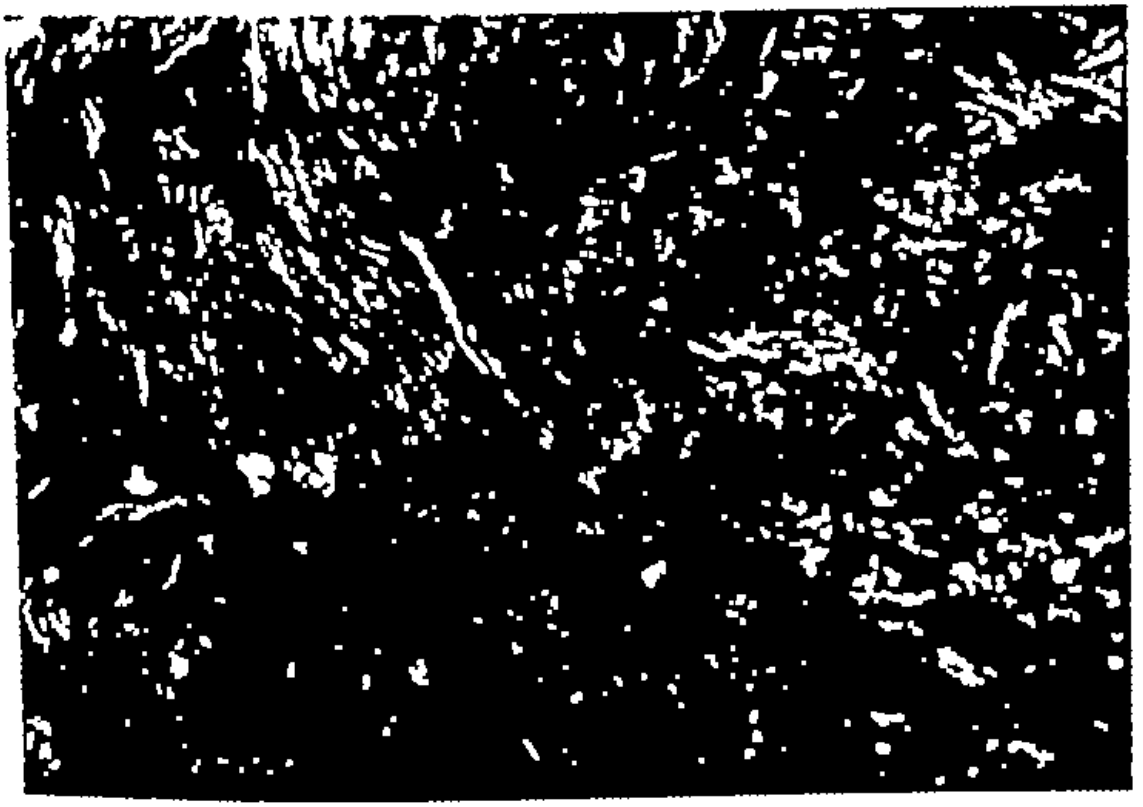


41 Iris transplant, 2 weeks. The animal was pretreated with the NA synthesis inhibitor *H44/68* (500 mg/kg i.p. 24 hrs) and received NA (0.2 mg/kg i.v.) 15 min before sacrifice The nerves in the transplant hav regained a fluorescence intensity and morphology comparable to that of a control ris treated in the same way 225.



42. Host iris, 2 weeks f[illegible] Treatment as Fig 41. Also in the host iris the nerves h[illegible]d -nce intensity and morphology comparable to that of [illegible]on r[illegible] ame way 225

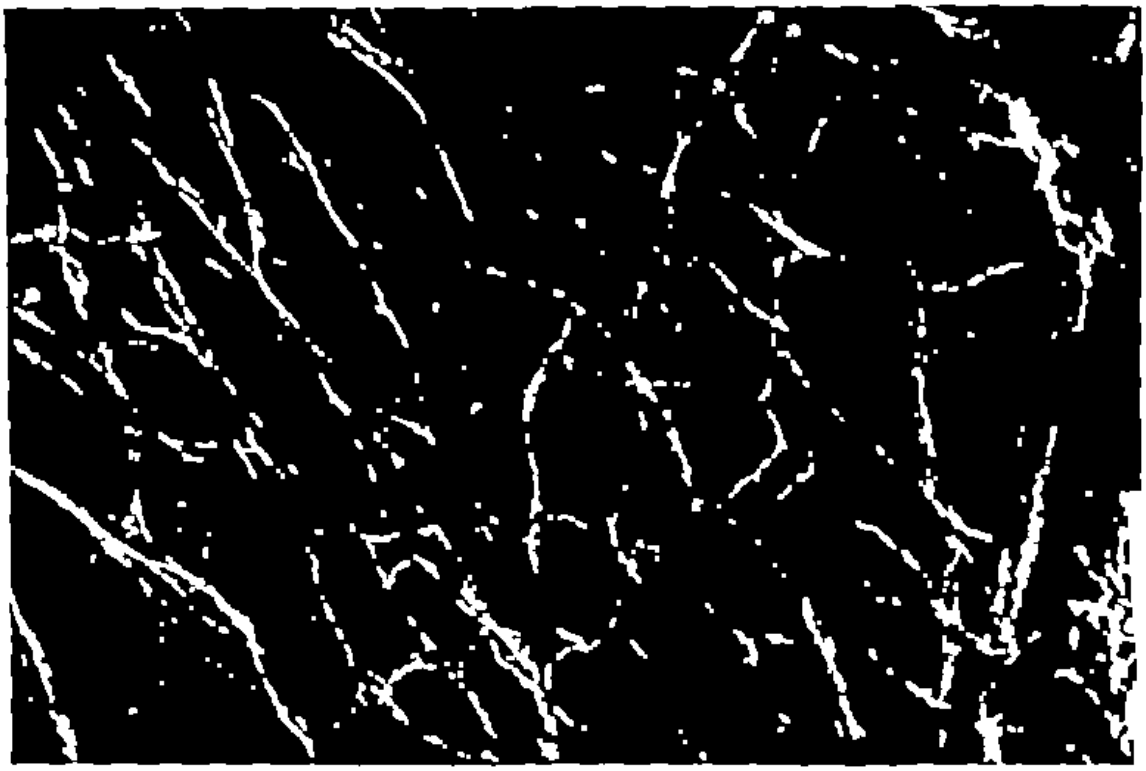
43. Iris transplant, 2 weeks. The animal was pretreated with reserpine (10 mg/kg i.p., 14 hrs) and nialamide (100 mg/kg i.p., 2 hrs) and received NA (0.2 mg/kg i.v.) 15 min before sacrifice. The nerve terminals are smoother than in an adult iris transplant but not as smooth as in the corresponding host iris. The nonterminal axons are beaded. 225



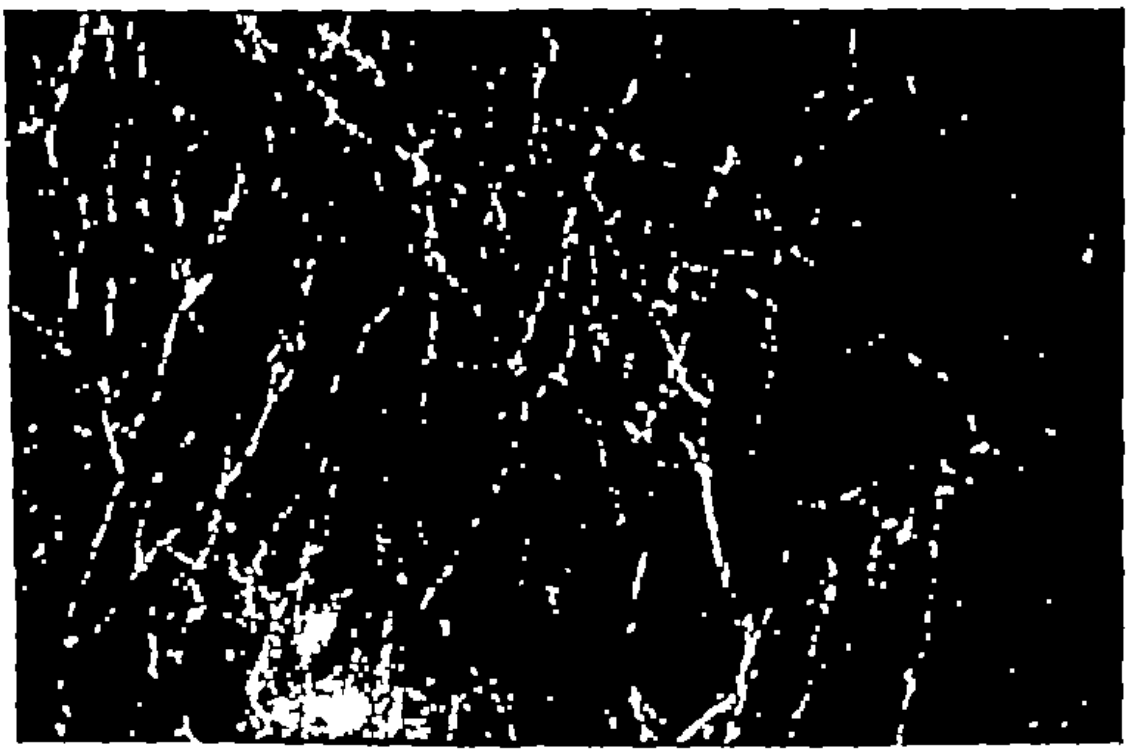
44. Host iris, 2 weeks after iris transplantation. Treatment as in Fig. 43. The terminals have a smooth appearance and the nonterminal axons are of fluorescence intensity. 225

45 Transplanted superior cervical ganglion, 1 week. Nerve cell bodies with varying fluorescence intensities and many relatively strongly fluorescent axon bundles. This figure serve as a control to Fig 46. 225

46. Transplanted superior cervical ganglion, 1 week. The animal was pretreated with reserpine (10 mg/kg, ip, 4 hrs) and nialamide (100 mg/kg, i.p., 2 hrs) and received NA (0.2 mg/kg,) 15 min before sacrifice. The axon bundles show strong fluorescence. 225



47 Transplanted superior cervical ganglion, 4 weeks. The animal was treated with the NA synthesis inhibitor H44/68 (500 mg/kg, i.p.) 24 hrs before sacrifice. The cell bodies have a low fluorescence intensity while the axon bundles show a rather strong fluorescence similar to that of an untreated transplant. 225.

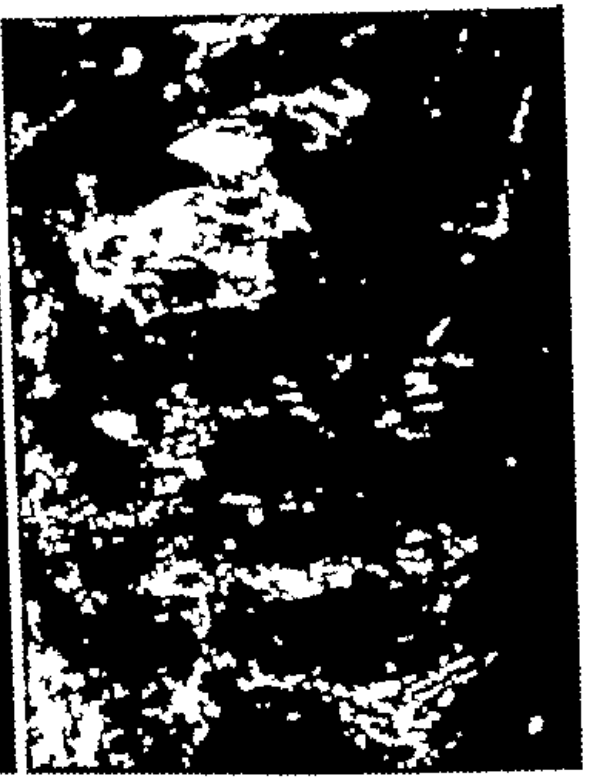


48. Transplanted supe
(10 mg/kg i p) 24 hrs
but stand out clearly

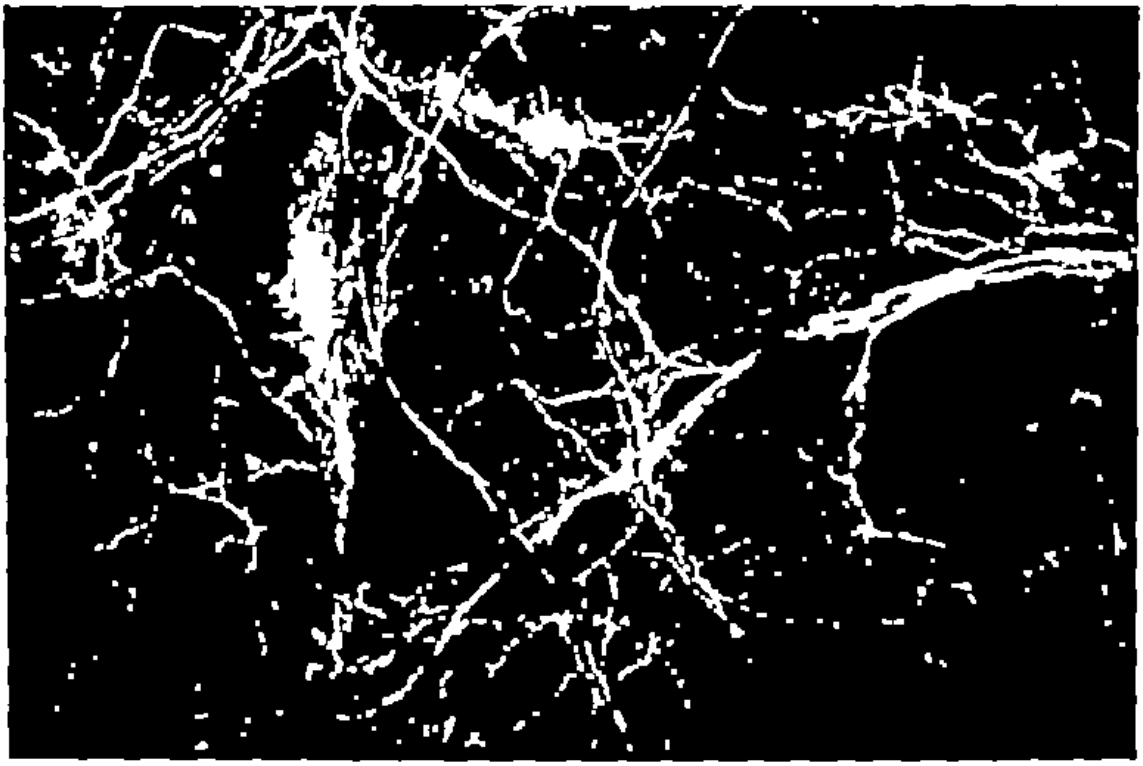
ganglion, 4 weeks. The animal was given reserpine
acrifice. The cell bodies show a weak fluorescence
the completely non-fluorescent axon bundles. 35.

49 Host iris, 1 week after ipsilateral transplantation of the superior cervical ganglion. The animal was given NA (0.2 mg/kg i.v.) 15 min before sacrifice. The newly formed nerves have a smooth appearance. 225

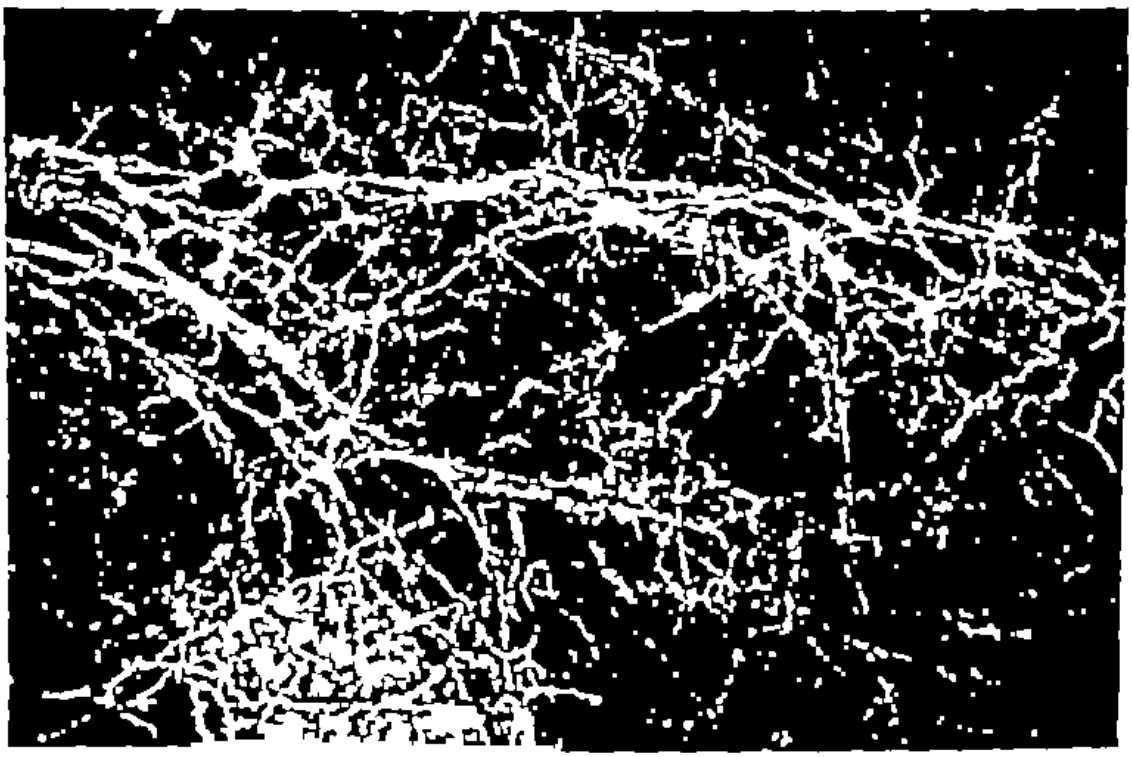
50 Host iris, 4 week[s] [after] ipsilateral transplantation of the superior cervical ganglion. Same trea[tment as] Fig. 49. The newly formed ground plexus has a varicose appearance in [contrast] to the smoother nerves found after 1 week. (Fig. 49). 225



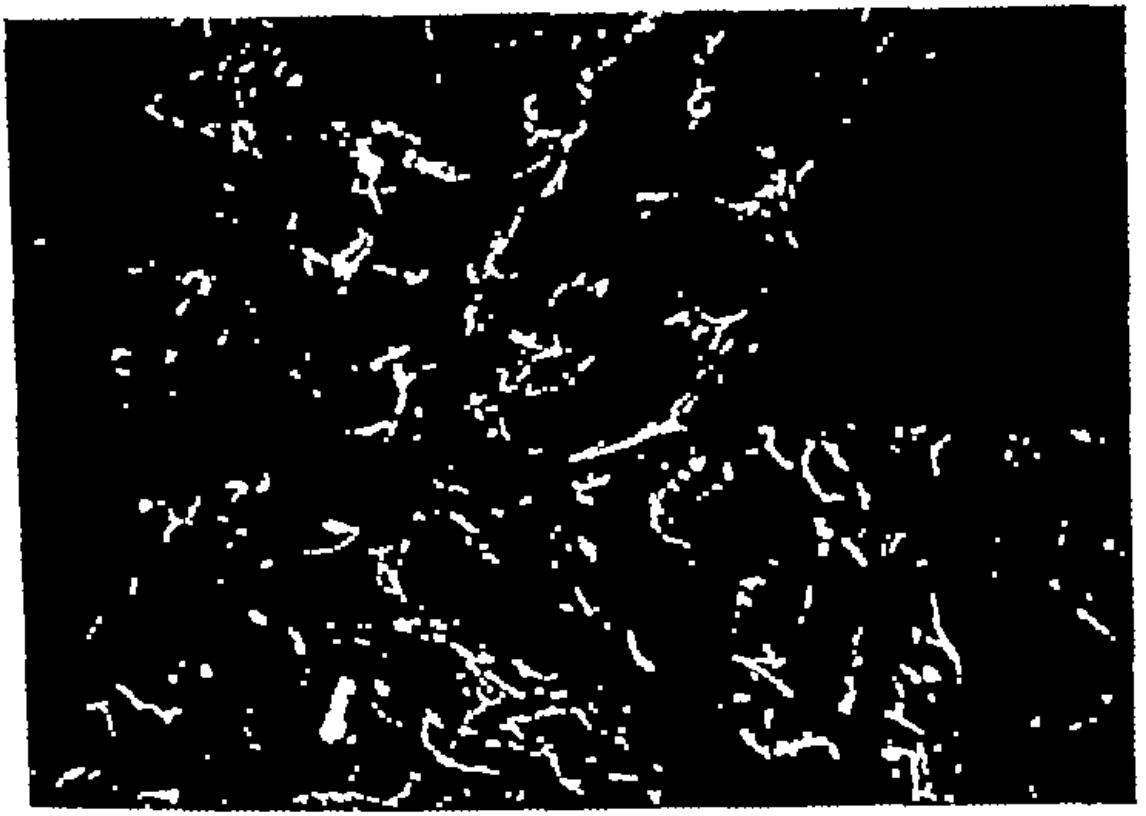
51 Connection between a host nrv and a transplanted duodenal muscle strip, 10 weeks. Detail of one slender connective tissue strand containing beaded, fluorescent non-terminal axons. 350



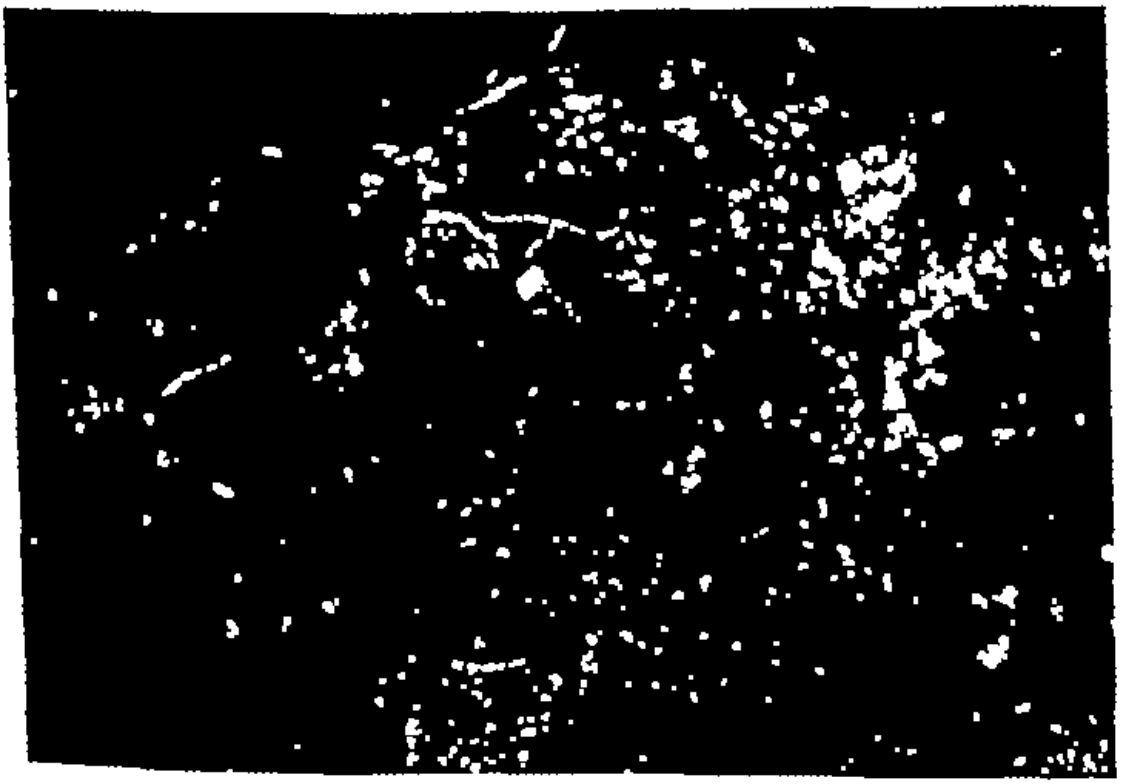
52. As Fig 51. Pretreatment with H44/68 (500 mg/kg, i.p., 140 min). The superior cervical trunk was stimulated during the last 10 min before sacrifice. The non terminal axons are essentially unaffected by the treatment. 350.



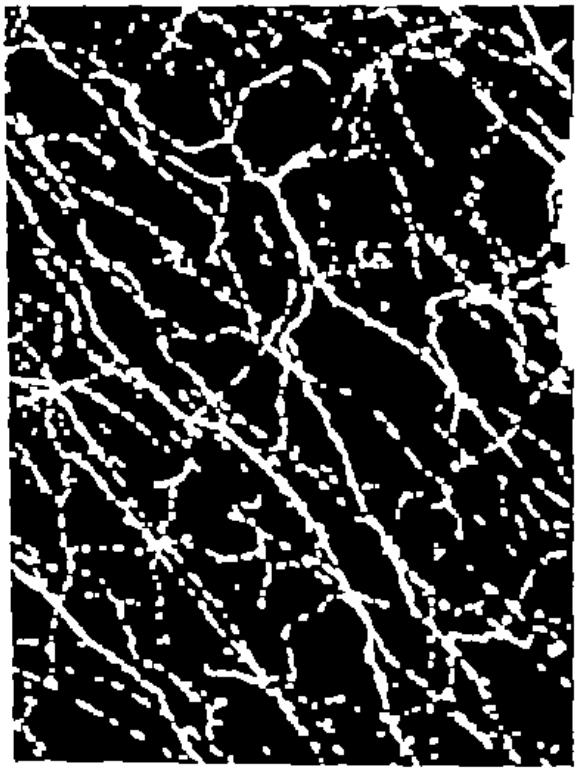
53 Transplanted vas deferens muscle strip 3 weeks. The smooth muscle bundles, here shown in cross-section, have become reinnervated by adrenergic nerves to an extent similar to that normally found in the vas deferens. 185



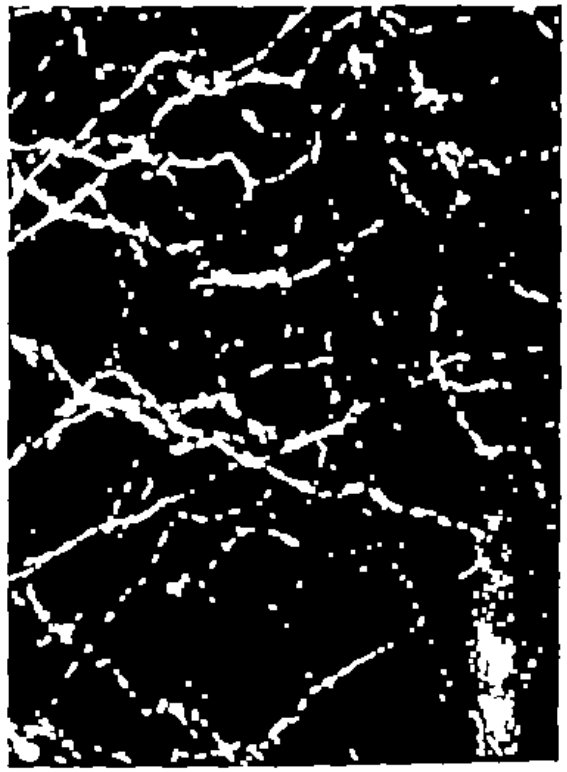
54 Transplanted duodenal muscle strip 9 weeks. Tangential section through the plexus of Auerbach between the two muscle layers. Several non fluorescent nerve cell bodies are surrounded by fine, varicose fluorescent nerves. 310.



55 Host iris, 30 days after homologous transplantation of the superior cervical ganglion to an iris with intact adrenergic innervation. The original nerve supply of the iris was removed 2 days before sacrifice by extirpation of the normally situated ipsilateral ganglion, thus leaving only those nerves that had grown out from the transplant. A very scanty meshwork of newly formed nerves, mainly made up by axon bundles is seen. Varicose nerve terminals are few (cf Fig 56). 140



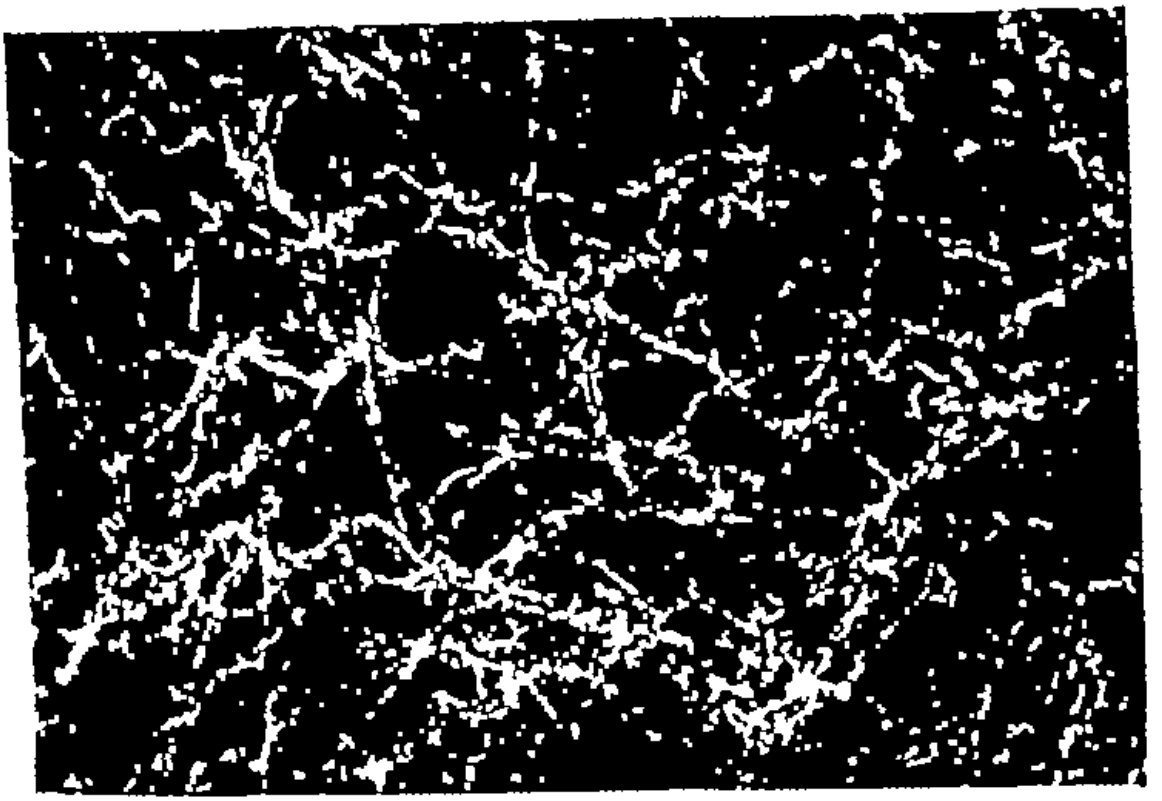
56. Host iris, 30 days after homologous transplantation of the superior cervical ganglion to an iris which was sympathetically denervated at the same time. Control to Fig 55. A well developed nerve ground plexus has been formed. 140.



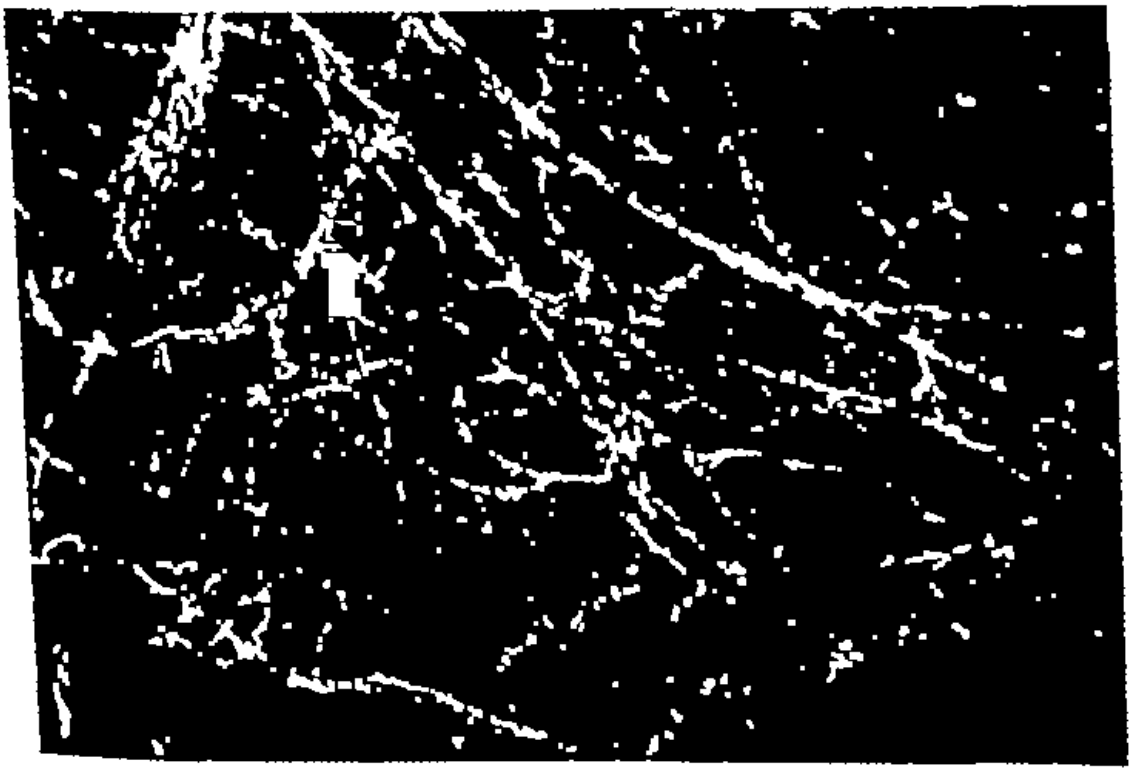
57 Transplanted piece of the submandibular gland, 4 weeks. The parenchyma of the transplant is richly supplied with new fluorescent nerves (cf Fig 58). Some tubular components are cystically dilated. 140.

58. Transplanted piece of the sublingual gland, 3 weeks. The parenchyma is almost completely devoid of fluorescent nerves (cf Fig 57). Cystic dilatation of some tubular components is seen. The many bright dots of varying sizes are brownish yellow non-specific fluorescence. 140.

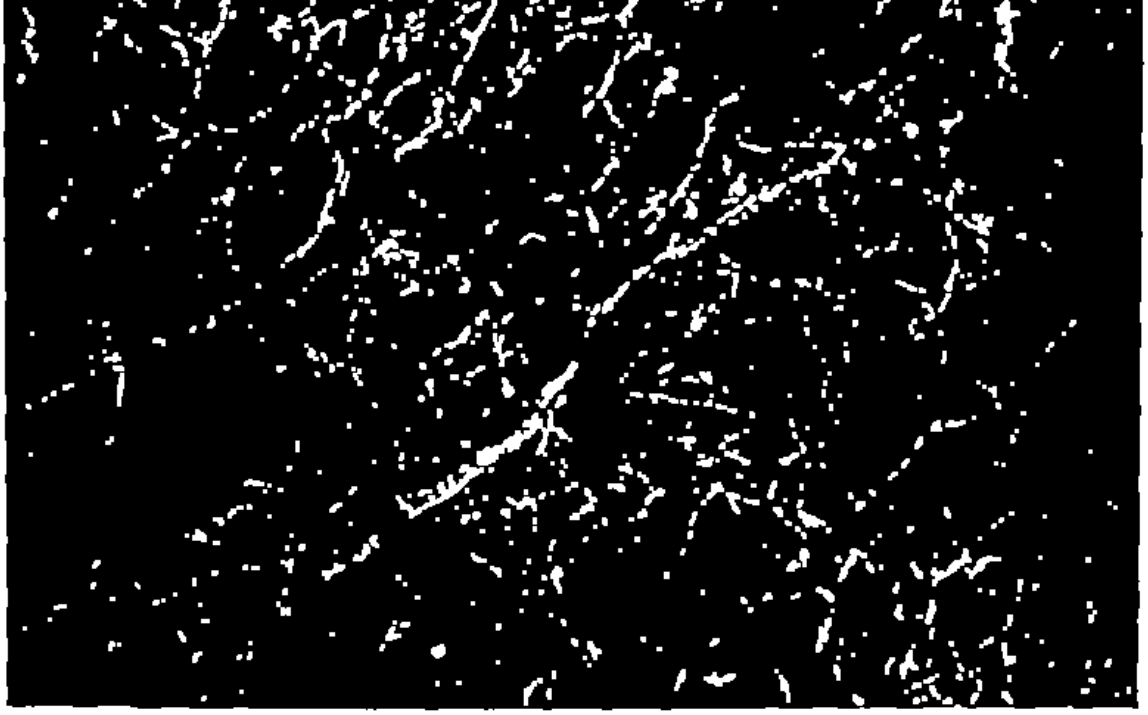
59 Normal albino hamster iris. An adrenergic ground plexus similar to that of the rat iris is found. 225



60. Autologous hamster iris transplant, 6 weeks. A new plexus of adrenergic nerves, similar to that normally found has been formed. 225

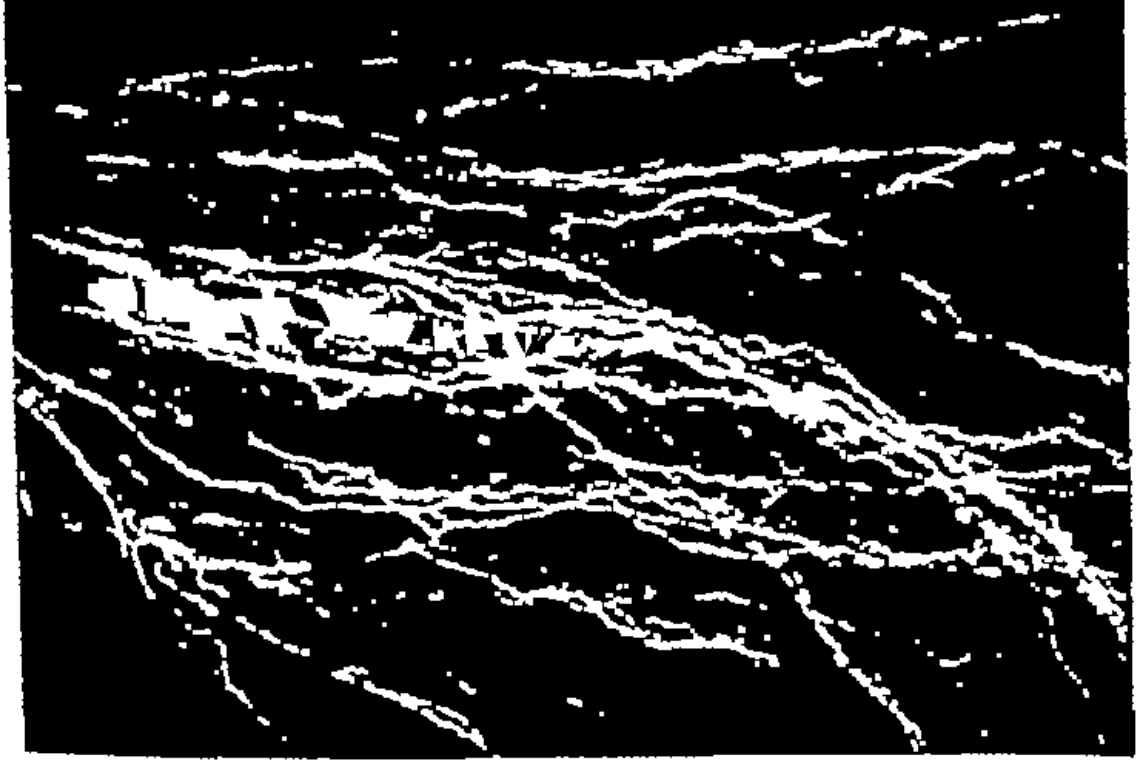


61 Heterologous transplantation of albino mouse iris to the rat eye 16 d Rat nerves have formed a sea ty w fluorescent plex on the mouse t plant. 350.



2 Heterologous transplantation of a ouse superior cervical ganglion to the mpathetically denervated rat ye. 10 A few mouse nerves are seen rning over the rat iris. 350.

63. Iris transplanted together with the anterior half of the eye to the submandibular gland, 24 days. The new adrenergic ground plexus is similar to normal and to that formed in irides transplanted to the anterior chamber 225.



64. Iris transplanted together with the anterior half of the eye to the vas deferens, 25 days. The adrenergic ground plexus is similar to normal and to that formed in irides transplanted to the anterior chamber 225

65 Host iris, 25 weeks after homologous transplantation of the superior cervical ganglion from a newborn rat to an iris which was sympathetically denervated at the same time. The adrenergic ground plexus is similar to normal and to that formed from an autologously transplanted ipsilateral superior cervical ganglion (cf Figs 33 and 34) 140.

66. Superior cervical ganglion transplanted under the conjunctiva, 15 days. A decreased number of moderately fluorescent nerve cell bodies and an increased amount of strongly fluorescent axons in bundles as compared to normal can be seen. The appearance is the same as that of superior cervical ganglion transplanted to the anterior chamber (cf Figs 29 and 30). 2.5

67 Spread preparation of a sciatic nerve to which the superior cervical ganglion was transplanted close to the area shown in he figure The nerve was compressed proximal to the site of transplantation A great umber of fluorescent axons coming from the transplanted ganglion can be seen (f Olson 1969) 225

68 T ansplanted adr l ll d adrenal medullary cells
days. Strongly fluor 3 ll host ns, 8 weeks. Strong-
cells, more loosely rr d m longated cells with a
elongated thi in he o t be seen. Fluorescent
can be seen A few 3 d t ca be seen to e
processes 170 medullary lls. 110.

70. Iris transplant, 19 weeks. The whole width and about a quarter of the whole length of the transplant is shown. The different parts of the transplant, the sphincter (right) dilator and ciliary body (left) can be seen. The distribution of the new nerves in these parts is similar to that of normal nerves (cf. Olson et al. 1968). 50.
